Kaposi's sarcoma is a vascular neoplasia characterized by endothelial cell proliferation with multisystem involvement. Human herpesvirus 8 has been identified in all variants of the lesions, although it is not known how this virus induces the proliferation of the microvasculature. Individuals infected with human immunodeficiency virus are at high risk for Kaposi's sarcoma. The use of highly active antiretroviral therapy has reduced the incidence by 10-fold. The clinical presentation of Kaposi's sarcoma is different from the classic form seen in elderly males of eastern European heritage. Patients with human immunodeficiency virus can present with widespread, numerous lesions. The lesions may be erythematous or violaceous macules that can progress to tumors or nodules. The lesions on the trunk may be arranged parallel to the skin tension lines and can occur in areas of trauma (**Figure 251-25**). Erosions, ulceration, crusting, and hyperkeratosis may be secondary changes seen. The trunk is an area of predilection, as are the hard palate, penis, and lower extremities.

Classic or European Kaposi's sarcoma occurs in elderly males of Mediterranean or Ashkenazi Jewish heritage. This variant predominantly arises on the lower extremities and can be associated with edema. It can also affect the lymph nodes and abdominal viscera.

Treatment depends on the extent and severity of the disease and underlying cause. Referral to infectious disease and hematology/oncology specialists is necessary in most cases.

CHAPTER 252

Skin Disorders: Groin and Skinfolds

Dean S. Morrell
Edith V. Bowers

INTRODUCTION

The skinfolds of the body include the groin, intergluteal cleft, axilla, inframammary, and pannus regions. The skinfolds have unique characteristics that set them apart from other regions of the body. For one, these areas are almost continuously occluded. As a result, scale does not develop; maceration and fissuring develop instead. This situation alters the appearance of papulosquamous diseases and inflammatory processes. The occlusion also allows for the development of a warm, moist environment favorable to the growth of fungi, yeast, and bacteria. Although many skin diseases can affect the skinfolds to some degree, this chapter focuses on common disorders where skinfold eruptions are the main finding. This chapter discusses common infections, infestations, and inflammatory and reactive conditions that involve the groin and skinfolds. Sexually transmitted infections are discussed in chapter 149. Molluscum contagiosum is discussed in chapter 251.

An important point for treatment of intertriginous diseases is avoiding combination corticosteroid/antifungal products. Although processes in the groin folds can be confusing and complicated by secondary change, using combination products may further cloud the clinical picture. If improvement is seen, it is difficult to ascertain which medication prompted the change. And, finally, the corticosteroid component of these medications is too strong to be used in the occluded intertriginous skin and may produce irreversible striae with long-term use.[1]

INFECTIONS

TINEA CRURIS

Tinea cruris is a fungal infection of the groin commonly called *jock itch*. It is very common in males, uncommon in females, and exceedingly rare in children. Tinea cruris results from invasion of the stratum corneum by the dermatophyte types of fungi (see Table 253-4). It is transmitted via direct contact (person to person, or animal [usually kittens or puppies] to person) or fomites.

Examination is significant for symmetric erythema with a peripheral annular slightly scaly edge (**Figure 252-1**). The groin is typically involved, and the process may extend onto the inner thighs and even the buttocks. The penis and scrotum are typically spared, a distinguishing feature of tinea cruris because most other eruptions will affect the scrotum. Frequently, tinea pedis is also found and the dermatophyte infection may be spread from the feet to the groin through putting on clothes.

Scraping the leading edge and performing a potassium hydroxide examination (see Table 252-6) will demonstrate branching hyphae (see Figure 252-1), unless the patient has recently applied topical antifungal preparations. If a potassium hydroxide examination is negative, consider one of the other disorders discussed in this chapter (**Table 252-1**).

Treatment is with antifungal creams, such as clotrimazole, ketoconazole, or econazole, twice a day (**Table 252-2**). Clotrimazole is often suggested initially because it is a low-cost treatment and is available without a prescription. Econazole also has antibacterial properties and is preferred if maceration is present. Treatment also includes keeping the affected area as cool and dry as possible, which is facilitated by wearing loose-fitting clothing. Use an antifungal powder daily to prevent recurrences. Recommend follow-up with a primary care provider or dermatologist if the eruption has not resolved in 4 to 6 weeks.

CUTANEOUS CANDIDIASIS

Candidal infections of the skin favor moist, occluded areas of the body. Although any skinfold may be involved, superficial *Candida* infections

FIGURE 252-1. Tinea cruris. Note raised, sharp-edged margins. [Photo contributed by University of North Carolina Department of Dermatology.]

TABLE 252-1 Inflammatory Disorders of the Skinfolds

Infection
Tinea cruris
Cutaneous candidiasis
Erythrasma
Lymphogranuloma venereum
Granuloma inguinale
Infestation
Scabies
Pediculosis pubis
Dermatitis
Seborrheic dermatitis
Intertrigo/irritant contact dermatitis
Allergic contact dermatitis
Atopic dermatitis
Lichen simplex chronicus
Psoriasis
Neoplasia
Bowen disease (squamous cell carcinoma in situ)
Extramammary Paget's disease
Langerhans cell histiocytosis X
Miscellaneous disorders
Hidradenitis suppurativa
Cutaneous Crohn's disease
Hailey-Hailey disease (benign familial pemphigus)

are commonly seen in the diaper area of infants, vulva and groin of women, glans penis (balanitis) of uncircumcised males, and inframammary and pannus folds of obese patients. Antibiotic therapy, systemic corticosteroid therapy, urinary or fecal incontinence, immunocompromised states, poorly controlled diabetes mellitus, and obesity are predisposing factors. Women with vulvar or inner thigh involvement will often have vaginal candidiasis as well. Frequently, *Candida* infection may complicate other inflammatory intertriginous disorders.

The typical presentation is erythema and maceration with peripheral small erythematous papules or satellite pustules (**Figure 252-2**). **The rim of satellite pustules helps to distinguish *Candida* infection from other eruptions of the skinfolds.** Patients will often complain of burning or itching. The other inflammatory disorders listed in Table 252-1 should be considered in the differential diagnosis.

A potassium hydroxide preparation of the pustules or of the leading edge scale may demonstrate short hyphae and spores, but these may be difficult to find in cases with just erythema and maceration. If *Candida* is suspected but not visualized on potassium hydroxide preparation and the diagnosis is in question, a skin swab should be performed and submitted for fungal culture.

Treatment involves keeping the affected area dry and cool. After bathing, air drying or drying with a hair dryer should be encouraged. Clothing should be loose and lightweight. Astringent solutions (such as aluminum acetate [Burow solution]) aid in drying weepy inflammatory eruptions. After compress application and drying, a topical antifungal cream, such as clotrimazole, ketoconazole, or econazole, should be applied. Once the infection is controlled, drying powders should be used on a daily basis to minimize recurrences. Patients with vulvar candidiasis should be evaluated for *Candida* vaginitis and treated appropriately (see chapter 102, "Vulvovaginitis"). Patients with *Candida* balanitis often have a female sexual partner with *Candida* vaginitis; therefore, partners should be evaluated and treated as well. In infants or in adults with urinary or fecal incontinence, diapers or sanitary pads should be changed frequently. Zinc oxide paste applied over the antifungal agent provides a protective barrier to the irritation of urine and feces.

INFESTATIONS

SCABIES

Infestation of the skin by *Sarcoptes scabiei*, or scabies mite, produces an intensely pruritic eruption. Symptoms manifest approximately 30 days following exposure to the organisms as a result of the host immune response to the mites and their excrement. Typically, history will elicit an encounter with another person, or with a new environment, approximately 4 to 6 weeks before the initiation of symptoms.

The main presenting feature is intense, intractable pruritus, most notable at night. In adults, the typical findings are slightly longitudinal erythematous or brown papules, predominantly on the lateral feet, wrists, ankles, and interdigital spaces of the fingers and toes. Involvement may be evident within the axillae, groin, and extensor extremities (**Figure 252-3**). The head and neck are characteristically spared. In immunocompromised hosts, or persons with significant psychiatric compromise, lesions may appear as thick, crusted, confluent plaques on the hands, feet, and scalp, with or without a generalized distribution. In such patients, the condition is termed *crusted scabies*.

Sampling of a longitudinal burrow by scraping with a scalpel blade is typically most helpful in establishing the diagnosis. Light microscopy of the sample, which is transferred to a glass slide and covered with a drop of mineral oil followed by a coverslip, may reveal intact scabies organisms, ova, or excrement (see Figure 252-4). However, sensitivity of this test is limited, and a negative result does not rule out the diagnosis.

Treat with 5% permethrin cream (pregnancy category B), apply from the neck down, leave on for 12 hours, and then bathe with soap and water. Treatment should be repeated in a similar fashion in 1 week. Treat all resident family members and household and intimate contacts.

Lindane should be avoided in children and pregnant women secondary to neurotoxicity.

TABLE 252-2 Comparison of Commonly Used Antifungal Preparations

Generic	Trade	Formulations	Pregnancy Category	Sizes (grams)	Cost (U.S. $)	Status
Clotrimazole	Lotrimin	1% cream or solution	B	Cream (15, 30)	Cream (8–16)	OTC
	Mycelex			Solution (10, 30)	Solution (12–22)	
Ketoconazole	Nizoral	2%	C	Cream (15, 30, 60)	Cream (15–36)	Prescription
	Kuric gel			Gel (15)		
	Xolegel					
Econazole	Spectazole	1%	C	Cream (15, 30, 85)	Cream (15–50)	Prescription
Miconazole	Zeasorb AF	2%	C	Powder (56)	Powder (9)	OTC

Abbreviation: OTC = over the counter (no prescription required in United States).

Oral ivermectin (pregnancy category C) is an alternative treatment to permethrin cream and is easier to administer; however, it may have a slightly lower cure rate.[2] **Ivermectin should be avoided in pregnant and lactating women.**

Supportive care involves use of oral antihistamines and topical corticosteroids after use of the appropriate scabicidal agent. Patients should be told to expect resolution of symptoms gradually over 1 to 2 weeks, although pruritus can sometimes persist for several weeks. Return of new lesions after initial improvement signifies incomplete treatment or reinfestation.

PEDICULOSIS PUBIS

Pediculosis pubis is infestation of the groin with *Phthirus pubis*. Rarely, the eyebrows, eyelashes, chest, or axillary hair may also be involved.

Close examination of the hair-bearing areas reveals multiple small flesh-colored or slightly reddish organisms grasping the hairs close to the skin surface (**Figure 252-4**). In severe infestations, small bluish-gray macules may be noted, called *maculae caerulea*. Secondary infection and excoriations may also be present. Diagnosis of pediculosis pubis in children should prompt evaluation for potential sexual abuse. Diagnosis is based on physical examination findings.

Treatment is the same as for scabies. Topical treatments should be applied liberally to all affected hair-bearing areas, including the perirectal

hairs.[3] Attempts to identify the source of the infestation are important because reexposure may continue to occur.

INFLAMMATORY AND REACTIVE CONDITIONS

Seborrheic Dermatitis Seborrheic dermatitis is one of the most common skin disorders. It most notably affects the scalp ("dandruff") and creases of the face and ears; however, other skinfolds, such as the intergluteal cleft, groin, axilla, inframammary folds, and umbilicus, can be affected (see chapters 250 and 251).

Seborrheic dermatitis of the scalp and skinfolds of the face presents as erythema with a greasy yellow scale (see Figure 250-4). When seborrheic dermatitis affects other skinfolds, erythema and maceration are evident (**Figure 252-5**).

Diagnosis is clinical and based on typical findings of seborrheic dermatitis on the face and scalp. By itself, groin or other skinfold involvement is hard to differentiate from the other inflammatory disorders such as cutaneous candidiasis, inverse psoriasis, allergic contact dermatitis, or streptococcal infection.

Treatment can relieve signs and symptoms, but there is no cure. The eruption will return after treatment ceases. Shampoos containing zinc pyrithione, selenium sulfide, salicylic acid, or tar preparations are used. Ketoconazole shampoo can be effective and is available by prescription (2%) or over the counter (1%). Hydrocortisone 1% cream can be used in mild cases, whereas hydrocortisone 2.5% cream or desonide cream or lotion may be required initially in more severe cases. Patients should be cautioned against long-term regular use of corticosteroids on facial or intertriginous skin, which may result in irreversible skin thinning and striae formation.

INTERTRIGO

Intertrigo is an irritant dermatitis of the skinfolds resulting from moisture, heat, friction, and irritating substances like urine and feces. Intertrigo presents as erythema, maceration, and fissures in the occluded area of skinfolds, especially the groin and inframammary folds (**Figure 252-6**). **Satellite papules and pustules are absent**, and the affected areas are pruritic and may burn. **Streptococcal superinfection** should be considered if there is marked erythema and tenderness, especially in the extremes of age and the immunocompromised.

Intertrigo is a diagnosis of exclusion (Table 252-1). Bacterial infection, especially with *Streptococcus*, is common. Differentiating cutaneous candidiasis from inflammatory intertrigo can be difficult. A diagnosis of cutaneous candidiasis is supported by the presence of satellite pustules and a positive potassium hydroxide examination. However, a negative potassium hydroxide examination does not exclude this possibility because yeast is difficult to obtain and visualize with this procedure. Scraping of peripheral scale or a pustule to send for fungal culture may help clarify the diagnosis.

Clinically, irritant dermatitis cannot always be distinguished from allergic contact dermatitis. A history should be taken to uncover any possible contact allergens or irritants such as neomycin-containing ointments, anesthetic creams, diphenhydramine cream, deodorants, feminine hygiene sprays, or other lotions, solutions, or home remedies.

Treat by keeping the affected areas dry and cool. All potential irritants should be avoided. Zinc oxide paste provides an excellent barrier to urine and fecal material.

For moist, weepy intertrigo, aluminum acetate (Burow solution) compresses can be used. Secondary bacterial infection should be treated with oral antibiotics with staphylococcal and streptococcal coverage. Topical antiyeast preparations, such as ketoconazole, may be helpful. If significant inflammation is present, a short course of 1% hydrocortisone cream or lotion may be helpful.

HIDRADENITIS SUPPURATIVA

Hidradenitis suppurativa is an inflammatory condition, typically affecting the apocrine gland–bearing areas of the skin with recurrent, painful, draining nodules. The inciting event is follicular occlusion, prompting rupture of the follicular contents and resulting intense inflammation.[4]

Axillary and inguinal skin demonstrates varying numbers of inflammatory nodules, many of which may form connecting tracts, with resultant drainage onto the skin surface (**Figure 252-7**). Lesions may heal with characteristic icepick scarring, which may facilitate diagnosis.

Diagnosis is clinical. **Treatment** is clindamycin 1% lotion twice daily and use of antibacterial soaps, such as chlorhexidine, once to twice weekly. Incision and drainage should be minimized because it may increase scarring. Further systemic treatments, such as acitretin, finasteride, or prednisone, may work in some cases and are best coordinated by a specialist. In severe cases, systemic biologics or surgical excision of apocrine-bearing skin has been attempted.

CHAPTER 253

Skin Disorders: Extremities

Rachna A. Bhandari
Dean S. Morrell

INTRODUCTION

This chapter focuses on common disorders of the hands, feet, and extremities and is organized into the following subgroups: ulcers, inflammatory conditions, cutaneous infections, and vascular cutaneous conditions.

ULCERS

VENOUS STASIS DERMATITIS AND VENOUS LEG ULCERS

The vast majority of leg ulcers are venous stasis ulcers resulting from chronic venous insufficiency.[1] Chronic venous insufficiency is usually caused by episodes of phlebitis or varicose veins, both of which damage venous valves. This results in poor venous return from the lower extremities, leading to increased hydrostatic pressure and lower extremity edema and stasis dermatitis.

Dependent edema, erythema, and orange-brown hyperpigmentation characterize early stasis dermatitis. The medial distal legs and the pretibial leg are the areas most frequently affected. More chronic and severe cases may have bright weepy erythema and even ulceration (**Figure 253-1**). Pruritus is common. Cellulitis and lymphangitis may complicate stasis dermatitis. The presence of honey-colored crust and pustules suggests secondary bacterial infection.

Stasis ulcers often begin within areas of stasis dermatitis. The bilateral malleoli and the medial aspect of the calf are the most common sites of involvement. Diagnosis is clinical. With acute exacerbation, secondary infection is common. **Table 253-1** lists the differential diagnosis of leg ulcers. Certain disorders, such as arterial ulcerations, pyoderma gangrenosum, and polyarteritis nodosa require immediate attention. If peripheral pulses are diminished or absent, obtain vascular blood flow studies to exclude arterial ulcers. If the patient reports a rapidly developing ulcer that began as a pustule or erythematous nodule and has violaceous overhanging borders, suspect pyoderma gangrenosum. If the diagnosis is in question, consult with a dermatologist.

TABLE 253-1 Differential Diagnosis of Extremity Ulcers

Trauma
Injuries, burns, injections, decubitus, chilblains (pernio), neuropathic ulcers
Infections
Viral: herpes simplex virus, cytomegalovirus
Bacterial: gangrene, ecthyma gangrenosum, ecthyma secondary to *Staphylococcus aureus* and/or group A *Streptococcus*; osteomyelitis, methicillin-resistant *S. aureus*
Mycobacterial: Buruli ulcer (West Africa, *Mycobacterium ulcerans*), Bairnsdale ulcer (Australia, *M. ulcerans*), tuberculosis, leprosy
Fungal: blastomycosis, coccidioidomycosis, paracoccidioidomycosis, chromomycosis, mucormycosis
Spirochetal: syphilis, yaws
Parasitic: leishmaniasis, amebiasis, schistosomiasis
Bites
Spiders, scorpions, snakes
Metabolic
Diabetes, gout, calciphylaxis (cutaneous necrosis from small- and medium-sized vessel calcification in diabetes, end-stage renal disease, or hyperparathyroidism)
Vascular
Venous: varicose veins, venous insufficiency
Arterial: hypertension, arterial insufficiency, thrombosis, embolism
Vasculitis
Polyarteritis nodosa, vasculitis, collagen vascular disease, Behçet's syndrome
Malignancy
Cutaneous: squamous cell carcinoma, basal cell carcinoma
Lymphoma: T-cell or B-cell lymphoma
Hematologic
Polycythemia, sickle cell anemia
Dermatologic
Bullous pemphigoid, necrobiosis lipoidica
Drugs
Hydroxyurea

Treatment of venous stasis dermatitis and ulcers begins with leg elevation and the use of support stockings. Weeping eruptions should be treated with an astringent compress. A low- to mid-potency topical steroid, such as fluocinolone acetonide 0.025% or hydrocortisone 2.5% ointment, should be applied twice a day until erythema, scale, and pruritus resolve. Oral antihistamines, such as diphenhydramine or hydroxyzine, should be used for pruritus and for nighttime sedation. Secondary bacterial infection should be treated with cephalexin, dicloxacillin, or ciprofloxacin for 7 to 10 days. **Topical neomycin, antihistamine creams, and anesthetic creams should be avoided because they may complicate the condition with allergic contact dermatitis.** Cellulitis or lymphangitis may require hospitalization for IV antibiotics. Otherwise, follow-up should be arranged with a chronic wound care team.[1]

PYODERMA GANGRENOSUM

Pyoderma gangrenosum is a recurrent cutaneous, necrotizing, and noninfective ulceration of the skin that most commonly occurs in women between 30 and 50 years of age.[2] Most cases are associated with underlying disease, such as inflammatory bowel disease, rheumatoid arthritis, and myeloproliferative disorders.[3]

The classic lesion of pyoderma gangrenosum begins as a superficial pustule or erythematous nodule that expands into a large painful ulcer on the lower extremity with a purulent base and irregular, undermined borders and gun metal gray hue (**Figure 253-2**). There is no associated lymphadenopathy. Up to 50% of patients develop lesions at the sites of trauma, such as surgery sites or injection sites, or after blood drawing.[2] A history of multiple surgical debridements with sterile cultures should suggest a potential diagnosis of pyoderma gangrenosum.

The diagnosis is clinical and one of exclusion. Search for associated conditions, such as inflammatory bowel disease and myeloproliferative disorders. The onset of new skin lesions or ulcers at previous sites of trauma can also be helpful in identifying pyoderma gangrenosum.[4]

Treatment of the underlying disorder and corticosteroids, either topical, intralesional, or combined local and systemic, are the standard therapy for pyoderma gangrenosum. Resistant disease may require adjunctive systemic therapy with immunosuppressive or cytotoxic agents.[4]

FIGURE 253-2. Pyoderma gangrenosum. [Photo contributed by University of North Carolina Department of Dermatology.]

DIABETIC AND NEUROPATHIC ULCERS

Most patients with diabetic foot ulcers have coexistent diabetic neuropathy.[5] Other causes of neuropathic leg ulcers are much rarer and include leprosy, tabes dorsalis, medications, and spinal cord lesions. In most patients with foot ulcers, one will note a triad of neuropathy, deformity, and trauma. Neuropathy leads to atrophy of the intrinsic muscles of the foot, collapse of the arch, and loss of stability of the metatarsal-

FIGURE 253-3. Diabetic foot and diabetic neuropathy. [Reproduced with permission from Wolff KL, Johnson R, Suurmond R: *Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology*, 5th ed. © 2005, McGraw-Hill, New York.]

phalangeal joints. The musculoskeletal alterations result in abnormal pressure points and greater friction on the foot during ambulation. Lack of sensation allows for repeat injury. The most common source of trauma is inappropriate footwear.[6]

Classic locations for neuropathic ulcers are the plantar surface underlying the first and fifth metatarsal heads, great toe, and heel. Ulcers are usually asymptomatic and "punched out" with a thick rim of surrounding callous (**Figure 253-3**). However, patients may complain of burning, numbness, itching, or paresthesias. The architecture of the foot is also altered, with flexed toes and prominent metatarsal heads secondary to neuropathy of the intrinsic muscles of the foot. Hypo- or anhidrosis from autonomic impairment may lead to dryness and fissuring of the surrounding skin. The diagnosis is clinical.

Patients with vascular insufficiency should be referred to a vascular specialist for further evaluation. A diabetic foot infection is diagnosed clinically when there are systemic signs of infection, purulence, or multiple signs of local inflammation (redness, warmth, pain, tenderness, or edema).[6] Osteomyelitis is suggested by the ability to probe bone with a blunt, sterile, stainless-steel probe and should be confirmed with imaging.

Treatment includes offloading or redistributing the pressure off the wound, maintenance of a moist wound environment, debridement of nonhealing tissue, and treatment of infection. Soft tissue infections can be treated for 7 to 14 days in an outpatient setting with oral cephalosporin, clindamycin, amoxicillin/clavulanate, or fluoroquinolones.[7]

More severe ulcers or those with associated cellulitis or osteomyelitis require admission and treatment with IV antibiotics for 4 to 6 weeks, such as cefotetan, ampicillin/sulbactam, or clindamycin and a fluoroquinolone. Vancomycin should be given if methicillin-resistant *Staphylococcus aureus* is suspected. Further discussion is provided in chapter 224, "Type 2 Diabetes Mellitus"; Table 224-4 lists the various cutaneous manifestations of diabetes.

BURULI ULCERS

Buruli ulcer is a new emerging disease and the third most common chronic mycobacterial infection in humans after tuberculosis and leprosy.[8] Buruli ulcers are rapidly growing ulcers caused by the acid-fast bacillus,

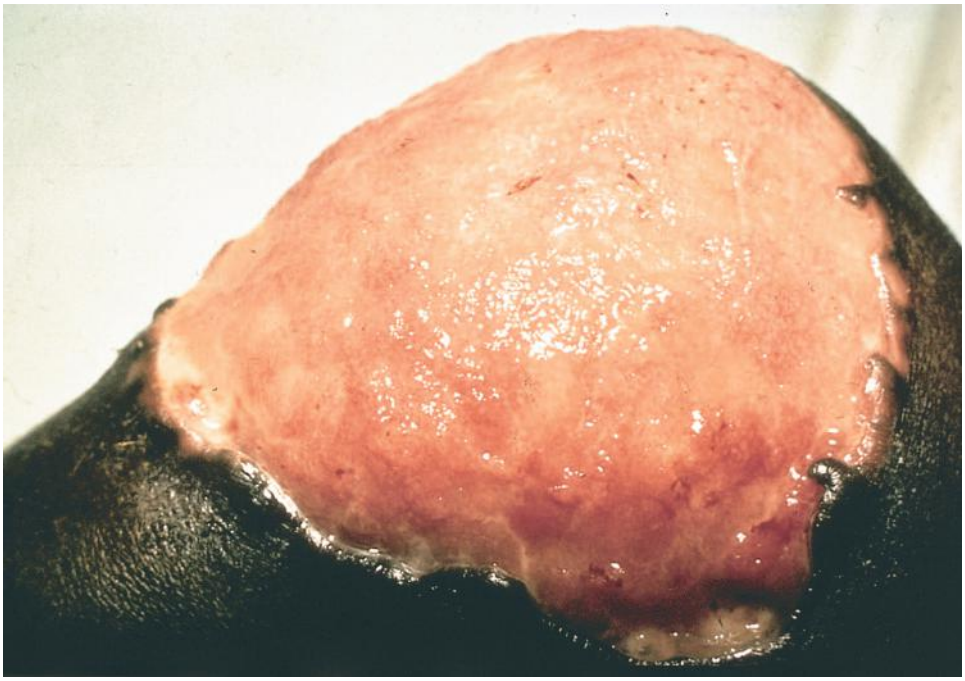

FIGURE 253-4. Buruli ulcer. [Reproduced with permission from Wolff KL, Johnson R, Suurmond R: *Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology*, 5th ed. © 2005, McGraw-Hill, New York.]

Mycobacterium ulcerans. It is usually confined to the tropical areas, with the highest rate in sub-Saharan Africa, but reports have come from subtropical and nontropical nations, including Australia, China, and Japan.[9]

M. ulcerans is an environmental saprophyte that is present on lush vegetation in swampy areas.[10] It infects humans after abrasions come into contact with contaminated soil, water, or vegetation.[10] *M. ulcerans* produces mycolactone, a cytotoxic lipid and necrotizing immunosuppressive polypeptide toxin that induces both apoptotic and necrotic changes in fibroblasts, lipid cells, macrophages, and keratinocytes.[11] Buruli ulcers are painless, and it is thought mycolactone damages the peripheral nerves.[12]

The Buruli ulcer begins as an erythematous nodule approximately 8 weeks after inoculation that eventually ulcerates. The lesions develop on exposed parts of the body, especially on the extremities and face. The resulting painless ulcer has a deep white or yellow necrotic base and undermined edges, as well as edematous surroundings (**Figure 253-4**). Regional lymphadenopathy and systemic symptoms are minimal to absent. Without treatment, ulcers may spontaneously heal within 6 to 9 months, or they may spread rapidly, causing extensive deformity.

Smears from the base of the ulcer or biopsy specimens should be cultured and examined for acid-fast bacilli. Visible growth by culture requires 6 to 8 weeks, and its success rate is low. Polymerase chain reaction performed on a fresh biopsy is the best method for early diagnosis. Surgical excision is the treatment of choice. Local heating and hyperbaric oxygen also promote healing.[13] Antimycobacterial treatment is often ineffective.[13] The World Health Organization recommends rifampin and streptomycin dual therapy for 8 weeks. New skin lesions may develop during antimicrobial therapy, and this is known as "paradoxical reactions."[8]

CUTANEOUS LEISHMANIASIS

Cutaneous leishmaniasis is transmitted by the bite of the sand fly, which is infected by protozoan parasites of the genus *Leishmania*. In tropical and subtropical regions, leishmaniasis is one of the most common and serious infectious diseases. It is endemic in North Africa, the Mediterranean, the Middle East, India, Central Asia, and Central and South America. Reactivation of latent leishmaniasis can occur in immunosuppressed, human immunodeficiency virus, malnourished, or organ transplant patients.[14] There are many varieties of cutaneous leishmaniasis. The typical cutaneous ulcer usually occurs on unclothed skin, is painless, varies in size from 0.5 to 3.0 cm in diameter, and is covered with an exudative crust (**Figure 253-5**). Diagnosis is clinical but can be confirmed with culture, biopsy, or polymerase chain reaction test. Most lesions heal spontaneously over several months.[15]

INFLAMMATORY CONDITIONS

HAND AND FOOT DERMATITIS

Hand and foot dermatitis simply means inflammation of the skin of the hands and/or feet. This nonspecific term is used for several more

FIGURE 253-5. Cutaneous leishmaniasis. [Reproduced with permission from Walter Reed Army Institute of Research.]

TABLE 253-2 Differential Diagnosis of Hand and Foot Dermatitis

Allergic contact dermatitis (poison ivy, poison oak, etc.)
Irritant contact dermatitis (soaps, detergents, shoe/glove leather, etc.)
Dyshidrosis
Atopic dermatitis
Dermatophytosis (see Table 253-4)
Psoriasis
Lichen planus
Pityriasis rubra pilaris
Palmoplantar keratoderma
Autoimmune bullous disease
Dermatomyositis
Scabies

FIGURE 253-7. Dyshidrosis. Clear, tapioca-like lesions with secondary encrustation. [Photo contributed by University of North Carolina Department of Dermatology.]

specific disorders (**Table 253-2**). The most common causes are contact dermatitis (allergic and irritant), dyshidrosis, and atopic dermatitis. Most contact dermatitis is caused by irritants as opposed to allergens. Atopic dermatitis affects children, usually before 5 years of age, and 2% to 3% of adults.[16]

Common irritants include soaps, detergents, friction, frequent hand washing, and cold, dry air, resulting in erythema, scaling, and fissuring. Strong irritants like an acid or alkali cause immediate burning, followed by erythema, vesiculation, and bullae formation.

Common allergens include poison ivy/poison oak, nickel, chromate, rubber components of gloves and shoes, dyes in leather and socks, and dichromates used in tanning leather. In acute allergic contact dermatitis, erythema with papules, vesicles, and/or bullae is present. Pruritus is intense, and excoriations are present. Distribution is the most helpful clue to aid in diagnosis. When the hands or feet are involved in allergic contact dermatitis, the eruption tends to be present on the dorsal surfaces, sparing the palms, soles, and web spaces. The thick stratum corneum of the palms and soles prevents penetration of potential allergens. Distribution with linear streaks suggests a plant allergy such as rhus (poison ivy or oak) hypersensitivity (**Figure 253-6**). Sharp demarcation of footwear indicates a reaction to a component of the patient's shoes.

Dyshidrosis initially begins as very small, deep-seated, pruritic vesicles on the lateral aspects and the volar surfaces of the palms and soles (**Figure 253-7**). The dorsal surface of the distal phalanges may also become involved. There is no erythema. Over time, the vesicles may form pustules or desquamate to leave small collarettes of scales. In chronic cases, erythema and scales become more prominent and may be difficult to distinguish from other forms of hand and foot dermatitis.

Atopic dermatitis is part of the "atopic triad" consisting of dermatitis, asthma, and allergic rhinitis.[17] Atopic dermatitis of the hands and feet often presents as erythematous, pruritic, scaly patches with prominent involvement of the dorsal surfaces as well as the palms and soles. Chronic atopic dermatitis will also have hyperpigmentation and lichenification and fissuring. Often, other areas of the body are involved. Common areas of involvement include the antecubital and popliteal fossae, posterior neck, and wrists and ankles (**Figure 253-8**).

The diagnosis is clinical. Differentiating contact dermatitis (allergic and irritant) from dyshidrosis and atopic dermatitis can be extremely difficult. More than one disorder may be present at a time, such as atopic dermatitis complicated by irritant dermatitis. Always consider a fungal infection (see later section "Tinea Pedis and Tinea Manuum"), and a potassium hydroxide preparation can exclude this possibility. A biopsy cannot differentiate between the different types of dermatitis. See **Table 253-3** for definitions of terms in superficial cutaneous fungal infections and **Table 253-4** for causes of superficial cutaneous fungal infections. Dermatologic consultation is often necessary for specific diagnosis.

Treatment is the removal of offending agents. Antihistamine, anesthetic, antibiotic, and anti-itch creams should be stopped because they may cause a second allergy. Lubricate with petroleum jelly, or thick ointments with a petroleum base, frequently and liberally.

For acute eruptions with vesiculation, use **aluminum acetate**, two to three times per day. Mix one aluminum acetate powder packet or tablet with 1 pint of water, and then apply with a towel or gauze to the affected

TABLE 253-3 Definitions of Terms for Superficial Cutaneous Fungal Infections

Dermatophytes: a group of fungi that infect nonviable keratinized cutaneous structures such as stratum corneum, nails, and hair. They most commonly include *Trichophyton* species, *Microsporum* species, and *Epidermophyton* species.
Dermatophytosis: an infection caused by dermatophytes
Tinea: a term used for specific clinical manifestations of dermatophyte or dermatophyte-like infections, with the addition of a term that usually indicates the anatomic area affected (tinea pedis, tinea manuum, etc.)
Malassezia species: a yeast causing tinea versicolor or pityriasis versicolor

area for 15 to 20 minutes. Use a high-potency topical corticosteroid, such as clobetasol ointment, twice a day, after the compress. Hydroxyzine, 25 to 50 milligrams up to four times a day, can relieve itching.

In severe cases with debilitating eruptions, systemic glucocorticoids are indicated. For **poison ivy or oak**, give oral prednisone, 60 milligrams/d, for 2 to 3 weeks. Shorter courses of prednisone can result in relapse.

Treat chronic eruptions with high-potency topical corticosteroids two to three times a day. Ointments are preferred because they help with lubrication. Systemic glucocorticoids should be avoided in chronic cases and atopic dermatitis. Although systemic steroids may provide temporary relief, rebound activity after cessation is common.

PSORIASIS

Psoriasis vulgaris or plaque-type psoriasis may involve only the palms and soles but often extends to other areas, especially the elbows, knees, scalp, umbilicus, and gluteal cleft (see chapter 251 for more discussion). If pustules are present, the disorder is called *pustular psoriasis*. Peak ages of onset are between 20 and 30 years old and between 50 and 60 years old.

Psoriasis is an inherited disease in which the principal abnormality is believed to be an abnormal T lymphocyte–driven immune process. These altered T cells are believed to secrete cytokines that shorten the keratinocyte cell cycle and produce arthropathy.

Psoriasis is characterized by discrete plaques of erythema, scales, and fissures on the extremities (**Figure 253-9**). Extensive disease may extend over the entire palms, soles, and dorsal surfaces of the hands or feet (**Figure 253-10**). Onycholysis (separation of the nail plate from the nail bed), nail pits, and yellow discoloration of the nails help support the diagnosis of psoriasis (**Figure 253-11**).

In pustular psoriasis of the palms and soles, erythema, minimal scale, and numerous sterile pustules are seen. The pustules are in various stages of evolution from small pustules to larger confluent "lakes of pus" to crusts to rings of scale (**Figure 253-12**). Pustules are most commonly seen bilaterally on the instep of the foot and the thenar and hypothenar eminences of the hands.

Complete examination of the skin focusing on the sites commonly affected by psoriasis, including the elbows, knees, scalp, lower back, gluteal cleft, umbilicus, and nails, may reveal other areas of involvement to aid in diagnosing psoriasis. If no other psoriatic plaques are noted, differentiation from hand and foot dermatitis can be difficult (**Table 253-5**). A biopsy may be helpful in this instance. A potassium hydroxide examination should be performed to exclude a dermatophyte infection. Bacterial and viral cultures should be obtained when disease is pustular and localized to one area.

Initial treatment includes the use of a high- or ultrahigh-potency topical corticosteroid such as fluocinonide, clobetasol propionate, or betamethasone dipropionate ointment. Encourage liberal use of white petrolatum-based topical emollients. **Do not prescribe systemic steroids because of the risk of rebound or induction of pustular psoriasis.** The disease is chronic and slow to respond to treatment. Arrange follow-up with a dermatologist.

ERYTHEMA NODOSUM

Erythema nodosum is an inflammatory eruption of the subcutaneous fat. It has many possible causes (**Table 253-6**) and is idiopathic in nearly half of cases. All age groups can be affected.

Tender, warm, ill-defined erythematous nodules characterize erythema nodosum (**Figure 253-13**). Nodules are most commonly seen on the pretibial area of the lower extremities, although the extensor aspects of the arms and torso can occasionally be involved. Ulceration is not a feature and suggests another diagnosis. Nodules can persist for weeks.

The diagnosis is clinical and should include evaluation for possible causes (Table 253-6). If the diagnosis is unclear (**Table 253-7**), refer for a biopsy.

Treatment is symptomatic, with leg elevation and nonsteroidal anti-inflammatory drugs. Treat the underlying cause. Refer refractory cases to a dermatologist.

LICHEN SIMPLEX CHRONICUS, CORNS, AND CALLUSES

Lichen simplex chronicus, corns, and calluses are all thickenings of the upper layer of the skin (stratum corneum) in response to chronic friction and scratching. Most commonly, ankles, lower extremities, neck, scrotum, and vulva are involved. When friction occurs in the absence of pruritus and is distributed over a large area, a callus is formed. When the

same frictional forces occur over a localized area of the foot, a corn is formed. Calluses and corns are most commonly located on the feet.

Lichen simplex chronicus presents as one or several intensely pruritic, well-demarcated plaques, with lichenification because of chronic scratching and rubbing (**Figure 253-14**). Erythema, hyperpigmentation, and excoriations are also present. Scale is minimal. The ankles, shins, dorsal feet, and hands may be affected.

Calluses and corns present as thickened plaques at areas of repetitive trauma. Corns form firm, dome-shaped papules with translucent central cores on the dorsal, lateral, and interdigital toes (**Figure 253-15**).

Diagnosis is clinical (**Table 253-8**). A potassium hydroxide examination can be helpful to rule out a dermatophyte infection. If the diagnosis is uncertain, refer for a skin biopsy. Paring of warts reveals punctuate thrombosed capillaries, which are not found in calluses or corns.

For lichen simplex chronicus, interrupting the scratch–itch cycle is the most important aspect of treatment. High-potency topical corticosteroids such as fluocinonide or clobetasol ointment should be applied to the plaque two to three times a day. Oral antihistamines help for pruritus.

Paring and keratolytics, such as salicylic acid, are first-line treatments for corns and calluses, as well as proper footwear and medical management.[18] For further treatment, refer to a podiatrist or dermatologist.

DERMATITIS HERPETIFORMIS

Dermatitis herpetiformis is a cutaneous manifestation of **gluten sensitivity**. It is most common in individuals of northern European descent.[19] Often, there is familial involvement, and there is almost universal association with HLA-DQ2 or HLA-DQ8, located on chromosome 6, with close relatives being affected by either dermatitis herpetiformis or celiac disease.[20]

Granular deposits of immunoglobulin A are found at the dermal–epidermal junction of all patients with dermatitis herpetiformis. These deposits are believed to attract neutrophils, which induce vesicle formation. The presence of immunoglobulin A antibodies to tissue transglutaminase is also highly sensitive and specific for the disorder.[21]

Extremely pruritic vesicles, papules, or urticarial plaques are symmetrically distributed on extensor surfaces of the extremities, back, and buttocks (**Figure 253-16**). Chronic scratching may result in excoriations and lichenification in these locations. Approximately 20% of patients will have clinical evidence of malabsorption.[22]

The diagnosis is supported by clinical, biopsy, and laboratory findings (**Table 253-9**). Diagnosis and treatment require dermatology referral.

Treatment for dermatitis herpetiformis includes oral dapsone and a gluten-free diet. Oral dapsone relieves pruritus within 72 hours of beginning therapy. Systemic steroids are ineffective.

CUTANEOUS INFECTIONS

FISH TANK GRANULOMA

Fish tank granuloma is an infection by *Mycobacterium marinum* that classically presents as an ulceration or suppurating abscess with a line of nodules along the corresponding lymphatic drainage. It most commonly affects individuals frequenting swimming pools or who clean fish tanks.[23] *M. marinum* is found in all aquatic environments, including fresh, salt,

FIGURE 253-17. Fish tank granuloma. Red-violet papules and plaques at sites of abrasion. [Photo contributed by University of North Carolina Department of Dermatology.]

and brackish water, swimming pools, and lakes. Infection requires exposure of abraded or traumatized skin to a contaminated environment.[23]

Two to three weeks after exposure, a solitary nodule or pustule forms. The skin breaks down into a crusted ulcer, suppurative abscess, or verrucous nodule (**Figure 253-17** and **Table 253-10**). Often, multiple lesions will form along the course of the draining lymphatics, with minimal lymphadenopathy.[24]

The history and clinical features should evoke suspicion, which should be confirmed by culture. A clinical distinction can also be made from cat-scratch fever and primary inoculation tuberculosis by noting an absence of significant lymphadenopathy in patients infected with *M. marinum*. Other diagnoses can be excluded by a skin biopsy.

M. marinum is sensitive to rifampicin, clarithromycin, tetracyclines, and trimethoprim-sulfamethoxazole.[24,25] After sensitivity testing, antibiotic therapy is usually continued for approximately 6 weeks, typically under direction of an infectious disease specialist.

CUTANEOUS LARVA MIGRANS

Cutaneous larva migrans is a cutaneous eruption caused by the migration of **hookworm larvae** within the epidermis. The disease is most commonly found in tropical and subtropical climates where people walk barefoot in environments contaminated with animal feces.

Erythematous and serpiginous tracts are formed as the larva migrates within the skin (**Figure 253-18**). The patient will often complain of pruritus. A CBC may demonstrate peripheral eosinophilia; patients are otherwise well. Diagnosis is clinical. A single oral dose of **albendazole** or **ivermectin** is usually effective.[26]

PLANTAR WARTS

Plantar warts are a common infection of children caused by the human papillomavirus. They may be acquired through direct contact with infected individuals or indirectly through contaminated surfaces. Most warts will spontaneously regress within 1 to 2 years.

Plantar warts occur on the sole of the foot, especially over pressure points, as thickened papules and plaques that disrupt normal skin lines (**Figure 253-19**). Black dots, representing thrombosed capillaries, will often cover the surface or become evident upon superficial paring. Diagnosis is clinical (**Table 253-11**).

Initial treatment is topical salicylic acid. Cryotherapy and electrodesiccation are other options.

TINEA PEDIS AND TINEA MANUUM

Tinea pedis, or athlete's foot, is a fungal infection of the feet, and tinea manuum involves the hand. Tinea manuum is often unilateral and associated with tinea pedis. Often, if one hand is involved, both feet are involved as well. It is unclear why the other hand is spared in this "two foot, one hand" type of fungal infection. Tinea pedis is very common and usually begins in early adulthood. It is rare in children. Predisposing factors include hot, humid weather, excessive sweating, and occlusive footwear. *Trichophyton rubrum*, *Trichophyton mentagrophytes*, and *Epidermophyton floccosum* are the most common organisms involved. *T. mentagrophytes* is most likely to cause inflammatory bullous tinea pedis. Infections are transmitted from person to person or from animal to person via fomites or direct contact.

There are three main clinical types: interdigital, hyperkeratotic (scaling), and bullous. Interdigital tinea pedis is the most common and is characterized by maceration and scale in the web spaces between the toes. Ulceration may even be present in severe cases that have a secondary infection with bacteria or yeast (**Figure 253-20**).

Hyperkeratotic, chronic, dry scales involve palms and soles, with little, if any, inflammation. When involving the medial and lateral aspects of

the feet, it is called "moccasin" tinea (**Figure 253-21**). Nails may be affected.

Bullous tinea consists of an acute, painful, erythematous and pruritic vesicular eruption on the palms or soles (**Figure 253-22**). Toenails and web spaces are usually not involved.

FIGURE 253-19. Plantar warts. Painless papules with red-black dots of thrombosed capillaries. [Photo contributed by University of North Carolina Department of Dermatology.]

Benign hair follicle tumor (poroma)

Diagnosis is based on clinical examination and identification of fungal elements on a potassium hydroxide preparation or with fungal culture. If the clinical examination is highly suspicious for a fungal infection, empiric therapy is reasonable. If the diagnosis is uncertain, obtain scrapings for fungal cultures before beginning therapy because culture results (whether positive or negative) can help the follow-up physician choose the most appropriate therapy.

Although a potassium hydroxide examination appears to be a simple test, it is often difficult for clinicians to perform and interpret (see Table 248-6). Scraping of scale can also be sent to the laboratory for potassium hydroxide examination and fungal culture. Hyphae appear as light-green, thin strands that cross over cells and have branches (see Figure 248-1).

Treat interdigital and hyperkeratotic (nonbullous) tinea with topical antifungals, such as clotrimazole, miconazole, ketoconazole, or econazole cream. Apply to affected areas twice a day and continue for 1 week after clearing. Although econazole cream is expensive, it is preferred for interdigital tinea pedis because it has antibacterial properties to treat secondary bacterial (often *Corynebacterium*) infection. Topical **terbinafine cream** is a nonprescription alternative and is applied once a day. Topical agents do not treat nail infections. For treatment of onychomycosis, an oral agent such as itraconazole, fluconazole, or terbinafine is needed, but this treatment is best managed by the primary care physician or dermatologist.

Bullous tinea pedis often does not respond to topical treatment. For mild cases, a topical agent can be tried initially. In more severe cases, oral antifungal treatment is necessary. Itraconazole, 200 milligrams PO each day for 14 days, or terbinafine, 250 milligrams PO each day for 14 days, is effective. **The prescribing physician should be familiar with the potential drug interactions and the uncommon, but serious, side effects (hepatotoxicity and erythema multiforme/toxic epidermal**

FIGURE 253-20. Interdigital tinea pedis. [Photo contributed by University of North Carolina Department of Dermatology.]

necrolysis) before prescribing these medications. Baseline liver function studies should be obtained when prescribing terbinafine.

Hands and feet should be kept as dry as possible. After bathing, web spaces should be thoroughly dried. Socks should be changed any time they become wet with sweat. If the eruption is not clear in 4 to 6 weeks, dermatology referral is needed. The disease is chronic, and recurrences are common.

VASCULAR CUTANEOUS CONDITIONS

ROCKY MOUNTAIN SPOTTED FEVER

Rocky Mountain spotted fever is a potentially fatal multisystem illness caused by *Rickettsia rickettsii*. Symptoms begin 2 to 14 days after an infected tick bite. The organism disseminates through the bloodstream and invades the vascular endothelium, causing a necrotizing vasculitis. Fever, headache, and myalgias develop about 1 week after exposure. The rash in classic Rocky Mountain spotted fever is evident 2 to 5 days after the onset of fever and other symptoms. In most patients, some type of rash develops during the illness, but about 10% never develop a rash.[27]

The rash first appears on the wrists and ankles and rapidly spreads to the palms and soles (**Figure 253-23, A and B**). As the rash moves centrally, the proximal extremities, trunk, and face become involved. The skin lesions at the onset are described as discrete macules or maculopapules that blanch with pressure. The initial lesions evolve into petechiae over 2 to 4 days, fade slowly over 2 to 3 weeks, and heal occasionally with hyperpigmentation. Rarely, the petechiae may coalesce into ecchymotic areas with eventual gangrene of the distal extremities, nose, ear lobes, scrotum, and vulva—purpura fulminans. Treatment for adults is doxycycline, 100 milligrams PO twice a day; for children under 45 kg with permanent teeth, treatment is doxycycline, 2.2 milligrams/kg twice a day. Doxycycline does not cause staining of permanent teeth. For further discussion of the treatment of this and other tickborne diseases, see chapter 160, "Zoonotic Infections."

Updated September 5, 2013.]

PURPURA

Purpura is visible hemorrhage into the skin or mucous membranes. Small, flat lesions are petechiae, and large, flat lesions are ecchymoses. Palpable purpura has a physically palpable elevation. Diverse abnormalities of coagulation and blood vessel function lead to hemorrhage into the skin. These include abnormalities of platelet number or function, procoagulant defects, poor dermal support of vessels, increased pressure within vessels, trauma, vascular inflammation, and vascular occlusion.

The cutaneous and systemic causes of purpura are broad. Nevertheless, some broad generalizations can be made. Large ecchymoses generally signify coagulation defects or trauma and may be associated with signs of external or internal bleeding. Petechiae are often associated with thrombocytopenia and bleeding in other locations. Palpable purpura

FIGURE 253-24. Purpura from cutaneous vasculitis. [Photo contributed by University of North Carolina Department of Dermatology.]

FIGURE 253-25. Pyogenic granuloma. Solitary vascular nodule that develops after minor trauma. [Photo contributed by University of North Carolina Department of Dermatology.]

and persistent, localized purpura suggest vasculitis (**Figure 253-24**). Because vasculitis can affect any organ system, a complete history and physical examination and a detailed laboratory investigation are required.

Major coagulation defects and platelet disorders can be diagnosed through coagulation studies. Cutaneous vasculitis is diagnosed by skin biopsy. Systemic vasculitis is diagnosed by laboratory investigation. Treatment and disposition are based on the underlying diagnosis. For additional discussion, see chapters 141, "Rashes in Infants and Children" and 249, "Generalized Skin Disorders."

PYOGENIC GRANULOMA

A pyogenic granuloma is a benign proliferation of immature capillaries occurring at the site of minor skin trauma. The name is a misnomer because it is neither an infection nor a granuloma. It most commonly occurs in children, young adults, and pregnant women. In pregnant women, it is called *granuloma gravidarum*. A pyogenic granuloma initially presents as a bright red, shiny papule with a surrounding thin collarette of hyperkeratosis (**Figure 253-25**). It may be ulcerated and tends to bleed profusely with minor injury. Later, the lesion reepithelializes and becomes a dull red to purple color. Although lesions can occur anywhere on the body, the extremities, especially hands, are the most common sites of involvement. If the lesion is bleeding profusely, obtain hemostasis with pressure or suturing. Refer for a biopsy of the lesion to exclude other disorders, especially an amelanotic melanoma (**Table 253-12**). Lesions do not resolve without specific treatment by laser therapy or electrodesiccation.

SECTION 21

Trauma

CHAPTER 254

Trauma in Adults

Peter Cameron
Barry J. Knapp

INTRODUCTION AND EPIDEMIOLOGY

Trauma accounts for 41 million annual ED visits and 2.3 million hospital admissions across the United States. Trauma is the number one cause of death for Americans between age 1 and 44 years and is the number three cause of death overall.[1] In all countries, the incidence of death from injury increases more than threefold with increasing poverty. For the 90% of patients who survive the initial trauma, the burden of ongoing morbidity from traumatic brain injury, loss of limb function, and ongoing pain is even more significant.

The major causes of death following trauma are head injury, chest injury, and major vascular injury. Trauma care should be organized according to the concepts of rapid assessment, triage, resuscitation, diagnosis, and therapeutic intervention.[2] Worldwide, there are few countries or regions that have comprehensive systems of trauma care, from roadside to rehabilitation, and that incorporate effective injury prevention strategies.

TRAUMA SYSTEMS AND TIMELY TRIAGE

A systematic approach is required to reduce morbidity and mortality that occur after traumatic injury (**Figure 254-1**).

Recognizing the need to establish a system to triage injured patients rapidly to the most appropriate setting and the importance of promoting collaboration among emergency medicine, trauma surgery, and trauma care subspecialists, the U.S. Congress passed the Trauma Care Systems Planning and Development Act of 1990.[3] This act provided for the development of a model trauma care system plan to serve as a reference document for each state in creating its own system. Each state must determine the appropriate facility for treatment of various types of injuries. Trauma centers are certified based on the institution's commitment of personnel and resources to maintain a condition of readiness for the treatment of critically injured patients. Some states rely on a verification process offered by the American College of Surgeons for the designation of certain hospitals as trauma centers.[2] In a well-run trauma center, the critically injured patient undergoes a multidisciplinary evaluation, and diagnostic and therapeutic interventions are performed with smooth transitions between the ED, diagnostic radiology suite, operating room, and postoperative intensive care setting. **Table 254-1** details the requirements for designation as a Level 1 trauma center. A complete list of trauma center requirements is available at the American College of Surgeons website (http://www.facs.org/trauma/verificationhosp.html).

A well-functioning trauma system defines trauma centers with specific triage criteria, so that patients can be initially transported by EMS to these centers or transferred to trauma centers from other hospitals after stabilization (**Table 254-2 and Figure 254-2**). In accordance with the principles of advanced trauma life support, injured patients are assessed and treated based on their presenting vital signs, mental status, and mechanism of injury.[4]

PRIMARY SURVEY

Prior to the patient's arrival at the hospital, EMS providers should inform the receiving ED about the mechanism of trauma, suspected injuries, vital signs, clinical symptoms, examination findings, and treatments provided. In preparation for the patient's arrival, ED staff should assign tasks to team members, prepare resuscitation and procedural equipment, and ensure the presence of surgical consultants and other care team members. For patients transported to EDs that are not trauma centers, consider immediately whether transfer to a trauma center is appropriate and what resuscitation or stabilization can or should be performed prior to transfer.

A focused history obtained from the patient, family members, witnesses, or prehospital providers may provide important information regarding circumstances of the injury (e.g., single-vehicle crash, fall from height, environmental exposure, smoke inhalation), ingestion of intoxicants, preexisting medical conditions (e.g., diabetes, depression, cardiac disease, pregnancy), and medication use (e.g., steroids, β-blockers, anticoagulants) that may suggest certain patterns of injury or the physiologic response to injury.

ED care of the trauma patient begins with an initial assessment for potentially serious injuries. A primary survey is undertaken quickly to identify and treat immediately life-threatening conditions, with simultaneous resuscitation and treatment. Specific injuries that should be immediately identified and addressed during the primary survey include airway obstruction, tension pneumothorax, massive internal or external hemorrhage, open pneumothorax, flail chest, and cardiac tamponade. After assessing the patient's airway, breathing, and circulation, perform a more thorough head-to-toe examination (the **secondary survey**) (**Table 254-3**). Follow the secondary survey with appropriate diagnostic testing, further therapeutic interventions, and disposition. When derangements are identified in any of the systems assessed in the primary survey, undertake treatment immediately.

AIRWAY MANAGEMENT WITH CERVICAL SPINE CONTROL

Determine airway patency by inspecting for foreign bodies or maxillofacial fractures that may result in airway obstruction. Perform a jaw thrust maneuver (simultaneously with in-line stabilization of the head and neck) and insert an oral or nasal airway as part of the first response to a patient with inadequate respiratory effort. Insertion of an oral airway may be difficult in patients with an active gag reflex. Avoid nasal airway insertion in patients with suspected basilar skull fractures. **Whenever possible, use a two-person spinal stabilization technique in which one provider devotes undivided attention to maintaining in-line immobilization and preventing excessive movement of the cervical spine while the other manages the airway.** If the patient vomits, logroll the patient and provide pharyngeal suction to prevent aspiration. Perform endotracheal intubation in comatose patients (Glasgow coma scale score between 3 and 8) to protect the airway and to prevent secondary brain injury from hypoxemia. Agitated trauma patients with head injury, hypoxia, or drug- or alcohol-induced delirium may be at risk for self-injury. Trauma patients are frequently difficult to intubate due to the need for neck immobilization, the presence of blood or vomitus, or upper airway injury. Video laryngoscopy devices are beneficial because they aid in vocal cord visualization while minimizing

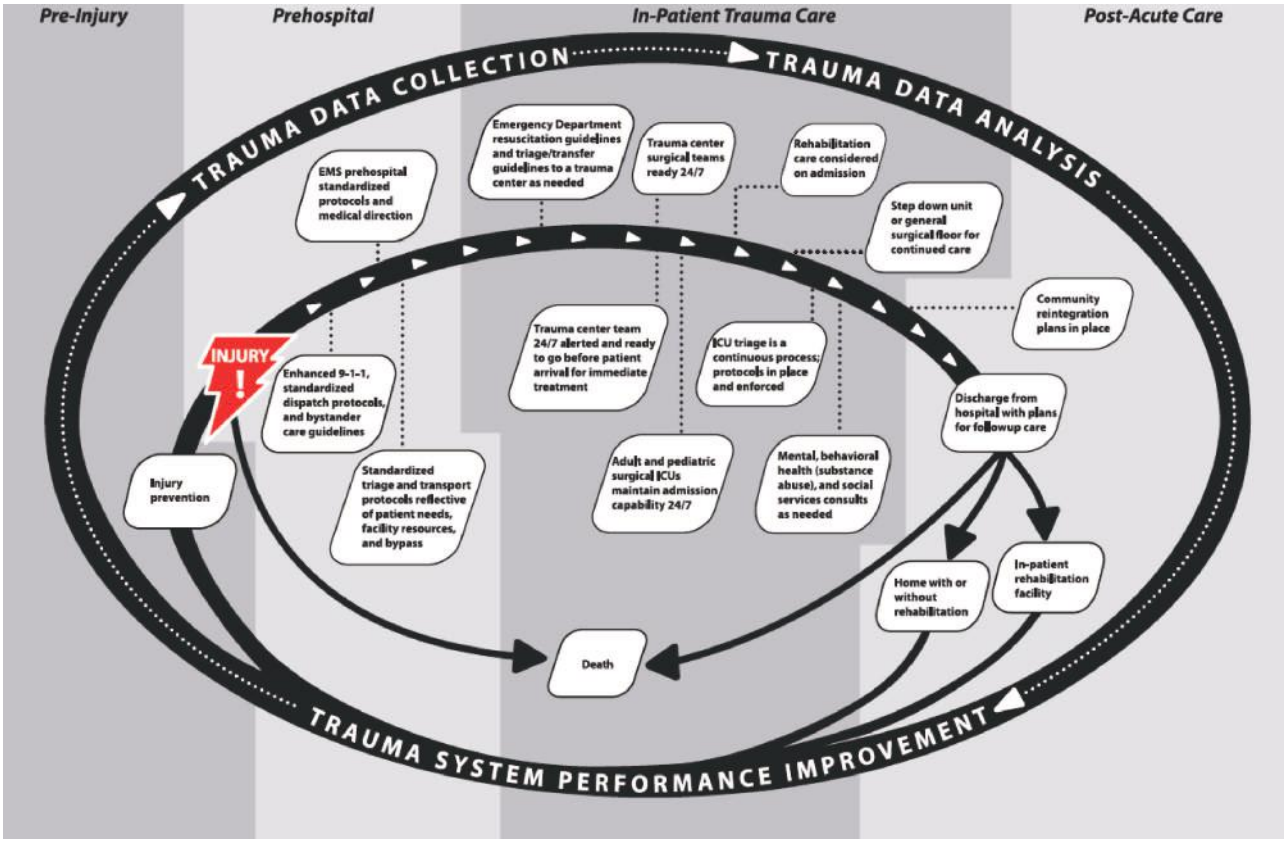

FIGURE 254-1. Phases of a preplanned trauma care continuum. [From U.S. Department of Health and Human Services, Health Resources and Services Administration. Model Trauma System Planning and Evaluation. Rockville, MD: U.S. Department of Health and Human Services; 2006. Available at: www.facs.org/trauma/tsepc/pdfs/mtspe.pdf. Accessed June 17, 2014.]

cervical spine manipulation. If anatomy or severe maxillofacial injury precludes endotracheal intubation, cricothyroidotomy may be needed. **Use a rapid-sequence intubation technique for intubation** (see chapter 29, "Intubation and Mechanical Ventilation").

Clearance of the cervical spine from serious injury involves careful clinical assessment, with or without radiologic imaging. Not all patients require cervical spine radiographs. The **National Emergency X-Radiography Utilization Study (NEXUS) criteria** (**Table 254-4**)[5] and the **Canadian cervical spine rule** (**Table 254-5**)[6] are useful only in awake and alert patients and are not a substitute for good clinical judgment. Patients meeting NEXUS or Canadian criteria for low risk of cervical spine injury should undergo full examination of the cervical spine, including active range-of-motion testing in all directions along with a thorough neurologic examination.

If the patient is obtunded, assume a cervical spine injury until proven otherwise. Even when plain radiographs or CT images show normal findings, it is possible for a patient to have unstable ligamentous injuries. Therefore, maintain spinal immobilization during the resuscitation. Imaging of the spine should not delay urgent operative procedures because imaging results will not change the immediate management. CT of the cervical spine is the preferred initial imaging modality. For full discussion of cervical spine imaging and management in trauma, see chapter 258, "Spine Trauma."

TABLE 254-1 Essential Characteristics of Level 1 Trauma Centers

Abbreviation: MVC = motor vehicle crash.

chest wall segment (flail chest); sucking chest wound; fractured sternum; and absence of breath sounds on either side of the chest (simple or tension pneumothorax, massive hemothorax, or right mainstem intubation). Any of these findings warrants immediate intervention, including needle thoracostomy for tension pneumothorax (see the section "Needle Decompression" in chapter 68, "Pneumothorax"); insertion of large-bore chest tubes (36-F) to relieve hemopneumothorax (see chapter 261, "Pulmonary Trauma"); and application of an occlusive dressing to a sucking chest wound. For asymmetric or absent breath sounds in the intubated patient, partially withdraw the endotracheal tube from the right mainstem bronchus or reintubate. If no breath sounds are heard, and if massive hemothorax or vascular injury is suspected (initial chest tube output of >1000 mL, or >200 mL/h), a thoracotomy or video-assisted thoracic surgery is indicated to identify and control the source of bleeding.

CIRCULATION AND HEMORRHAGE CONTROL

Assessment of the patient's overall hemodynamic status is critical. This assessment includes evaluation of level of consciousness, skin color, and presence and magnitude of peripheral pulses. Note the heart rate and pulse pressure (systolic minus diastolic blood pressure), particularly in young, previously healthy trauma patients.

As part of the primary survey in the prehospital and hospital settings, identify and control external hemorrhage. Apply direct pressure, a compression bandage, or a hemostatic dressing to control active external bleeding. QuikClot Combat Gauze is a kaolin-impregnated rayon and polyester hemostatic dressing that is safe and effective for arterial or venous bleeding.[2,7] For exsanguinating extremity injury, apply a tourniquet (see "Tourniquets"). Prehospital use of tourniquets on the battlefield has become commonplace. With aggressive tourniquet use, death rates from isolated limb exsanguination in Iraq dropped to 2% compared to 9% in the Vietnam War.[8]

Tourniquets

Robert L. Mabry

More than a decade of combat operations in Afghanistan and Iraq have provided the opportunity to evaluate methods for minimizing morbidity and mortality from traumatic injury. One of the greatest advances in the prevention of death on the modern battlefield is the rediscovery of the tourniquet.[9] During the war in Vietnam, tourniquet application was generally felt to be a technique of last resort.[10] The myth arguing against tourniquet use was primarily based on World War I and II experiences when evacuation to definitive care took many hours, and tourniquets were felt to increase ischemia in an already vulnerable extremity.

However, proper tourniquet application, coupled with rapid transport times to definitive care, can be life- and limb-saving in military and civilian settings.[7] Tourniquets saved lives at the Boston Marathon bombing, and as a result, the Boston Police Department and Boston EMS now carry tourniquets.[11-13]

Civilian tourniquet use is based on the military Tactical Combat Casualty Care guidelines for first responder care in the battlefield. Tourniquet use is a key component to Tactical Combat Casualty Care.

The Tactical Combat Casualty Care guidelines currently recommend three different tourniquets[14]: the Combat Application Tourniquet (C-A-T®), the SOF Tactical Tourniquet (SOF TT®), and the Emergency and Military Tourniquet (EMT®). The C-A-T® (**Figure 1**) is a lightweight windlass tourniquet, which can be applied with one hand. The SOF TT® (**Figure 2**) is another windlass tourniquet. The EMT® (**Figure 3**) is a pneumatic device, which carries the disadvantage of potential tourniquet failure if it were to be damaged or punctured by debris. Do not use narrow, elastic, or bungee-type tourniquets.[7]

If direct pressure is ineffective or impractical in controlling external bleeding, apply the tourniquet directly to the skin or over clothing, 2 to 3 inches above the wound. Tighten the tourniquet to eliminate the distal pulse. Do not release the tourniquet until the patient reaches definitive care and there is a positive response to resuscitation efforts.

The Tactical Combat Casualty Care guidelines recommend the application of a junctional tourniquet (SAM JT®) (**Figure 4**) if the bleeding site is appropriate (groin or axilla, where the torso meets the extremities) and the application of a hemostatic dressing with pressure has no effect.[14] However, as of this writing, the American College of Surgeons Committee on Trauma has not provided recommendations for the application of junctional tourniquets in the civilian environment.[7]

Pre-Hospital Trauma Triage Criteria
Adult/Pediatrics

Indications: Trauma patients who meet any of the following criteria shall be transported to the closest appropriate trauma center within a 30-minute ground transport time. Trauma patients who are not within 30 minutes ground transport time of a trauma center should be transported to the closest hospital if they cannot be delivered to an appropriate facility more rapidly by air ambulance.

Physiologic Criteria
- Glascow Coma Scale less than 14, or
- Systolic blood pressure of less than 90 mm/Hg, or
- Respiratory rate of less than 10 or greater than 29 breaths per minute (less than 20 breaths per minute in infants less than 1 year old)

Anatomic Criteria
- Penetrating injuries to head, neck, torso and extremities proximal to elbow or knee
- Flail Chest
- 2 or more proximal long bone fracures
- Crushed, degloved or mangled extremity
- Amputation proximal to wrist or ankle
- Pelvic fractures
- Open or depressed skull fractures
- Paralysis

Mechanism of Injury
- **Falls**
  - Adults – greater than 20 feet
  - Children less than 15 years old – greater than 10 feet, or 2-3 times the child's height
- **High-risk auto crash**
  - Intrusion- more than 12 inches to the occupant site or more than 18 inches to any site
  - Ejection (partial or complete) from automobile
  - Death in the same passenger compartment
  - Vehicle telemetry data consistent with high risk of injury
- **Auto versus pedestrian / bicyclists**- thrown, run over or with significant (greater than 20 mph) impact
- **Motorcycle crash** at speed greater than 20 mph
- **Special Considerations**
- **Burns** (with or without other trauma) – absent other trauma, burns that meet Burn Center criteria should be transported to a burn center
- **Pregnancy**- Injured women who are more than 20 weeks pregnant should be considered for transport to a trauma center or a hospital with obstetrical resources
- **Age** – greater than 55 years of age
- **Anticoagulation and Bleeding Disorders** – EMS should contact medical control and consider transport to trauma center
- **Time- Sensitive Extremity Injury** – open fracture(s) or fracture(s) with neurovascular compromise
- **EMS Provider Judgment** – EMS provides, based on experience and expertise, may always exercise clinical judgment regarding atypical patient presentations

FIGURE 254-2. Current Tidewater EMS (Norfolk, VA) prehospital trauma triage guidelines. [Photo contributed by Current Tidewater EMS (Norfolk, VA) Prehospital Trauma Triage Guidelines.]

CIRCULATION

Any hypotensive trauma patient is at risk for development of hemorrhagic shock, a common cause of postinjury death. One system is commonly used for classifying the degree of hemorrhage (**Table 254-6**), although it has not been validated and there is wide variability in individual patient response to hypovolemia. Hemorrhage and shock are on a continuum, and some patients can compensate for significant blood loss better than others. Hemorrhage of up to 30% of total blood volume may be associated with only mild tachycardia and a decrease in pulse pressure, but may quickly progress to profound hypoperfusion and decompensated shock if not recognized early. Be aware that medications, such as β-blockers, can mask early hemodynamic indicators of shock.

Establish two large-bore IV lines (18 gauge or larger), infuse lactated Ringer's or normal saline, and obtain blood samples or specimens for laboratory studies, particularly blood type and screen. In patients who are in unstable condition or in whom upper extremity peripheral veins are not easily cannulated, establish central venous access via the subclavian, internal jugular, or femoral vein. Avoid placement of a central venous line distal to a potential venous injury. Intraosseous access is an alternative technique for providing rapid vascular access in difficult clinical situations. Most medications including blood products can be administered through the interosseous route. Use a pressure bag to maximize flow rates. Decades of study have failed to demonstrate an advantage of colloid therapy over crystalloid infusion. Therefore, a balanced salt crystalloid (normal saline or lactated Ringer's) is the fluid of choice for initial resuscitation. There is some theoretical advantage of lactated Ringer's over saline when large volumes are given in order to avoid hyperchloremic acidosis, although this is unlikely to be significant for most patients during initial resuscitation.

Reassess hypotensive patients without an obvious indication for surgery after rapid infusion of 2 L of crystalloid solution (lactated Ringer's or normal saline). If there is no marked improvement, then transfuse type O blood (O-negative for females of childbearing age). Aggressive volume resuscitation is not a substitute for definitive hemorrhage control. A full discussion of the long-standing controversies over volume, timing, and composition of fluid resuscitation is beyond the scope of this chapter. One major study demonstrated higher mortality in patients receiving immediate IV fluid resuscitation than in those from whom fluid was

TABLE 254-3 Primary and Secondary Survey in Trauma Resuscitation

Primary Survey (rapid identification and management of immediately life-threatening injuries)

A. Airway and cervical spine

Assess, clear, and protect airway: jaw thrust/chin lift, suctioning.

Perform endotracheal intubation with in-line stabilization for patient with depressed level of consciousness or inability to protect airway.

Create surgical airway if there is significant bleeding or obstruction or laryngoscopy cannot be performed.

B. Breathing

Ventilate with 100% oxygen; monitor oxygen saturation.

Auscultate for breath sounds.

Inspect thorax and neck for deviated trachea, open chest wounds, abnormal chest wall motion, and crepitus at neck or chest.

Consider immediate needle thoracostomy for suspected tension pneumothorax.

Consider tube thoracostomy for suspected hemopneumothorax.

C. Circulation

Assess for blood volume status: skin color, capillary refill, radial/femoral/carotid pulse, and blood pressure.

Place two large-bore peripheral IV catheters.

Begin rapid infusion of warm crystalloid solution, if indicated.

Apply direct pressure to sites of brisk external bleeding.

Consider central venous or interosseous access if peripheral sites are unavailable.

Consider pericardiocentesis for suspected pericardial tamponade.

Consider left lateral decubitus position in late-trimester pregnancy.

D. Disability

Perform screening neurologic and mental status examination, assessing:

- Pupil size and reactivity
- Limb strength and movement, grip strength
- Orientation, Glasgow coma scale score

Consider measurement of capillary blood glucose level in patients with altered mental status.

E. Exposure

Completely disrobe the patient, and inspect for burns and toxic exposures.

Logroll patient, maintaining neutral position and in-line neck stabilization, to inspect and palpate thoracic spine, flank, back, and buttocks.

Secondary Survey (head-to-toe examination for rapid identification and control of injuries or potential instability)

Identify and control scalp wound bleeding with direct pressure, sutures, or surgical clips.

Identify facial instability and potential for airway instability.

Identify hemotympanum.

Identify epistaxis or septal hematoma; consider tamponade or airway control if bleeding is profuse.

Identify avulsed teeth or jaw instability.

Evaluate for abdominal distention and tenderness.

Identify penetrating chest, back, flank, or abdominal injuries.

Assess for pelvic stability; consider pelvic wrap or sling.

Inspect perineum for laceration or hematoma.

Inspect urethral meatus for blood.

Consider rectal examination for sphincter tone and gross blood.

Assess peripheral pulses for vascular compromise.

Identify extremity deformities, and immobilize open and closed fractures and dislocations.

withheld until operative intervention. The study speculated that aggressive fluid resuscitation before operative control of bleeding was harmful.[15]

Patients requiring massive transfusions generally require urgent surgical intervention to control hemorrhage. A well-defined source of bleeding may be evident on external examination, assessment of chest tube output, extended FAST examination (**Figure 254-3**), or conventional or

TABLE 254-4 NEXUS (National Emergency X-Radiography Utilization Study) Criteria for Omitting Cervical Spinal Imaging*

No posterior midline cervical spine tenderness
No evidence of intoxication
Alert mental status
No focal neurologic deficits
No painful distracting injuries

*Failure to meet any one criterion indicates need for cervical spine imaging.

TABLE 254-5 Canadian Cervical Spine Rule

Any high-risk factor that mandates radiography? (Age >64 y or dangerous mechanism or paresthesias in extremities) **No**	**If Yes, radiography indicated**
Any low-risk factor that allows safe assessment of range of motion? (Simple rear-end collision or sitting position in the ED or ambulatory at any time or delayed onset of neck pain or absence of midline cervical spine tenderness) **Yes**	**If No, radiography indicated**
Able to rotate neck actively? (45 degrees left and right) **Yes**	**If No, radiography indicated**
No radiography indicated	

TABLE 254-6 Classification of Hemorrhage Based on Estimated Blood Loss at Initial Presentation

	Class I	Class II	Class III	Class IV
Blood loss (mL)*	Up to 750	750–1500	1500–2000	>2000
Blood loss (% blood volume)	Up to 15	15–30	30–40	40
Pulse rate (beats/min)	<100	100–120	120–140	>140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal or increased	Decreased	Decreased	Decreased

*Assumes a 70-kg patient with a preinjury circulating blood volume of 5 L.

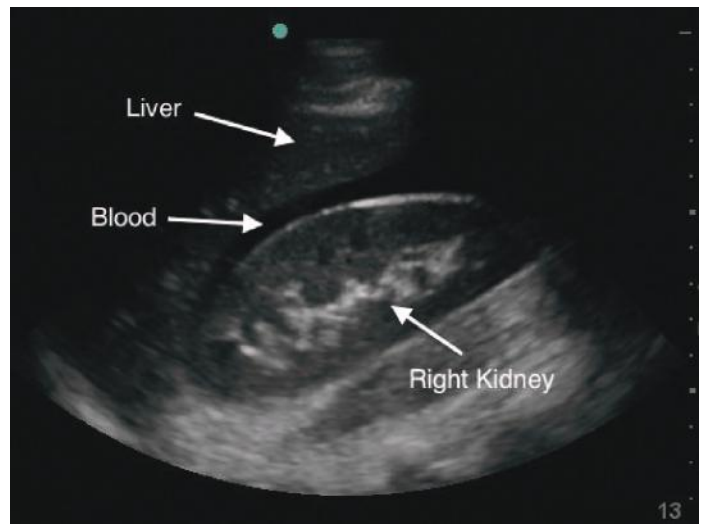

FIGURE 254-3. Positive extended FAST exam with blood identified in Morison's pouch. [Photo contributed by Barry Knapp, MD.]

CT imaging of the chest or abdomen. There may also be considerable blood loss from blunt trauma to the pelvis and limbs without a discrete source. Immobilize open pelvic fractures in a pelvic wrap or sling and reduce and immobilize limb fractures to tamponade bleeding from fractured bone ends.

Major trauma patients may develop a bleeding diathesis almost from the time of injury, which results in defective clotting and platelet function. Data from both military and civilian experience reveal that patients receiving >10 units of packed red blood cells showed decreased mortality when they simultaneously receive fresh frozen plasma in a ratio of packed red blood cells to fresh frozen plasma of 1:1 rather than 1:4 (26% vs 87.5% mortality, respectively).[16] Another consensus article examining use of blood products worldwide supported the administration of platelets in massive transfusion protocol in a 1:1:1 ratio with packed red blood cells and fresh frozen plasma.[17] Both acidosis and hypothermia contribute to the coagulopathy and should be corrected as quickly as possible.

TRANEXAMIC ACID

Tranexamic acid is an antifibrinolytic agent that reduces blood loss after surgery and may reduce blood loss after traumatic injury. It prevents cleavage of plasmin and degradation of fibrin. It is on the World Health Organization list of essential medications affecting coagulation.[18] Studies involving >20,000 patients reported a risk reduction of death from bleeding of 10% to 15%. There was no reported difference in risk of death from myocardial infarction, vascular occlusion, stroke, pulmonary embolism, mutiorgan failure, or head injury.[19] Criticism of CRASH-2 was that the patient populations studied were heterogeneous in terms of injury and were in low- to middle-income countries with basic and very limited resources for major trauma management.[20] For these and other reasons, major Western nation trauma centers have not rushed to adopt the use of tranexamic acid in trauma management algorithms.[21] Nevertheless, the evidence to date indicates that tranexamic acid may reduce mortality without significant adverse side effects when given as early as possible after injury, with administration within 1 hour of injury reported to decrease the relative risk of death from bleeding by 32% and within 1 to 3 hours by 21%.[22] Administration of tranexamic acid more than 3 hours after injury is less effective and potentially harmful.[19] Tranexamic acid must be given before transfer/arrival to a trauma center in order to meet the time requirement of early administration.[20] The dose is 1 gram of tranexamic acid IV bolus over 10 minutes, followed by 1 gram IV over 8 hours.

DISABILITY

Once airway, breathing, and circulation have been addressed and stabilized, perform a focused neurologic evaluation to assess level of consciousness, pupillary size and reactivity, and motor function. Assess the Glasgow coma scale (see chapter 257, "Head Trauma"). A search for the cause of depressed level of consciousness should include measurement of capillary blood glucose level and consideration of possible intoxicants. Despite the concomitant use of drugs and alcohol in many trauma patients, do not simply attribute altered mental status in the setting of trauma to intoxication. Assume that a patient with an appropriate mechanism for head trauma and with altered mental status or a Glasgow coma scale score of <15 has a significant head injury until proven otherwise. **The Glasgow coma scale assessment can be insensitive in patients with normal or near-normal scores, and a Glasgow coma scale score of 15 does not completely exclude the presence of traumatic brain injury.** However, patients with a persistent Glasgow coma scale score of ≤8 generally have a graver prognosis; secure a definitive airway to protect against aspiration or asphyxia. Direct efforts toward resuscitating brain-injured patients in order to maintain normal cerebral perfusion. Monitor serum glucose levels and maintain euglycemia. Mild hyperventilation may reduce intracranial pressure, although at the expense of cerebral vasoconstriction and hypoperfusion. Avoid hyperventilation during the first 24 hours after injury when cerebral blood flow is often critically reduced. **Prophylactic hyperventilation (partial pressure of arterial carbon dioxide of 25 mm Hg or less) is not recommended.**[23]

EXPOSURE

No primary survey is complete without completely disrobing the patient and examining carefully for occult bruising, lacerations, impaled foreign bodies, and open fractures. After completing the primary survey, logroll the patient, with one team member assigned to maintain in-line cervical stabilization. **Palpate the spinous processes of the thoracic and lumbar spine for tenderness or deformity, and then carefully logroll the patient back to a neutral position.** The utility of routine rectal examination is debated, but it is useful to identify gross rectal bleeding or loss of rectal tone in patients with suspected spinal injury. Examine the perineum for bruising, laceration, or bleeding. Cover the patient with warm blankets to prevent heat loss. Some have advocated the use of hypothermia in cases of severe brain injury. However, as of this writing, there is no conclusive evidence in favor of this therapy. Potential therapeutic benefits must be weighed against the coagulopathy and increased bleeding that hypothermia also causes in trauma patients.

SPECIFIC INJURIES OF IMPORTANCE

Place special emphasis on identifying the injuries described in the following sections during the primary survey, because they can be rapidly fatal if not recognized and treated.

SEVERE HEAD AND SPINAL TRAUMA

Rapidly assess neurologic status in patients with suspected traumatic brain injury. **To quickly identify patients with intracranial injuries who may benefit from operative treatment, defer any procedures that do not correct a specific problem discovered during the primary survey until after the head CT is performed.** In patients requiring intubation, provide in-line immobilization when the cervical collar is removed during intubation, and then reapply after intubation. Obtain a chest radiograph to assess endotracheal tube placement and exclude pneumothorax. The use of US to rapidly confirm endotracheal tube placement and exclude large pneumothorax is also an option.

TENSION PNEUMOTHORAX, OPEN PNEUMOTHORAX, AND MASSIVE HEMOTHORAX

Tension pneumothorax, open pneumothorax, and massive hemothorax all should be readily apparent during the primary survey. If tension pneumothorax is clinically suspected, immediately perform tube thoracostomy. If equipment is not immediately available, needle thoracostomy can be a temporizing measure. Delays in diagnosis and treatment (including awaiting confirmatory chest x-ray) can result in complete hemodynamic collapse. In equivocal cases, US can confirm the presence of pneumothorax and prompt emergent intervention. Perform tube thoracostomy in a timely manner in patients with a significant pneumo- or hemithorax, as determined by US, chest x-ray, or CT (see chapter 261).

PENETRATING ABDOMINAL TRAUMA

Abdominal tenderness or distention on palpation, coupled with hypotension, indicates the emergent need for exploratory laparotomy in a patient who has sustained a penetrating abdominal injury; this should prompt immediate transport to the operating room. Early operative intervention in patients experiencing penetrating trauma who are in shock results in better outcomes. Placement of nasogastric, urinary, and

IV catheters may proceed in the ED only if they do not delay definitive operative intervention. Otherwise, these procedures should take place in the operating room as the patient is being prepared for general anesthesia. In the setting of a penetrating gunshot wound to the abdomen, diagnostic imaging (US, CT) is rarely indicated because almost all cases undergo emergent exploratory laparotomy.

IMPALED OBJECTS

Objects deeply impaled in the chest and abdomen should be left in place and the patient emergently transported to the operating room for surgical removal under direct visualization to ensure vascular control and hemostasis. The impaled object may be cut or shortened outside the skin to facilitate transport.[24]

TRAUMATIC CARDIAC ARREST

Unless obvious signs of death are present in the field, providers in most emergency medical systems continue to transport patients without pulse or respiration to a hospital once cardiopulmonary resuscitation has been initiated. For patients in traumatic arrest upon arrival to the ED, a critical decision must be made regarding the appropriate level of intervention and, specifically, the use of emergent thoracotomy. One study analyzing 862 patients undergoing ED thoracotomy at a regional trauma center showed that the proportion of neurologically intact survivors was 3.9%. The best outcomes were in patients with stab wounds to the chest. Further analysis revealed that the survival rate was 23% among thoracic stab wound victims who showed breathing or pulse in the field and 38% among those who were moribund but had some indication of respiration or pulse on arrival to the ED. Therefore, **the strongest recommendation for performing ED thoracotomy can be made for patients with penetrating chest trauma with witnessed signs of life during transport to or in the ED and at least cardiac electrical activity upon arrival.**[25-27] There were no survivors among patients with blunt trauma and no respiration or pulse in the field. ED thoracotomy for this group is not indicated (including in the presence of myocardial electrical activity) (**Table 254-7**).[4]

An extended FAST examination performed upon arrival can be useful in identifying cardiac tamponade or the absence of ongoing cardiac activity and can prevent an unnecessary ED thoracotomy.

SECONDARY SURVEY

The secondary survey is a rapid but thorough head-to-toe examination for injuries (Table 254-3). Do not start the secondary survey until basic functions have been corrected in conjunction with the primary survey (airway, breathing, circulation, disability, exposure) and resuscitation has been initiated. The secondary survey can help set priorities for ongoing evaluation and management. Frequent reassessment of the patient's blood pressure, pulse rate, and response to interventions should continue during this period.

Scalp lacerations can bleed profusely. Bleeding can be controlled with plastic Raney clips (see chapter 42, "Face and Scalp Lacerations") or staples that grasp the full thickness of the scalp. Inspect the tympanic membranes for hemotympanum and repeat the pupil examination. Repeat the examination of the neck and thorax for any changes. When there is facial trauma or evidence of basilar skull fracture, insert the gastric tube through the mouth rather than the nose.

Inspect the urinary meatus, scrotum, and perineum for the presence of blood, hematoma, or laceration. Perform a rectal examination, noting sphincter tone, gross blood, and prostatic bogginess or displacement. The rectal examination is no longer routinely performed in alert patients without evidence of pelvic or spinal injury. If the prostate is normal and there is no blood at the urethral meatus, a urinary catheter can be placed in the bladder. **If meatal blood is present or the prostate is displaced, which suggests a urethral injury, perform retrograde urethrography before inserting a Foley catheter.** If there is vaginal bleeding, perform a manual and speculum examination to identify a possible vaginal laceration in the presence of a pelvic fracture. Evaluate the extremities for fracture and soft tissue injury, with attention to peripheral pulses. Perform a more thorough neurologic examination, carefully checking motor and sensory function.

Certain conditions are typically not evident during the secondary survey unless specifically sought. Injuries to the esophagus, diaphragm, and small bowel often remain undiagnosed, even with diligent examination, and further imaging and hospital observation for delayed presentation may be required. The most frequently missed conditions are orthopedic. Careful consideration of orthopedic extremity injuries is essential in patients with multisystem trauma. A tertiary survey has been recommended in patients with multisystem trauma within the first 24 hours to lessen the risk of missed injury.[28]

TABLE 254-7 Indications for ED Thoracotomy upon Arrival to ED

Penetrating Thoracic Trauma	
CPR (pulseless) with signs of life (Signs of life include reactive pupils, spontaneous movement, or myocardial electrical activity)	Consider ED thoracotomy
CPR (pulseless) without signs of life	No further resuscitative efforts indicated
Blunt Trauma	
CPR (pulseless) with myocardial electrical activity	No further resuscitative efforts indicated

IMAGING AND LABORATORY TESTING

For patients who are not rapidly transported to the operating room or CT suite after the initial assessment, standard radiographic imaging may include cervical spine, chest, and pelvic radiographs. The chest and pelvic radiographs image regions outside the peritoneal cavity that can accommodate volumes of blood sufficient to produce hypotension and shock. In patients with gunshot wounds to the torso, a chest radiograph is required, with or without abdominal films, depending on the site of injury.

The **extended FAST** examination is a rapid and effective screening tool for the identification of major intraperitoneal bleeding, pericardial tamponade, pneumothorax, and hemothorax as the source of hypotension or shock.[29] It should be performed to identify causes of shock immediately after the primary survey (Figure 254-3). Perform a CT scan with IV contrast for definitive imaging of the abdomen. Obtain appropriate extremity radiographs to exclude fractures as directed by the physical examination findings.

In obtunded patients or those with multisystem trauma, consider imaging of the **entire spine** if the mechanism of injury warrants it. In patients undergoing head CT, most EDs perform cervical spine CT at the same time. If chest and abdominal CTs are performed, CT images of the thoracic and lumbar spines can be reconstructed.

The liberal use of CT scanning in the setting of traumatic injury has the potential to detect injuries that are not clinically apparent. In one study of cooperative patients with no obvious signs of chest or abdominal injury, this "pan scan" method identified clinically significant abnormalities in 4% of head CT scans, 5% of cervical spine CT scans, 20% of chest CT scans, and 7% of abdominal CT scans. Overall treatment was changed in 19% of patients.[30] This approach should be balanced by the estimation that approximately 29,000 future cancers could be related to CT scans performed in the United States in 2007 alone.[31] Children represent a subgroup that deserve special consideration because exposure to radiation in childhood significantly increases the incidence of cancer later in life.[32] **In younger patients in whom the clinical indication for CT scan may be equivocal, avoid the use of ionizing radiation whenever possible.** In general, use clinical judgment to direct focused application of diagnostic imaging.

Routine laboratory studies often include blood type and screen, hemoglobin level, urine dipstick testing for blood, and ethanol level. In women of childbearing age, always perform a pregnancy test. Check capillary blood glucose level in patients with altered mental status or a

history of diabetes mellitus. In patients older than 55 years, consider obtaining an ECG and measuring levels of markers for cardiac ischemia, such as troponin I.

DISPOSITION AND FOLLOW-UP

Expeditiously transport patients with hemodynamic instability and ongoing bleeding to the operating room or transfer the patient to another facility with appropriate surgical or critical care resources. Complete a rapid but thorough primary and secondary survey prior to transfer. In most urban Level 1 trauma centers, the trauma surgeon will have been present for the primary and secondary surveys. In rural hospitals that transfer the most severely injured trauma patients, the resuscitating physician should relate all the physical findings discovered during the primary and secondary surveys to the physician receiving the patient. Laboratory results, imaging studies, and the chronologic record of the patient's blood pressure, pulse, fluids infused, urine output, gastric output, and neurologic findings should accompany the patient. Personnel capable of performing ongoing resuscitation of the patient should accompany a patient transported to another facility.

Serial examinations are essential for patients without clear indications for surgery identified on initial assessment. Patients may be admitted to the hospital or an ED observation unit. Blunt abdominal injuries such as those involving the pancreas and bowel may not be readily apparent on initial CT. These injuries may become clinically apparent upon serial examinations. In addition, consider admission or observation for patients with closed head trauma who have normal levels of consciousness and require repeat neurologic examinations as well as patients at risk for delayed pneumothorax or pulmonary contusion that require repeat chest radiography.

CHAPTER 255

Trauma in the Elderly

Ross J. Fleischman
O. John Ma

INTRODUCTION AND EPIDEMIOLOGY

The elderly have worse outcomes following trauma because of physiologic changes that occur with aging. They are more susceptible to serious injury from low-energy mechanisms, less able to compensate from the stress of injury, and more likely to suffer complications during treatment and recovery. Emergency physicians should have a higher suspicion for injury and lower threshold for diagnostic testing and admission than in younger patients.

Studies have variously defined the lower limits of the geriatric age group to be as young as 55 years and as old as 80 years. Some have shown mortality to increase with individuals as young as 45 years of age.[1] Regardless of the definition, caring for injured elders constitutes a large and growing portion of emergency medicine practice. The U.S. Census Bureau projects that those ≥65 years old will increase from 13% to 16% of the population by 2020 and to 20% by 2040.[2,3] Geriatric patients represented 12% of the population in the Major Trauma Outcomes Study.[4] Although the elderly are less likely to be involved in trauma, they are more likely to have fatal outcomes when injured, with a mortality rate twice that of younger patients. Those age 65 years and older consumed a disproportionate share of trauma hospitalizations (23%) and trauma costs (28%) relative to the 12% of the U.S. population they comprised in 1985.[5]

PATHOPHYSIOLOGY

Part of the difficulty in describing the elderly population derives from the discrepancy between chronologic and physiologic age. Chronologic age is the actual number of years the individual has lived, whereas physiologic age describes the functional capacity of the patient's organ systems. Studies have shown a clear association between age and mortality. Comorbid diseases have been shown to be associated with increased mortality after minor and moderate injuries in all age groups.[6]

The physiologic changes of aging complicate recovery from injury and make assessment of injury more difficult. With age, myocytes are lost and replaced by collagen. This results in decreased contractility and compliance for any given preload.[7] An 80-year-old person will have approximately 50% of the cardiac output of a 20-year-old, even without significant atherosclerotic coronary artery disease. Maximal heart rate and cardiac output decrease with age. Aging myocardium has a decreased chronotropic response to catecholamines and is dependent on preload (intravascular volume); hypovolemia can easily result in shock. Deterioration of the cardiac conduction system leads to atrial fibrillation and bundle-branch blocks. Medications, especially digoxin, β-blockers, and calcium channel blockers, impair the tachycardic response to catecholamines, both impairing the body's inability to compensate for hemorrhage and making heart rate an unreliable predictor of hypovolemia.

Chest wall compliance, respiratory muscle strength, and the capacity for oxygen exchange all decrease with age. The response to hypoxia may decline by 50% and that to hypercarbia by 40%, such that the patient may not appear to be in respiratory distress despite impending respiratory failure.[8] Because of weakened respiratory muscles and degenerative changes in the chest wall, maximum inspiratory and expiratory force may be decreased by up to 50% compared with younger patients. Age-related reductions in vital capacity, functional residual capacity, and forced expiratory volume can limit older patients' ability to compensate for chest injuries.

Renal function declines with age, predisposing patients to dehydration, requiring medication dose adjustments based on calculated creatinine clearance, and making them susceptible to contrast-induced nephropathy.

COMMON MECHANISMS OF INJURY

Falls Falls are the most common cause of fatal and nonfatal injury in people ≥65 years of age.[9,10] One third of older adults fall annually, and the rate of falls increases with age. Hip fractures are the most common fracture in elders hospitalized for injury, but the overall incidence of nonhip, nonspine fractures in women >55 years old is five times greater than hip fractures.[11,12] There are age-related changes in postural stability, balance, motor strength, coordination, and reaction time that make the elderly more prone to tripping and falling. Other causes of falls in the elderly are listed in **Table 255-1**. Bathroom falls are concerning because hard bathroom surfaces can result in head and spinal injuries, and slippery surfaces can cause falls. Falls on stairs involve higher energy and potential for injury than those on flat ground. Falls in which an individual is unable to get help for a prolonged period should prompt investigation for rhabdomyolysis and dehydration with a check of the creatinine kinase and electrolytes.

Motor Vehicle Crashes Motor vehicle crashes are the second most common cause of injury in the elderly and are the leading cause of death, with a case fatality rate twice that of those under 65 years.[4] The elderly make up 17% of U.S. traffic fatalities.[13]

Pedestrian–Motor Vehicle Collisions The elderly are second only to children as victims of pedestrian–motor vehicle collisions. Those ≥65 years old account for 19% of pedestrian–automobile fatalities in the United States.[14] Pedestrian–motor vehicle collisions are one of the most lethal mechanisms of injury in this age group, with a 53% case fatality rate.

Burns There is a direct relationship between age and burn mortality, as evidenced by the traditionally taught **Baux score**, in which the sum of age and body surface area burned yield the percentage likelihood of mortality. Although the Baux score still has prognostic value, advances in

TABLE 255-1 Common Causes of Falls in the Elderly

Associated with syncope/loss of consciousness
Dysrhythmias
Seizures
Acute coronary syndrome
Hypoglycemia
Pulmonary embolism
Associated with near-syncope, positional change, vasodilation (e.g., hot water)
Antihypertensive medications (especially β-blockers, calcium channel blockers)
Dehydration, diuretic medications
Hemorrhage (GI bleed, abdominal aortic aneurysm)
Hot bath or shower
Sepsis
Anemia
Nonsyncopal, "mechanical" causes
Deconditioning
Decreased visual acuity
Unsafe home conditions (e.g., poor lighting, loose rugs)
Alcohol
Sedating medications (narcotics, benzodiazepines, antihistamines, sleep aids)
Neurologic disease (cerebrovascular attack, Parkinson's disease)

critical care and burn treatment have raised the point of futility of treatment to a Baux score of 160 (rather than 100) and a 50% risk of mortality to a Baux score of 110.[15] In patients >65 years old, a 50% mortality is anticipated with a body surface area of burn of 28%. The presence of inhalation injury adds the equivalent of 17 years or points of body surface area burned to the predictive score.[16]

Elder Abuse Maintain a high suspicion for intentional injuries and injuries caused by neglect. Warning signs include poor hygiene, untreated decubitus ulcers, injuries not explained by the reported mechanism, and subacute injuries in various stages of healing.

CLINICAL FEATURES

HISTORY

Treat injured elders as both trauma and medical patients. Ask the patient, family, and prehospital care providers about the exact events leading up to the injury. Avoid skipping the review of systems, past medical history, and medications list. **Investigating the cause of a fall may uncover serious underlying medical causes or prevent future trauma.**

PRIMARY SURVEY

Avoid feeling reassured by "normal" vital signs. A tachycardic response to pain, hypovolemia, or anxiety may be absent or blunted in the elderly trauma patient. Medications such as β-blockers may mask tachycardia and hinder the evaluation of the elderly patient. One study demonstrated that eight of 15 geriatric blunt trauma patients initially considered to be hemodynamically "stable" had cardiac outputs <3.5 L/min, and none had an adequate response to volume loading. Of seven patients with normal cardiac outputs, five had inadequate oxygen delivery.[17] Another study reported that 39% of patients with a systolic blood pressure >90 mm Hg and heart rate <120 beats/min had occult hypoperfusion, defined by lactate >2.2 or base deficit less than −2.[18] The elderly also have blunted responses to hypoxia, hypercarbia, and acidosis, which can mask the signs of respiratory failure.

Blood pressures are also misleading in the elderly patient. Because of the high incidence of underlying hypertension approaching 90%, the clinician must use a higher cutoff for hypotension than in younger patients. **In blunt trauma patients ≥65 years old, there is an association between hypotension and mortality starting with systolic blood pressures below 110 mm Hg and heart rates above 90 beats/min.** Therefore, it is reasonable to use these more conservative cutoffs as markers of abnormal vital signs.[19] A decrease in blood pressure of 30 mm Hg below a known baseline or a falling trend is also a marker of instability.

Remain highly concerned about the elderly patient with abnormal vital signs. One study found that geriatric trauma patients with a respiratory rate <10 breaths/min had 100% mortality.[20] Likewise, a systolic blood pressure <90 mm Hg in the elderly blunt trauma patient is associated with a mortality between 82% and 100%.[21]

Anatomic variations may complicate airway management. These include the presence of dentures (which may occlude the airway and make laryngoscopy more difficult), cervical arthritis (which adds danger to extending the neck), or temporomandibular joint arthritis (which may limit mouth opening).

SECONDARY SURVEY

A thorough secondary survey is essential to uncover less serious injuries. **Patients with no apparent life-threatening injuries can have potentially fatal injuries if there is some degree of limited physiologic reserve.** Seemingly stable geriatric trauma patients can deteriorate rapidly and without warning. Undertake a medication review early in the patient's evaluation, paying particular attention to medications that affect heart rate, blood pressure, and coagulation.

DIAGNOSIS

HEAD INJURY

Head injuries in the elderly cause almost 142,000 United States ED visits resulting in discharge, 82,000 survivable hospitalizations, and 14,000 deaths annually.[22] Age is an independent predictor for morbidity and mortality in patients with moderate or severe head trauma. When evaluating the patient's mental status, it would be a grave error to assume that alterations in mental status are due solely to dementia or senility.

Elders are less prone to develop **epidural hematomas** than the general population because of the denser fibrous bond between the dura mater and the inner table of the skull. There is, however, a higher incidence of **subdural** and **intraparenchymal hematomas** in the elderly than in younger patients. As the brain mass decreases with age, there is greater stretching and tension of the bridging veins that pass from the brain to the dural sinuses. Bridging veins are more susceptible to traumatic tears. Diagnosis of intracranial bleeding may be delayed because brain atrophy increases intracranial free space, allowing blood to accumulate without initial signs or symptoms.

One study of blunt head trauma patients taking warfarin who were experiencing no or minimal symptoms found a rate of injury on head CT that changed disposition in 7%.[23] Therefore, **immediate noncontrast head CT is recommended for patients who take warfarin and have a mechanism of injury concerning for even a minor head injury**. Check the INR, because the degree of anticoagulation correlates with the risk of adverse outcomes.[24] The risk conferred by other anticoagulant medications is less known. Some studies have shown the antiplatelet medication clopidogrel to confer an increased risk of intracranial bleeding after head injury.[25] There is insufficient evidence to delineate the risk conferred by aspirin, low-molecular-weight heparins, or the newer oral anticoagulants.[26,27]

CERVICAL SPINAL INJURIES

The incidence of cervical spine injury is about twice as great in elders as in a younger cohort of blunt trauma patients. Odontoid fractures are particularly common in geriatric patients, accounting for 20% of geriatric cervical spine fractures, as compared with 5% of nongeriatric fractures.[28] Preexisting cervical spine pathology, such as osteoarthritis, bulging discs, and osteoporosis, may predispose elderly patients to spinal cord injuries. With hyperextension injuries, elderly patients may develop a **central cord syndrome**, which causes motor deficits in the upper extremities more often than the lower extremities, variable sensory loss, and bladder dysfunction. The **Canadian Cervical-Spine Rule**, but not the **National Emergency X-Radiography Utilization Study** criteria, excludes patients age ≥65 years from being considered low risk for cervical spine injury.[29,30]

Thus, liberal imaging of the cervical spine in geriatric trauma patients is warranted. **Because of the higher pretest probability of injury, as well as the difficulties in interpreting plain radiographs in a patient with age-related degeneration, CT scan is the preferred initial modality for assessing the geriatric cervical spine.** Many fractures in one section of the spine are accompanied by fractures in another section, **so identification of one fracture should prompt imaging of the entire spinal column**.[31]

THORACOLUMBAR SPINAL INJURIES

Thoracic and lumbar spine fractures account for almost half of all osteoporotic fractures.[32] They are most common at the thoracolumbar junction (T12-L1) and midthoracic areas (T7-T8).[33] Anterior wedge compression fractures are the most common. Because of the low sensitivity of plain films for identifying thoracolumbar fractures in trauma patients, CT scan is the first-line imaging modality for adult patients.[34] This is even more significant in elders, in whom osteoporosis and degenerative changes make plain radiographs more difficult to interpret. See chapter 258, Spine Trauma, for more information on specific fracture types and management.

CHEST TRAUMA

The elderly are more susceptible to chest injuries from blunt trauma and have a decreased ability to compensate for these injuries. In blunt trauma, rib fractures are the most common injury found. Rib fractures in the elderly often lead to morbidity, pneumonia, and death. The adjusted odds of death in the elderly with rib fractures is about five times that of a younger cohort.[35] Rates of pneumonia and mortality in patients ≥65 years old are twice that of younger patients, with the rates increasing with each additional fractured rib.[36] In young adults, a chest radiograph to exclude complications such as pneumothoraces may be sufficient evaluation for suspected rib fractures, as isolated fractures may be treated conservatively at home. Because of the significant mortality associated with rib fractures in elders, a CT may be necessary to assess the extent of injuries that might not be seen on plain radiographs.

ABDOMINAL TRAUMA

The abdominal examination in elderly patients is unreliable. The FAST examination is an ideal imaging study to detect free intraperitoneal fluid. Even with an initially benign physical examination, maintain a high suspicion for intra-abdominal injuries in those with associated pelvic and lower rib cage fractures. As in younger patients, many solid organ injuries can be managed nonoperatively. Rates of successful nonoperative management of splenic injuries in elderly patients range from 62% to 85%.[37] Therefore, CT with contrast is a valuable diagnostic test for evaluating the extent of injury and ongoing hemorrhage; however, the risk of contrast-induced nephropathy increases with age, hypovolemia, diuretic and nephrotoxic medications, diabetes, and preexisting renal disease. **The risk can be reduced by volume expansion with isotonic crystalloids.** Oral *N*-acetylcysteine does not appear to prevent contrast-induced nephropathy in patients undergoing coronary angiography.[38] Other strategies, including sodium bicarbonate, ascorbic acid, and use of iso-osmolar versus low osmolar contrast, have had mixed results in studies.[39-43]

ORTHOPEDIC INJURIES

Pelvic Fractures While pelvic fractures in the young are generally caused by high-energy mechanisms, the elderly, especially women, frequently suffer pelvic fractures from low-energy falls to the ground from standing or from a seated position. Pubic ramus fractures are the most common injuries, and lateral compression is the most common mechanism.[44]

CT of the pelvis should be ordered in stable patients with pelvic tenderness after an injury if plain radiographs are negative.[45,46] Plain radiography is especially insensitive for posterior fractures involving the sacrum and iliac wings, so tenderness of the posterior pelvis strongly suggests the need for cross-sectional imaging.[47] Plain radiography may be omitted in stable patients who will be going promptly to CT.[48] Even CT may be only 77% sensitive for pelvic fractures in the elderly, particularly with nondisplaced posterior fractures in osteoporotic bone. Therefore, consider MRI for patients with pelvic pain or pain on weight bearing with negative CT imaging.[49]

Studies have been contradictory on whether age is an important predictor of the need for angiographic assessment for bleeding in pelvic fractures.[50] One study found that 94% of patients 60 years of age and older taken to angiography required embolization, which is significantly higher than the 52% in younger patients.[51] Therefore, these authors advocate liberal use of angiography in elderly patients with significant pelvic fractures, even in the absence of hemodynamic instability or need for transfusion. Other studies have not demonstrated an association between age and the need for angioembolization.

Hip Fractures Hip fracture is the single most common injury diagnosis that leads to hospitalization in the elderly. Hip fractures are a significant cause of morbidity and mortality, with about 25% of elderly patients dying within a year of injury.[54] The vast majority of hip fractures are caused by falls to the ground. The age-adjusted incidence of hip fractures in women is approximately twice that of men. Hip fractures in men occur at older ages than in women. Femoral neck (intracapsular) and intertrochanteric fractures are about equally common, with subtrochanteric fractures comprising the remaining 5% to 10%.[55] Bleeding from closed pelvic and long-bone fractures can cause hypovolemia in elderly patients.

Obtain anteroposterior radiographs of the pelvis, as well as dedicated anteroposterior and cross-table lateral radiographs of the affected hip. Because plain radiographs are only 90% sensitive for hip fractures, and delay in operative repair is associated with an increase in morbidity and mortality, **normal plain radiographs should be followed by more definitive imaging in patients in whom suspicion of hip fracture persists**.[56] MRI has higher sensitivity than CT for detecting hip fractures, with one study finding that 17% of hip fractures that were occult on plain radiographs were seen by MRI but not CT.[57] The sensitivity of CT is likely lower in patients with risk factors for osteoporosis (older age, female sex, chronic steroid use, alcoholism, inactivity, poor calcium intake, endocrine disorders) and a lower energy mechanism of injury, in which fractures are less likely to be displaced. If MRI is difficult to obtain, CT may yield a diagnosis, but should be followed by MRI if nondiagnostic. Nuclear medicine scintigraphy is highly sensitive for fractures but has the disadvantages of low specificity, difficulty obtaining the study from the ED, and limited ability to delineate the full nature of the fracture. Consider admitting patients with hip fractures to a multidisciplinary team of geriatricians, orthopedists, and rehabilitation specialists.

Upper Extremity Injuries Distal radius fractures (**Colles' fractures**) are the most common fractures in women up to age 75, with a lifetime risk of about 15%.[58,59] Such fractures are often caused by a fall onto an outstretched hand and are associated with low bone mineral density or osteoporosis. Assess median nerve function before and after reduction, as a deficit will require immediate orthopedic consultation for possible nerve decompression. Unstable or displaced fractures require closed reduction with a hematoma block for anesthesia. A systematic review of unstable distal radius fractures in the elderly reported that functional outcomes were similar with nonoperative and operative management, even though nonoperative management was associated with a less satisfactory radiographic appearance.[60] So while elderly patients with active lifestyles and good functional statuses may benefit from surgical treatment, many can do as well with conservative treatment.

Fractures of the proximal humerus and humeral shaft are also common after falls from standing. Carefully assess for axillary nerve injury by checking sensation at the area of deltoid muscle insertion and deltoid muscle engagement with shoulder abduction. Note that the initial 18 degrees of shoulder abduction are generated by the supraspinatus muscle, so movement in this range may still be possible with an axillary nerve injury.

LABORATORY TESTING

Elderly trauma patients should receive more intensive laboratory evaluation than younger patients (**Table 255-2**). This may be helpful to identify comorbid diseases (e.g., creatinine for renal dysfunction) or acute causes of syncope (e.g., troponin for myocardial infarction) or to uncover occult

physiologic insults (e.g., lactate, INR, and base deficit). As discussed earlier, vital signs are an unreliable marker of shock in the elderly. **Base deficit and lactate levels are useful initial indicators of shock, and serial measurements can guide resuscitation progress.** Elevated lactate levels correlate with systemic hypoperfusion, intensive care unit and hospital length of stay, and mortality.[61,62] A "normal" or mild base deficit of –3 to –5 correlates with 24% mortality, a moderate base deficit of –6 to –9 correlates with 60% mortality, and a severe base deficit of ≤–10 correlates with 80% mortality.[63] Check creatine kinase levels to assess for rhabdomyolysis in patients who have fallen and been unable to receive assistance for a prolonged period.

TREATMENT

OUT-OF-HOSPITAL CONSIDERATIONS

EMS providers should recognize that seemingly minor trauma mechanisms, such as ground-level falls and low-speed motor vehicle crashes, may result in significant injury to older persons. For these reasons, the threshold for scene triage or transfer to a trauma center should be lower for elderly patients than for younger patients.[64]

Rates of prehospital undertriage are higher in older than in younger patients, with significant associated mortality.[65,66] For the reasons discussed earlier, traditional triage criteria of physiology (e.g., heart rate and blood pressure), anatomical injury, and mechanism are unreliable in elderly patients. Therefore, the 2011 U.S. Centers for Disease Control and Prevention National Expert Panel on Field Triage recommended a lower threshold for triage of injured elderly patients, giving three key recommendations: **"Risk of injury/death increases after age 55 years. Systolic blood pressure < 110 mm Hg might represent shock after age 65 years. Low impact mechanisms (e.g. ground level falls) might result in severe injury."**[67] The American College of Surgeons recommends that EMS providers consider contacting medical control and transporting injured patients ≥55 years old to a trauma center regardless of apparent injury severity.[68]

The elderly can rapidly develop tissue damage leading to decubitus ulcers. Consider padded backboards or vacuum splints for prolonged transports. Patients with cervical kyphosis may need firm padding placed behind the head when in spinal immobilization in order to prevent forcing the spine into an abnormal position.

BLEEDING AND HEAD INJURY

The volume of intracranial blood and hematoma expansion are the most important determinants of morbidity and mortality in head injury.[69] Rapidly reverse anticoagulation in patients taking warfarin with intracranial bleeding on CT scan. Despite a lack of sufficient positive or negative evidence, it is reasonable to reverse other forms of anticoagulation (e.g., aspirin, clopidogrel, heparin) in patients with diagnosed intracranial hemorrhage. Studies have not shown a benefit to platelet transfusion in patients on aspirin.[70,71]

Admit patients with bleeding on CT scan to an intensive care unit. The disposition of patients taking warfarin but with a normal initial CT scan is challenging because such patients have a reported rate of delayed intracranial hemorrhage between 1% and 8%.[72,73] Admission for a repeat head CT at 24 hours will catch most, but not all, delayed hemorrhages. Discharge after an initial negative head CT may also be reasonable in patients with lower INRs, with caregivers to watch them closely at home, and who are reliable to return if they develop symptoms and who have a plan for next-day follow-up by telephone or in person.

RIB FRACTURES AND RESPIRATORY FAILURE

Maintain a low threshold for admitting elderly patients with rib fractures for a period of observation until good pain control and pulmonary toilet are assured. More severe thoracic injuries, such as hemopneumothorax, pulmonary contusion, flail chest, and cardiac contusion, can quickly lead to decompensation in the elderly, especially those with baseline respiratory insufficiency. Pain control after chest wall trauma is vital to encourage ventilation in order to reduce atelectasis and the risk of infection. Pain control is challenging because the elderly may have decreased tolerance for opioid analgesics, which can have profound respiratory (hypoventilation), hemodynamic (hypotension), and CNS effects.

Continuous pulse oximetry and capnometry are helpful to assess oxygenation and ventilation. Administer supplemental oxygen to maintain oxygen saturation at >95%. Serial arterial blood gas analysis may provide early insight into respiratory function and reserve. Consider prompt tracheal intubation and use of mechanical ventilation in patients with more severe injuries, respiratory rates >40 breaths/min, or when the partial pressure of arterial oxygen is <60 mm Hg or the pressure of arterial carbon dioxide is >50 mm Hg.

SHOCK

One study of elderly trauma patients showed a marked increase in survival from 7% to 53% with early placement (within 2.2 hours) of a pulmonary artery catheter followed by goal-directed volume resuscitation and inotropic support.[17] This study also identified a subset of patients with occult shock despite "stable vital signs." Given the complications associated with pulmonary artery catheters, research on the assessment of shock by serum lactate and central or mixed venous oxygen saturation, and ongoing advances in less invasive hemodynamic monitoring and echocardiography, the optimal approach to recognizing and treating occult hypoperfusion is uncertain. A general strategy is to perform the initial imaging necessary to identify life-threatening injuries (e.g., chest radiograph, CT of the head, spine, chest, abdomen, and pelvis) and then transport to the intensive care unit for aggressive optimization of hemodynamics, after which nonessential imaging and interventions (e.g., extremity radiographs and suturing) can be performed.

Resuscitate the elderly trauma patient with small volumes of isotonic crystalloid (normal saline or lactated Ringer's), watching for a response, to avoid underresuscitation or volume overload. Strong consideration should be made for early and liberal use of red blood cell transfusion, which may enhance oxygen delivery, minimize tissue ischemia, and prevent volume overload. Depending on the type of injury and severity of blood loss, consider switching to blood transfusion after 1 to 2 L of crystalloid resuscitation.

ENVIRONMENTAL AND IATROGENIC INJURY

The decreased lean muscle mass and impaired peripheral circulation associated with aging makes the elderly patient more susceptible to pressure sores and hypothermia. Patients with prolonged extrications or transport in cool climates may be hypothermic. Expose the patient as needed for a thorough examination, but keep the patient covered as much as possible to maintain body heat. Hypothermia not explained by environmental factors may be a sign of sepsis or endocrine abnormalities. Log-roll patients onto a padded surface as soon as possible.

DISPOSITION AND FOLLOW-UP

Have a low threshold for admitting geriatric trauma patients. Admit elderly patients with polytrauma, significant chest wall injuries, abnormal

vital signs, or evidence of overt or occult hypoperfusion to the intensive care unit.

Even in patients without the need for inpatient treatment or observation, consider whether the patient is immediately ready to return home. In patients whose preinjury mobility was already tenuous, pain, decreased mobility, and medications may make a return to home dangerous. While opioid analgesics may be necessary, they may also cause delirium, decrease balance, and impair ambulation. Observation for establishment of a safe and effective pain regimen, consultation with physical therapy, and assurance of a safe home environment may be advisable to prevent a secondary injury.

OUTCOME

The ultimate goal is to return the elderly trauma patient to the preinjury state of function. Immediately after discharge, about half of survivors return home, and half go to skilled nursing or rehabilitation facilities.[74] The general consensus is that elderly trauma patients benefit from preferential triage to trauma centers and from aggressive and thoughtful resuscitation. In light of investigations showing that elderly patients often return to preexisting health status after trauma and the value of early invasive monitoring, it appears that **aggressive resuscitation efforts for geriatric trauma patients are warranted**.

CHAPTER 256

Trauma in Pregnancy

Nicole M. Delorio

INTRODUCTION AND EPIDEMIOLOGY

Trauma remains the leading cause of nonobstetric morbidity and mortality in pregnant women.[1] The severity of maternal injuries may be a poor predictor of fetal distress and outcome after a traumatic event (even minor ones). Trauma during pregnancy is associated with an increased risk of preterm labor, placental abruption, fetomaternal hemorrhage, and pregnancy loss. Achieving successful outcomes for both mother and fetus requires a collaborative effort by the prehospital provider, emergency physician, trauma surgeon, obstetrician, and neonatologist.

Trauma during pregnancy is common. One study estimated that 32,810 pregnant women sustain injuries in motor vehicle crashes every year in the United States, a rate of 9 per 1000 live births.[2] **Motor vehicle crashes** are the most common cause of blunt abdominal trauma, accounting for up to 70% of acute injuries. This is followed by **falls** and **direct assault** in decreasing order of frequency.[3] The incidence of falls appears to increase with the advancement of pregnancy, presumably due to alterations in maternal balance and coordination. Penetrating injuries are less common than blunt trauma during pregnancy.

PHYSIOLOGY OF PREGNANCY

Physiologic changes in pregnancy are discussed in detail in chapter 25, "Resuscitation in Pregnancy." In addition to normal physiologic changes, conditions such as pregnancy-induced hypertension, placenta previa, preeclampsia, and eclampsia may significantly alter the presentation and complicate evaluation and treatment in the setting of trauma (see chapter 100, "Maternal Emergencies after 20 Weeks of Pregnancy and in the Postpartum Period").

Table 25-1 summarizes important physiologic changes in pregnancy that affect resuscitation. Maternal blood volume expands at approximately week 10 of gestation and peaks at about a 45% increase from baseline at week 28. Because plasma volume increases more than red cell mass, mild physiologic anemia may be evident. Cardiac output increases by 1.0 to 1.5 L/min at week 10 of pregnancy and remains elevated until the end of pregnancy. Heart rate in the mother is generally increased by 10 to 20 beats/min in the second trimester, accompanied by decreases in systolic and diastolic blood pressures of 10 to 15 mm Hg.

The relative hypervolemic state can mislead the clinician during maternal resuscitation after trauma and make clinical findings difficult to interpret. **A pregnant patient may lose 30% to 35% of circulating blood volume before manifesting hypotension or clinical signs of shock.** Uterine blood flow is directly proportional to maternal mean arterial pressure, so maintain and replace maternal blood volume aggressively and adequately.

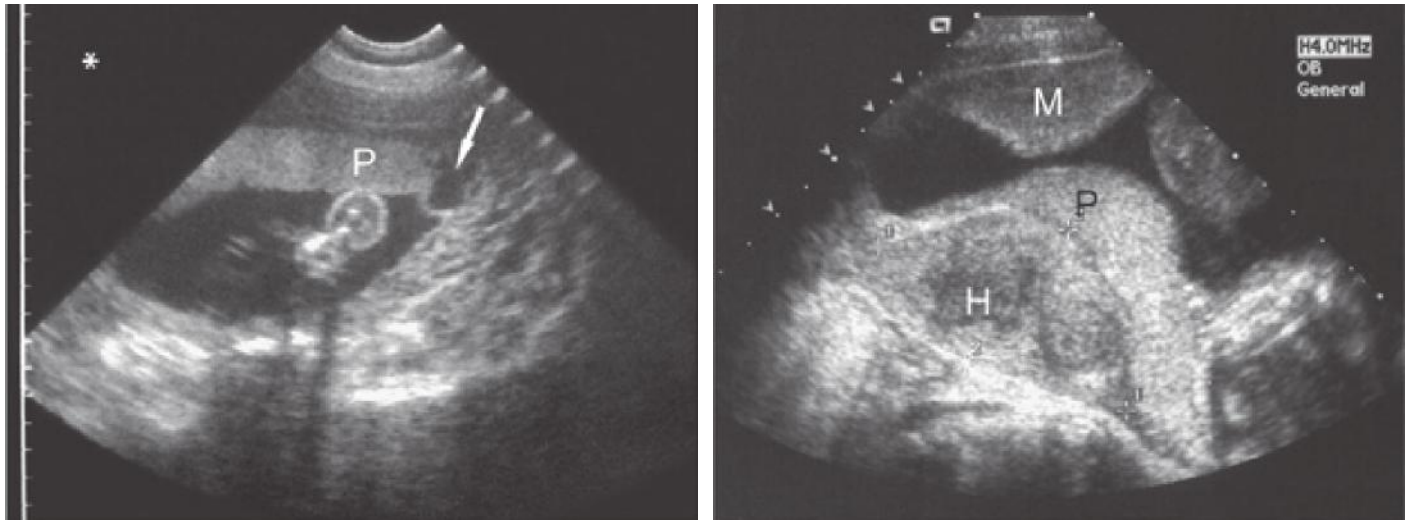
After week 12 of gestation, the uterus becomes an intra-abdominal organ, removing it from the relative protection of the maternal pelvis and making it susceptible to direct injury. The bladder moves anteriorly into the abdomen in the third trimester of pregnancy, increasing its vulnerability to injury. Uterine blood flow may increase to upward of 600 mL/min; severe maternal hemorrhage from uterine injury enters the equation at this point. The gravid uterus also causes passive stretching of the abdominal wall and peritoneum as it enlarges, and this may lead to diminished sensitivity to injury and irritation from intraperitoneal blood. **At approximately weeks 18 to 20 of gestation, the expanding mass of the gravid uterus may put the mother at risk for the "supine hypotension syndrome," in which venous return and cardiac output are diminished by compression of the maternal inferior vena cava in the supine position.** The enlarging uterus may also cause engorgement of lower extremity and lower abdominal vessels, which predisposes the patient to severe retroperitoneal injury. Avoid placing IV lines in the femoral region and lower extremity because of inferior vena cava compression by the uterus and the possibility of pooling in engorged or injured pelvic veins.

As pregnancy progresses, the diaphragm elevates by as much as 4 cm, and tidal volume increases by 40% as residual volume diminishes by 25%. These changes may significantly impair the ability of a pregnant trauma patient to compensate for respiratory compromise and can result in rapid development of hypoxia from pulmonary disorders or during intubation. **Consider diaphragmatic elevation when thoracostomy tube placement is indicated during maternal resuscitation.**

Gastric emptying is delayed, increasing the likelihood of gastroesophageal reflux and the potential for aspiration from acute injuries or endotracheal intubation. The small bowel is moved upward in the abdomen by the enlarging uterus, which increases the chance of complex bowel injuries in penetrating trauma of the upper abdomen.[4] The liver is typically unaffected by pregnancy, and the most common cause of abdominal hemorrhage remains splenic injury, as in nonpregnant patients.

CLINICAL FEATURES

Rapidly assess gestational age by palpating uterine fundal height. At week 12 of gestation, the uterine fundus is at or about the level of the pubic symphysis, and at week 20, it is at the umbilicus. The uterus then expands approximately 1 cm beyond the umbilicus per additional week of gestation. Assessing fetal age helps determine fetal viability. **Gestation ≥24 weeks is compatible with fetal viability.** Examine the abdomen and uterus for evidence of injury as well as for uterine tenderness or contractions. Placental abruption may be suggested by a rigid, boardlike uterus, or no signs may be evident at all.



A B

FIGURE 256-1. **A.** Placental abruption. Transabdominal long-axis scan shows an anterior placenta with a contained marginal abruption (arrow). [Image used with permission of L. Sens and L. Green, Gulfcoast Ultrasound.] **B.** Placental abruption. Transabdominal scan, sagittal plane, demonstrating retroplacental hematoma (H) in an 18-week pregnancy. The placenta (P) is located on the posterior wall. A myometrial contraction (M) of the anterior wall is evident.

MATERNAL AND FETAL INJURIES

Direct fetal injury is relatively rare in blunt abdominal trauma during the first trimester. When fetal injuries do occur, they are typically seen later in gestation and tend to involve the fetal skull and brain. Such injuries can be sustained in association with fractures to the maternal pelvis when the fetal head is engaged. When the uterus is penetrated by a sharp object or projectile, the fetus can be injured.

Uterine rupture accounts for <1% of all injuries in pregnancy and is more likely to occur during the late second and third trimesters and when there is direct and forceful impact on the uterus.[3] The fetal mortality rate is high. The clinical presentation of uterine rupture is quite nonspecific, but loss of the palpable uterine contour, ease of palpation of fetal parts, or radiologic evidence of abnormal fetal location suggests the diagnosis.

Uterine irritability and the onset of preterm labor may be precipitated by acute abdominal trauma during pregnancy. The use of tocolytic agents to manage premature labor in pregnant trauma patients is not generally recommended, so consult an obstetrician before considering tocolytics. Tocolytic agents have numerous adverse side effects, such as fetal and maternal tachycardia, that may complicate trauma evaluation.

Placental abruption is second only to maternal death as the most common cause of fetal death (**Figure 256-1**). Placental abruption complicates 1% to 5% of minor injuries during pregnancy and up to 40% to 50% of major traumatic injuries. During direct abdominal or deceleration injury, intrauterine pressures increase, the relatively elastic uterus deforms at the relatively inelastic placenta, and the placenta shears from the uterine wall. Even "minor" maternal injuries such as minor motor vehicle crashes, falls, and assaults can be associated with placental abruption and sudden fetal demise.[5] The most sensitive clinical finding for placental abruption after trauma is uterine irritability (more than three contractions per hour), most evident immediately after trauma, on initial presentation to the ED.[5,6] Other clinical findings of placental abruption include abdominal pain, painful vaginal bleeding, and tetanic uterine contractions. Placental abruption may also lead to the introduction of placental products into the maternal circulation, stimulating **disseminated intravascular coagulation** or **amniotic fluid embolism.**

Fetomaternal hemorrhage is the entry of fetal red blood cells into the maternal blood stream and should be assumed in the setting of maternal trauma. If the mother is Rh negative and the fetus is Rh positive, if as little as 0.1 μL of fetal blood enters the maternal circulation, it can sensitize the mother[7] and endanger the pregnancy and subsequent pregnancies. This is the basis for administering Rho(D) immunoglobulin to Rh-negative mothers after maternal trauma.

PREHOSPITAL CARE

Prehospital care providers should ask about the possibility of pregnancy when evaluating injured women of childbearing age. Prioritize attention to the fundamentals of resuscitation (airway, breathing, circulation) in the mother. Administer supplemental oxygen because compensation for hypoxia is limited in pregnancy. Similarly, consider early endotracheal intubation when indicated by the nature or severity of injuries. Establish peripheral IV lines, and provide 50% more volume than would be given to the nonpregnant patient.

For patients at >20 weeks of gestation who must be transported in the supine position or in whom spinal immobilization is indicated, place a wedge under the right hip area, tilting the patient approximately 30 degrees to the left, to prevent hypotension from inferior vena cava compression by the gravid uterus. Triage to a hospital with trauma, obstetric, and neonatal services if at all possible.[4,8]

MATERNAL DIAGNOSIS

Follow the traditional airway, breathing, circulation, disability, and exposure assessment for maternal injury, and simultaneously stabilize and resuscitate the mother. After completing the primary survey and performing resuscitative steps, proceed with secondary assessment.

ULTRASOUND

Begin with bedside expanded focused assessment with sonography for trauma to identify intra-abdominal or thoracic injury, and identify fetal activity and fetal heart rate. Transvaginal US can be performed once the mother is stabilized to complete the fetal survey and identify placental location. The sensitivity and specificity of abdominal US for the detection of intraperitoneal fluid are similar in pregnant and nonpregnant patients.[9]

RADIOGRAPHS

Carefully select imaging studies to minimize fetal exposure to the potential adverse effects of ionizing radiation**. Do not withhold imaging needed for appropriate maternal trauma management.** The greatest risk to fetal viability from ionizing radiation is within the first 2 weeks after conception, and the highest potential for malformation is during embryonic organogenesis from 2 to 8 weeks after conception. The risk of CNS teratogenesis is highest when exposure occurs between weeks 8

and 15 (see Table 99-9). **A dose <5 rad is the threshold for human teratogenesis.**[9] Fetal exposure can be decreased by shielding the maternal abdomen and pelvis during many studies and by performing modified studies and using dose-reducing techniques, such as decreasing the number of imaging slices obtained.

Standard trauma plain radiographs, such as cervical spine, chest, and pelvis films, deliver <1 rad (10 mGy) each. Abdominopelvic CT and pelvic angiography result in the highest delivered doses of radiation. The amount is typically 2.5 to 3.5 rad (25 to 35 mGy), with some variation due to equipment quality, techniques used, and duration of study. If abdominal-pelvic CT scanning is necessary to evaluate maternal status, CT also detects placental abruption, with a reported sensitivity of 86% and specificity of 98% for abruption.[10] Table 99-10 provides the estimated amounts of fetal radiation exposure for some common trauma imaging studies.[11]

Potential effects of contrast agents employed in CT scanning are not well studied, and their use requires individualization, because iodinated agents can potentially cause neonatal hypothyroidism.

PELVIC EXAMINATION

Perform pelvic examination only after US to determine placental location and exclude placenta previa.[6] **Do not perform pelvic examination if placenta previa is identified.** A sterile pelvic examination can identify injuries of the lower genital tract, vaginal bleeding, and rupture of amniotic membranes.

To assess for amniotic membrane rupture, test vaginal fluid with pH paper. **Fluid in the vagina with a pH of 7 is suggestive of amniotic fluid, whereas fluid with a pH of 5 is consistent with vaginal secretions.** A branchlike pattern, or "ferning," seen upon drying of vaginal fluid on a microscope slide, also suggests amniotic fluid.

LABORATORY TESTING

Obtain a CBC, serum chemistries, blood type and Rh status, coagulation profiles with fibrin degradation products and fibrinogen to assess for disseminated intravascular coagulation, and additional laboratory studies as clinically indicated. An Apt test or Kleihauer-Betke test can be performed by the laboratory. The Apt test is a qualitative determination of the presence of fetal hemoglobin in maternal blood. The Kleihauer-Betke test applies acid elution to an aliquot of maternal blood, and then maternal and fetal red blood cells are counted under the microscope. An extrapolation is then made regarding the volume of fetomaternal hemorrhage.

Serial Kleihauer-Betke testing can assess ongoing fetomaternal transfusion. If there is doubt whether the woman is pregnant or not, confirm pregnancy at the bedside with qualitative urine testing or with point-of-care US.

FETAL DIAGNOSIS

For pregnant trauma patients >20 weeks gestation (clinically identified by uterus at or above the umbilicus), obtain bedside US to assess fetal size, heart rate, gestational age, amniotic fluid volume, placental location, and fetal activity or demise. **Fetal viability is ≥24 weeks' gestation. Normal fetal heart rate is 120 to 160 beats/min. US may not detect uterine rupture or fetal-placental injuries, does not monitor for fetal distress, and is not sensitive for placental abruption.**[5,12] US sensitivity for placental abruption is about 25%, although specificity is >90%.[12]

Even for women ≥20 weeks, gestation with "minor" direct or indirect abdominal trauma, **as soon as possible apply cardiotochodynamometry** to monitor uterine contractions and fetal heart rate pattern. Decelerations, tachycardia, and bradycardia are signs of fetal distress. **The most sensitive clinical finding for placental abruption after trauma is uterine irritability, which is frequent uterine contractions (more than three uterine contractions in an hour).**[5,6] Fetal distress and demise can occur quickly and abruptly, so vigilant monitoring is necessary. If fetal heart tones are confirmed to be absent, then direct the remainder of treatment efforts solely at maternal resuscitation.[11]

TREATMENT

Develop a protocol involving the ED, trauma service, obstetrician, and obstetrics nurse for major trauma. For minor direct or indirect abdominal trauma (such as minor motor vehicle accident, simple fall, or assault), a simpler protocol involving ED and the obstetrics team is effective. Because most emergency physicians are unfamiliar with the patterns of early, late, and variable decelerations, the labor and delivery nurse is an essential part of the ED monitoring team. In case of fetal deterioration, the labor and delivery nurse can identify the need for emergency cesarean section.

Follow the standard steps for trauma resuscitation. **Maternal resuscitation is the best fetal resuscitation.** Manage the airway, ensure adequate ventilation, and provide supplemental oxygen. Place a nasogastric tube early, because delayed stomach emptying and diminished lower esophageal sphincter tone increase the risk of aspiration of gastric contents. **Keep the patient in the semi-left lateral decubitus position to the extent possible to minimize vena caval compression.** Identify and control sources of hemorrhage since maternal blood loss and hypovolemia exacerbate fetal hypoperfusion. Increase crystalloid infusions by 50% to account for the patient's additional plasma volume. Do not administer vasopressors until volume and blood are replaced to minimize risk of uteroplacental hypoperfusion. If vasopressors are needed for maternal resuscitation, however, do not restrict their use (see chapter 25 for further discussion).

Table 256-1 summarizes critical ED interventions for trauma in pregnancy. Do not withhold critical maternal interventions or diagnostic procedures out of concern for potential adverse fetal consequences.

Administer Rho(D) immunoglobulin to Rh-negative pregnant women with abdominal trauma. Two dose options are acceptable: 50 micrograms IM for gestation of ≤12 weeks and 300 micrograms IM for gestation of ≥13 weeks, or 300 micrograms IM for all gestational ages. The rationale for the lower dose for ≤12 weeks gestation is that the total fetal blood volume at 12 weeks gestation is about 4.2 μL, and a 50-microgram dose is effective for up to 5 μL of fetomaternal hemorrhage. A 300-microgram dose will protect for up to 30 μL of fetomaternal hemorrhage. The obstetrician can best determine if doses of >300 micrograms should be administered. Because the 72-hour window for Rho(D) immunoglobulin therapy established for postpartum administration has been extrapolated to apply after abdominal trauma, serial fetomaternal hemorrhage testing may be performed in the hospital.[7,13]

Provide **tetanus prophylaxis** as needed. Although tetanus toxoid is a category C drug for all trimesters of pregnancy, it is commonly accepted as safe. Tetanus antibody crosses the placenta, so it can also reduce the incidence of neonatal tetanus.

Continue to carefully monitor fetal heart rate patterns and frequent uterine contractions with cardiotochodynamometry. If fetal distress develops, consult obstetrics if not already at the bedside. Treat maternal hypovolemia, hemorrhage, and hypoxia and continue assessment for

TABLE 256-1 Checklist for Trauma in Pregnancy

Before arrival: Assemble ED, obstetrics, and trauma team, as appropriate for >20 wk gestation
Attend to maternal airway, breathing, and circulation as a priority for both mother and fetus. Increase volume resuscitation 50% above that given to nonpregnant patients.
Maintain patient in the semi-left lateral decubitus position, or manually deflect the uterus to the left.
Bedside US: FAST for intraperitoneal fluid and to determine fetal heart rate and estimate fetal age to determine viability.
Initiate fetal cardiotocographic monitoring as soon as possible and continue for at least 4–6 h even if the patient is apparently uninjured and > 20 weeks gestation.
Perform needed imaging.
Include blood typing and Rh status in laboratory studies.
Administer Rho(D) immunoglobulin to Rh-negative mothers. Give tetanus as indicated.
Screen for potential intimate partner violence.

Abbreviation: FAST = focused assessment with sonography for trauma.

placental abruption. In a viable gestation, the presence of fetal tachycardia, lack of beat-to-beat or long-term variability, or late decelerations on tocodynamometry indicate fetal distress and may be indications for emergency cesarean delivery.[6]

A minimum of 4 to 6 hours of external tocodynamometric monitoring of the potentially viable fetus appears sufficient to predict immediate adverse pregnancy outcomes and is indicated for all pregnant patients evaluated for trauma, even those without obvious abdominal injury. In patients demonstrating persistent contractions or uterine irritability, extend tocodynamometry to a minimum of 24 hours. Although no uniform standards exist, many obstetricians believe that patients with fewer than three contractions per hour during an initial 4-hour observation period can be safely discharged.

LAPAROTOMY

The indications for emergent laparotomy in the management of pregnant trauma patients remain unchanged from those for nonpregnant patients. The fetus appears to tolerate surgery and anesthesia well if adequate oxygenation and uterine perfusion are maintained. Do not withhold surgery out of concern for fetal compromise. Emergency cesarean delivery in the setting of trauma results in a fetal survival rate as high as 75% when gestation is ≥26 weeks, fetal heart tones are present on admission, and the procedure is performed at the earliest indication of fetal distress (see "Perimortem Cesarean Section" in chapter 25).[14]

DISPOSITION AND FOLLOW-UP

Disposition of a pregnant trauma patient after the emergency assessment and management is based on the nature and severity of presenting injuries and the gestational length of the pregnancy. Manage patients with multisystem trauma or with minor but potentially serious injuries jointly with trauma surgeons and obstetricians. Women at ≥20 weeks of gestation require observation or admission for fetal monitoring. If there is evidence of fetal distress or uterine irritability during the initial assessment, then immediately consult an obstetrician. When the patient needs transfer to other facilities for definitive care, stabilize the patient's condition as much as possible prior to transfer, with provisions for an appropriate level of care during transport. Adhere to transfer policies that comply with federal regulations. If the patient can be discharged, ensure adequate follow-up obstetrical care.[15]

SPECIAL CONSIDERATIONS

AUTOMOBILE RESTRAINT

Motor vehicle seat belt use during pregnancy helps protect both the mother and the fetus, and pregnant drivers and passengers should wear safety belts throughout pregnancy. The best predictors of fetal loss or adverse outcome are crash severity and lack of, or improper use of, seat belts.[16] The lap belt should be placed as low as possible under the gravid uterus (across both the anterior superior iliac spines and the pubic symphysis), and the shoulder harness should be positioned snugly between the breasts but off to the side of the uterus.[17,18] Pregnant women should use both seat belts and air bags. **Do not disconnect air bags for pregnant women.**[17] Although there is a risk of injury to the more proximally located gravid uterus, as long as the pregnant woman is properly seated and uses properly placed seat belts, the benefits of air bags appear to outweigh the risks.[19]

INTERPERSONAL VIOLENCE

Assaults are the third most common mechanism of injury for pregnant women after falls and motor vehicle crashes.[3] To screen for the possibility of interpersonal violence, encourage a social services evaluation or referral in all but the most obvious cases of accidental injury (**Table 256-2**).[1]

TABLE 256-2 Special Considerations Regarding Mechanism of Injury (in order of prevalence)

Motor vehicle crash	Fetus most at risk during third trimester
Intimate partner violence	Prevalence increases during pregnancy Increased risk of multiple adverse fetal outcomes not just due to fetal injury
Falls	More common in pregnancy due to changing center of gravity, ligamentous laxity Most indoors, due to stairs
Toxic exposure	Most reported events due to deliberate ingestion Fetal risk highest during first weeks due to birth defects
Burns	Can increase risk of spontaneous abortion Risks to fetus due to maternal sepsis, smoke inhalation Maternal-fetal risks from carbon dioxide intoxication

CHAPTER 257

Head Trauma

David W. Wright
Lisa H. Merck

INTRODUCTION AND EPIDEMIOLOGY

Traumatic brain injury is brain function impairment that results from external force.[1] The clinical manifestations represent a broad constellation of symptoms from brief confusion to coma, severe disability, and/or death. The underlying pathology ranges from temporary shifts in cellular ionic concentrations to permanent structural damage.

Traumatic brain injury (TBI) is classified as mild, moderate, and severe based on the Glasgow Coma Scale (GCS) score. Over 80% of TBI is defined as **mild** (GCS 14 to 15) (**mTBI**) and is often called "concussion."[2] The label of mild, however, is a misnomer. mTBI may lead to significant, debilitating short- and long-term sequelae. **Moderate** TBI (GCS 9 to 13) accounts for approximately 10% of head injuries. Mortality rates for patients with isolated moderate TBI are <20%, but long-term disability can be higher. Overall, 40% of patients with moderate TBI have an abnormal finding on CT scan, and 8% will require neurosurgical intervention. In **severe** TBI (GCS 3 to 8), mortality rate approaches 40%, with most deaths occurring in the first 48 hours after injury. Fewer than 10% of patients with severe TBI experience good recovery.[2,3]

The prevalence of TBI is twice as high in males as in females. Distribution of age at injury is trimodal, with peaks at 0 to 4 years, 15 to 24 years, and >75 years of age. Mortality rate increases with age at time of injury.[4,5] Motor vehicle collisions are the primary cause of blunt head injury in young adults and children, and falls are more common in the elderly.[2] TBI has been called the "signature injury" of the conflicts in Iraq and Afghanistan.[6]

PATHOPHYSIOLOGY

CEREBRAL BLOOD FLOW

Autoregulation, cerebral perfusion pressure (CPP), mean arterial pressure (MAP), and intracranial pressure (ICP) are interrelated factors that affect cerebral blood flow (**Table 257-1**). Under normal circumstances,

TABLE 257-1 Factors that Affect Cerebral Blood Flow

MAP = DBP + [(SBP – DBP)/3]
CPP = MAP – ICP

Abbreviations: CPP = cerebral perfusion pressure; DBP = diastolic blood pressure; ICP = intracranial pressure; MAP = mean arterial pressure; SBP = systolic blood pressure.

TABLE 257-2 Intracranial Pressure by Age Group

Age Group	Intracranial Pressure (mm Hg)
Adults	<10–15
Young children	3–7
Infants	1.5–6.0

autoregulation regulates local cerebral blood flow to maintain equilibrium between oxygen delivery and metabolism.[7] Other systemic factors, such as hypertension, hypocarbia, and alkalosis, can affect cerebral blood flow by causing vasoconstriction.

Under normal situations, autoregulation can adjust to CPPs from 50 to 150 mm Hg to maintain local cellular oxygen demands and regional cerebral blood flow. In brain injury, autoregulation is often impaired, so even modest drops in blood pressure can decrease brain perfusion and result in cellular hypoxia. A CPP <60 mm Hg is considered the lower limit of autoregulation in humans, below which local control of cerebral blood flow cannot be adjusted to maintain flow adequate for function.[8] Traumatic hypotension leads to ischemia within low flow regions of the injured brain, so aggressive fluid resuscitation may be required to prevent hypotension and secondary brain injury. In the absence of an ICP monitor, it is important to maintain a MAP of ≥**80 mm Hg**, because **low blood** pressure in the setting of elevated ICP will result in a low CPP and brain injury.

The cranium is an enclosed space with a fixed volume. Any changes to the volume of the intracranial contents (such as bleeding) affect the **ICP**, and an increase in ICP can decrease the CPP. ICP is determined by the volume of the three intracranial compartments: the brain parenchyma (<1300 mL in the adult), cerebrospinal fluid (100 to 150 mL), and intravascular blood (100 to 150 mL). When one compartment expands, there is a compensatory reduction in the volume of another, and/or the baseline ICP will increase (**Figure 257-1**). Elevations in ICP are life threatening and may lead to a phenomenon known as the **Cushing reflex** (hypertension, bradycardia, and respiratory irregularity). Hypertension is an attempt to maintain cerebral perfusion. Normal values for ICP vary with age (**Table 257-2**).

PRIMARY BRAIN INJURIES

The initial insult associated with moderate and severe TBI imparts mechanical forces that produce high levels of direct damage and strain to the brain parenchyma. The **primary injuries** include contusions (bruises to brain parenchyma), hematomas (subdural, epidural, intraparenchymal, intraventricular, and subarachnoid), diffuse axonal injury (stress or damage to axons), direct cellular damage (neurons, axons, and other supportive cells), loss of the blood–brain barrier, disruption of the neurochemical homeostasis, and loss of the electrochemical function.

SECONDARY BRAIN INJURIES

A wave of secondary damage is unleashed by the impact that results in a series of deleterious cellular and subcellular events (also known as the **secondary neurotoxic cascade**).[10,11] The secondary neurotoxic cascade causes ongoing damage to the brain and ultimately results in a poorer neurologic outcome than might have occurred based on the original mechanism.

The secondary neurotoxic cascade should not be confused with the term **secondary insults**, a term used in the clinical literature to describe conditions or circumstances (e.g., hypotension, hypoxemia, hyperglycemia) that accelerate neurotoxic damage and worsen long-term outcome.[12,13] Mediation of secondary insults reduces morbidity and mortality and is discussed in the treatment section.

The **secondary neurotoxic cascade** is a massive release of neurotransmitters, such as glutamate, into the presynaptic space, with activation of *N*-methyl-D-aspartate, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid, and other receptors.[10] Ionic shifts activate cytoplasmic and nuclear enzymes, induce mitochondrial damage, and lead to cell death and necrosis.[10,14,15] Proinflammatory cytokines and other enzymes are released in an attempt to clean and repair the damage. Secondary injury, however, is indiscriminant and produces extensive neuronal loss. Additionally, many survivable cells undergo apoptosis, or programmed cell death, during secondary injury.[16] Apoptosis has been reported to occur longer than a year after injury.[16,17]

BRAIN EDEMA

Brain edema results from two distinct processes and can be fatal in TBI.[18] Cellular swelling, or **cytotoxic edema**, results from large ionic shifts and the loss of cellular membrane integrity from mitochondrial damage (loss of adenosine triphosphate, ion pump productivity, and

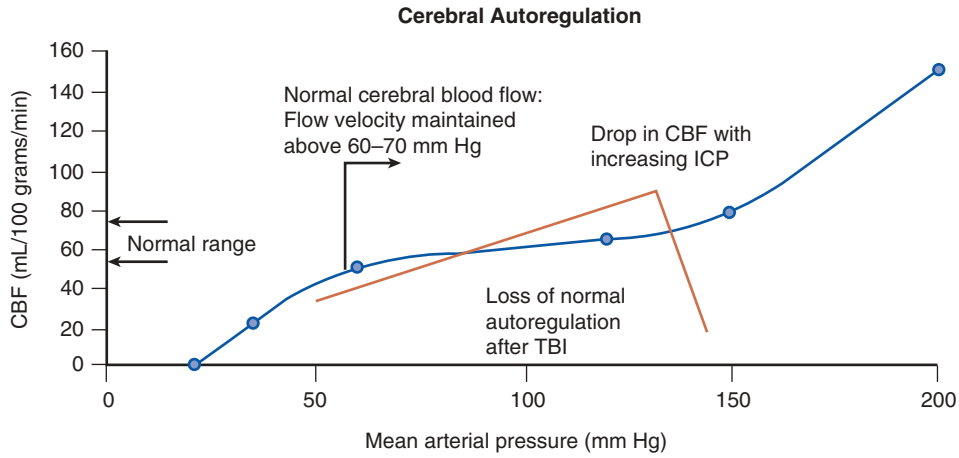

FIGURE 257-1. Pressure–volume relationship in brain injury. Normal cerebral blood flow autoregulation curve and the abnormal curve with traumatic brain injury (TBI). Normal autoregulatory control (*blue line*) maintains a relatively constant cerebral blood flow over a broad range of mean arterial pressure (MAP).9 Loss of autoregulation results in a more linear relationship between cerebral blood flow (CBF) and MAP. Elevated intracranial pressure (ICP) can dramatically decrease CBF when autoregulation is impaired (*inflection point of red line*). Increases in ICP may result in a net loss in CBF.

increased free radical production). **Extracellular edema** results from direct damage to, or the breakdown of, the blood–brain barrier, ionic shifts, and alteration of water exchange mechanisms (e.g., aquaporins).[19,20] As intracellular and extracellular water content rises, the brain swells and the ICP increases, leading to direct compressive tissue damage, vascular compression-induced ischemia, brain parenchyma herniation, and brain death.

BRAIN HERNIATION

There are four major brain herniation syndromes: uncal transtentorial, central transtentorial, cerebellotonsillar, and upward posterior fossa. The most common is uncal herniation, which occurs when the uncus of the temporal lobe is displaced inferiorly through the medial edge of the tentorium. This is usually caused by an expanding lesion in the temporal lobe or lateral middle fossa. **Uncal transtentorial herniation leads to compression of parasympathetic fibers running with the third cranial (oculomotor) nerve, causing an ipsilateral fixed and dilated pupil due to unopposed sympathetic tone. Further herniation compresses the pyramidal tract, which results in contralateral motor paralysis.** In some cases, the pupillary changes can be contralateral, whereas the motor changes are ipsilateral.

Central transtentorial herniation is less common and occurs with midline lesions, such as lesions of the frontal or occipital lobes, or vertex. **The most prominent symptoms are bilateral pinpoint pupils, bilateral Babinski's signs, and increased muscle tone.** Fixed midpoint pupils follow along with prolonged hyperventilation and decorticate posturing.

Cerebellotonsillar herniation occurs when the cerebellar tonsils herniate through the foramen magnum. **This may lead to pinpoint pupils, flaccid paralysis, and sudden death.** Upward transtentorial herniation results from a posterior fossa lesion and leads to a conjugate downward gaze with absence of vertical eye movements and pinpoint pupils.

THE GLASGOW COMA SCALE

TBI severity is classified using the GCS (Table 257-3). The scale is composed of three components: eye opening (1 to 4 points), verbal response (1 to 5 points), and motor response (1 to 6 points) (Table 257-3). The sum of these components defines the TBI severity classification into **severe** (GCS score of 3 to 8), **moderate** (GCS score of 9 to 13), and **mild** (GCS score of 14 or 15). The motor score independently correlates with outcome, almost as well as the full score.[21]

The GCS is an objective measurement of clinical status, correlates with outcome, is a reliable tool for interobserver measurements, and is effective for measuring patient recovery or response to treatment over time. However, the scale has several limitations. It measures behavioral responses, not the underlying pathophysiology. Patients with similar GCS scores may have dramatically different underlying structural injuries and require different clinical interventions (**Figure 257-2**). It is not as useful as a single acute measure of severity as it is as a tool to measure disease progression over time. The GCS may additionally be affected by drugs, alcohol, medications, paralytics, or ocular injuries. Finally, the scale lacks the granularity necessary to assess mTBI.

TABLE 257-3 Glasgow Coma Scale for All Age Groups

	4 y to Adult	Child <4 y	Infant
Eye opening			
4	Spontaneous	Spontaneous	Spontaneous
3	To speech	To speech	To speech
2	To pain	To pain	To pain
1	No response	No response	No response
Verbal response			
5	Alert and oriented	Oriented, social, speaks, interacts	Coos, babbles
4	Disoriented conversation	Confused speech, disoriented, consolable, aware	Irritable cry
3	Speaking but nonsensical	Inappropriate words, inconsolable, unaware	Cries to pain
2	Moans or unintelligible sounds	Incomprehensible, agitated, restless, unaware	Moans to pain
1	No response	No response	No response
Motor response			
6	Follows commands	Normal, spontaneous movements	Normal, spontaneous movements
5	Localizes pain	Localizes pain	Withdraws to touch
4	Moves or withdraws to pain	Withdraws to pain	Withdraws to pain
3	Decorticate flexion	Decorticate flexion	Decorticate flexion
2	Decerebrate extension	Decerebrate extension	Decerebrate extension
1	No response	No response	No response
3–15			

Note: In intubated patients, the Glasgow Coma Scale verbal component is scored as a 1, and the total score is marked with a "T" (or tube) denoting intubation (e.g., 8T).

CLINICAL FEATURES

The results of history, examination, and diagnostic imaging will allow the distinction into two categories of injury: moderate-severe brain injury and mild brain injury. Treatment and disposition are quite different in the two categories and are detailed below.

HISTORY

Obtain an accurate history from the patient, witnesses, and EMS crews to gain important insight into the mechanism of injury and overall severity of TBI (e.g., height of fall, impact surface condition, damage sustained to vehicle, airbag deployment, seat belt use, history of ejection from the vehicle, or report of fatalities at the scene). Premorbid medical history, medications (especially anticoagulants), drug use, and/or alcohol intoxication are also important in the assessment and treatment of acute TBI. **Initial clinical findings and physical exam as reported by EMS are an essential component of triaging and managing TBI.** The presence of a focal neurologic deficit, seizures, emesis, or depressed level of consciousness increases concern for underlying brain injury.

PHYSICAL EXAMINATION

Follow Advanced Trauma Life Support principles to perform the trauma-focused examination, with simultaneous lifesaving procedures as needed. Protect the cervical spine during evaluation, treatment, and imaging.

Obtain the GCS. Classify the injury as **severe (GCS score of 3 to 8), moderate (GCS score of 9 to 13), or mild (GCS score of 14 or 15). If emergency intubation is necessary, obtain a preintubation GCS and record the patient's best score.**

Determine **pupillary response**.[22] In an unresponsive patient, a single fixed and dilated pupil may indicate an intracranial hematoma with uncal herniation that requires rapid surgical decompression. **Bilateral fixed and dilated pupils** suggest increased ICP with poor brain perfusion, bilateral uncal herniation, drug effect (such as atropine), or severe hypoxia. Bilateral pinpoint pupils suggest either opiate exposure or central pontine lesion.

Altered **motor function** can indicate brain, spinal cord, or peripheral nerve injuries. Assess movement in a coma patient by observing the patient's reaction to noxious stimuli, such as pressure to a nail bed. **Decorticate posturing** (upper extremity flexion and lower extremity extension) indicates severe intracranial injury above the level of the midbrain. **Decerebrate posturing** (arm extension and internal rotation with wrist and finger flexion and internal rotation and extension of the

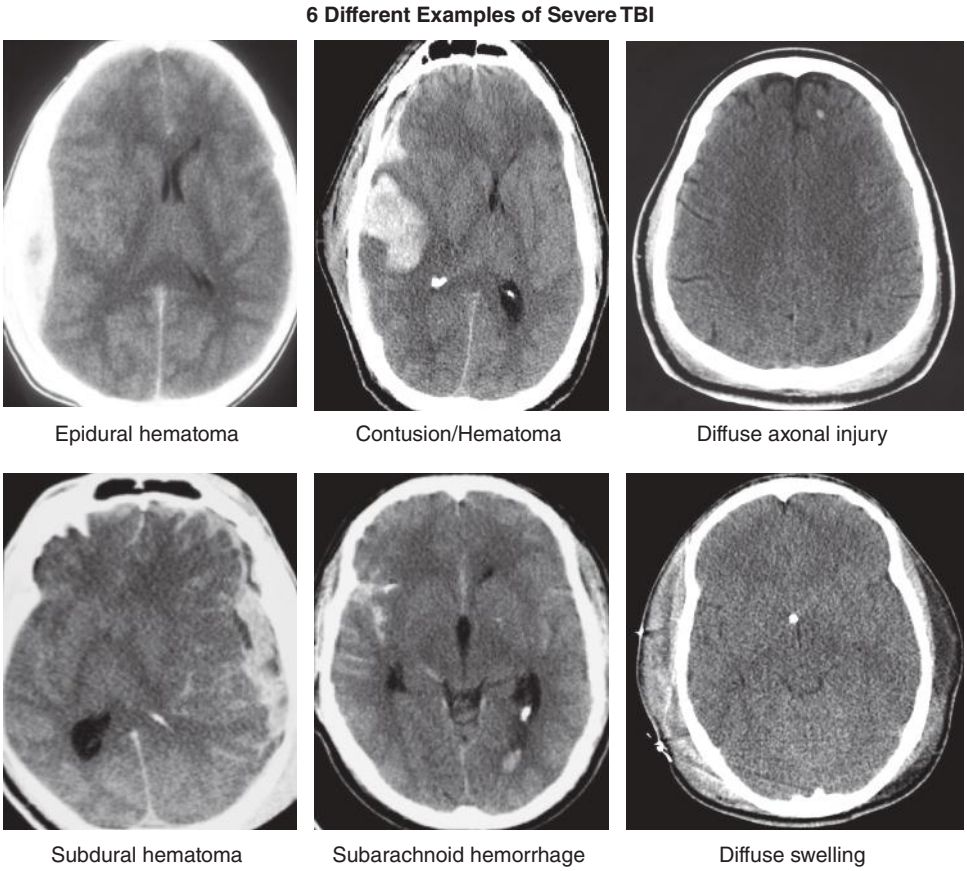

FIGURE 257-2. Each of these CT images shows a distinct trauma-induced pathophysiologic abnormality, yet all patients had a Glasgow Coma Scale score of 4. [Image used with permission of Alisa Green, MD, University of California, San Francisco.]

lower extremities) indicates a more caudal injury. For completely unresponsive patients, respiratory pattern and eye movements can provide information regarding brainstem function. Remember, do not assess oculovestibular (cold caloric) and oculocephalic (doll's eyes) responses in a patient under cervical spine precautions.

IMAGING

Individually assess each patient's mechanism of injury, history, comorbidities, and signs and symptoms when determining the need for CT imaging of the head and cervical spine.

Head CT is exquisitely sensitive to the presence of blood and guides ED management. Do not delay head CT, because expanding hemorrhagic lesions need emergency neurosurgical intervention. Therefore, **if the patient is uncooperative or combative, intubation and sedation are often the best options to enable rapid CT imaging.** Other means to control agitated patients with TBI include midazolam (1 to 2 milligrams IV) and propofol (20 milligrams every 10 seconds to desired effect).

Several decision rules have been developed to minimize unnecessary head CT imaging.[23-27] The guidelines strive to identify patients with surgical emergencies. These studies do not specifically address the relationship between minor CT findings (which may place the patient at risk for the development of seizures), the duration of postconcussive symptoms, and progressive changes on CT during the course of a patient's evaluation. Adults with mTBI and a GCS score of 14 or 15 will have an intracranial lesion on CT about 15% of the time, but <1% will require neurosurgical intervention.[28]

The prevalence of **cervical fractures** in comatose TBI patients is approximately 8%, and an estimated 4% of injuries are missed on the initial assessment of the trauma patient.[23] Cervical imaging is a vital component in the care of the brain-injured patient. Perform CT imaging of the cervical spine in patients with altered mental status and who were injured by a mechanism that increases the risk of cervical spine injury. CT is superior to plain radiography in patients with altered mental status and can be performed at the same time as the head CT.

The **NEXUS** and **Canadian Cervical Spine Rules** are discussed in detail in chapter 258, "Spine Trauma."

MRI can detect subtle lesions missed by CT imaging and can better define the extent of contusions. However, MRI may not detect subtle lesions, cannot be performed if the patient is unstable, and is not always available.

DECISION RULES FOR HEAD CT IMAGING IN ADULTS

Decision rules can guide clinical practice, but each patient must be assessed individually, and none of the rules described below address short- or long-term nonoperative sequelae of TBI. See chapter 110, "Pediatric Trauma," for a discussion of the role of head CT imaging in children with minor head injury.

The two most commonly used evidence-based clinical decision rules for head CT in adults are the **New Orleans Criteria**[29] and the **Canadian CT Head Rule**.[23] Both rules have been validated and are 100% sensitive in detecting patients who will need neurosurgical intervention, but they have limited specificity (5% versus 37%, respectively). The Canadian CT Head Rule is less sensitive (83%) if intracranial lesion is the defined end point. *A negative feature of these two decision rules is that loss of consciousness or amnesia is required as the entry point.* **Most minor brain injury events do not result in loss of consciousness, and loss of consciousness is not the best predictor of intracranial pathology (Table 257-4). Do not apply these rules to patients taking anticoagulants or antiplatelet agents, or to children, because these variables were not included in the validation studies.**

The *National Institute for Clinical Excellence* and the *Neurotraumatology Committee of the World Federation of Neurosurgical Societies* have evaluated clinical signs and symptoms associated with TBI in adults and adolescents and adults, respectively.[27,30] The resultant decision rules for head CT have been applied to large data sets and shown to be relatively sensitive (National Institute for Clinical Excellence: 94% for neurosurgical lesions, 82% for intracranial lesions; Neurotraumatology Committee: 100% for neurosurgical lesions and intracranial injuries). One study evaluated 1101 patients with mTBI who had GCS scores of 14 or 15;

TABLE 257-4 New Orleans Criteria and Canadian CT Head Rule Clinical Decision Rules

New Orleans Criteria—GCS 15*	Canadian CT Head Rule—GCS 13–15*
Headache	GCS <15 at 2 h
Vomiting	Suspected open or depressed skull fracture
Age >60 y	Age ≥65 y
Intoxication	More than one episode of vomiting
Persistent antegrade amnesia	Retrograde amnesia >30 min
Evidence of trauma above the clavicles	Dangerous mechanism (fall >3 ft or struck as pedestrian)
Seizure	Any sign of basal skull fracture
Identification of patients who have an intracranial lesion on CT	
100% sensitive, 5% specific	83% sensitive, 38% specific
Identification of patients who will need neurosurgical intervention	
100% sensitive, 5% specific	100% sensitive, 37% specific

Abbreviation: GCS = Glasgow Coma Scale.

*Presence of any one finding indicates need for CT scan.

TABLE 257-6 CT Scanning for Adults with Brain Injury (American College of Emergency Physicians Guidelines)

Adults with a Glasgow Coma Scale score of <15 at the time of evaluation should undergo CT imaging

Mild traumatic brain injury with or without loss of consciousness: if one or more of the following is present:

- Glasgow Coma Scale score <15
- Focal neurologic findings
- Vomiting more than two times
- Moderate to severe headache
- Age >65 y
- Physical signs of basilar skull fracture
- Coagulopathy
- Dangerous mechanism of injury (e.g., fall >4 ft)

Mild traumatic brain injury with loss of consciousness or amnesia: if one or more of the following is present:

- Drug or alcohol intoxication
- Physical evidence above the clavicles
- Persistent amnesia
- Posttraumatic seizures

approximately 2% of these patients without loss of consciousness had intracranial lesions and 0.6% required surgery (rates similar to patients with loss of consciousness).

One of the most important findings from these studies is the relative significance of certain elements of the history and physical examination. For example, nausea and vomiting after concussion has an odds ratio comparable to that of loss of consciousness for a positive CT finding (**Table 257-5**). Importantly, the predictive value of individual clinical signs and symptoms differs between adults and children (see chapter 138, Head Injury in Infants and Children).

A summary of the American College of Emergency Physicians recommendations[28] is given in **Table 257-6**. A combination of rules helps identify patients *at risk* and determine the possible need for a head CT (**Tables 257-4, 257-5 and 257-6**).

TREATMENT

PREHOSPITAL CARE

Early appropriate management can have a profound impact on the patient's final outcome. For patients with moderate to severe head injury, provide stabilization and rapid transport to a facility with experience in the management of brain injury. The most important prehospital interventions are airway and blood pressure management. If the patient needs prehospital intubation, avoid hyperventilation (which causes cerebral vasoconstriction and can negatively affect outcome), and use **capnometry** to keep P_{CO_2} at 35 to 45 mm Hg. Treat hypotension aggressively. If transport times are short, do not give mannitol or hypertonic saline for elevated ICP. Guidelines for prehospital care are available at http://www.braintrauma.org.

TABLE 257-5 Odds Ratio (OR) for Head CT and Clinical Features

	Smits et al[30]	Ibanez et al[26]	Fabbri et al[27,70]
	OR (95% CI)	OR (95% CI)	OR (95% CI)
Glasgow Coma Scale score of 14	2 (1–3)	7 (4–14)	19 (14–26)
Neurologic deficits	2 (1–3)	7 (2–25)	19 (13–28)
Signs of basilar skull fracture	14 (8–22)	11 (6–23)	10 (6–16)

*For severe headache.

ED TREATMENT

Principles for ED care of moderate/severe brain injury are provided at http://www.braintrauma.org and are discussed in the following section. The primary goals of treatment are to maintain cerebral perfusion and oxygenation by optimizing intravascular volume and ventilation; prevent secondary injury by correcting hypoxia, hypercapnia, hyperglycemia, hyperthermia, anemia, or hypoperfusion; recognize and treat elevated ICP; arrange for neurosurgical intervention to evacuate intracranial mass lesions; and treat other life-threatening injuries.

Systolic blood pressure of <90 mm Hg and hypoxemia (Pa_{O_2} <60) are associated with a 150% increase risk in mortality.[31]

Observe for the **signs/symptoms of elevated ICP**: change in mental status, pupillary irregularities, focal neurologic deficits, decerebrate or decorticate posturing, or CT pathology. Some CT signs of intracranial hypertension are attenuation of the visibility of sulci and gyri, because the brain is compressed against the skull; compressed lateral ventricles; and poor grey/white matter distinction. Papilledema may not be evident if pressure rises rapidly. **Sedation and analgesia** may decrease baseline ICP and prevent transient rises in ICP from agitation, coughing, or gagging from the endotracheal tube. Prevent and control **seizure activity**.

Treat hypotension, hypoxemia, hypercarbia, and hyperglycemia. A single occurrence of hypotension and hypoxia after brain injury is associated with a 150% increase in mortality.[22] TBI is progressive, so appropriate early management will have a greater impact on outcome than treatments initiated after neuronal cell death and the development of secondary injury, such as cerebral edema. Jointly develop and apply goal-directed protocols with emergency medicine, trauma, neurosurgery, and intensive care teams. An example of early goal-directed therapy is provided in **Table 257-7**.

Airway and Breathing Treat any condition that compromises ventilation (e.g., altered mental status, facial/neck trauma, pneumothorax). **Patients with severe injury (GCS score of ≤8) require intubation.** Use short-acting induction agents that have limited effect on blood pressure

TABLE 257-7 Checklist for ED Treatment of Brain Injury

	Treatment	Comments
Cervical spine	Spinal precautions	
Airway	Maintain airway, intubate for GCS <8 or as needed	
Oxygenation and ventilation	Oxygen saturation >90; P_{CO_2} 35–5	No prophylactic hyperventilation
BP	Systolic BP >90 mm Hg, MAP 80 mm Hg; give NS, blood products, or transfuse as needed	No permissive hypotension; pressors may be required if fluids not sufficient
Exam and GCS	GCS before paralytics if possible; treat life-threatening injuries and active bleeding	Serial GCS is helpful in identifying change; keep goal of "brain resuscitation" as top priority
Stat head CT and cervical spine CT	Identify mass lesions and signs of increased ICP	Protect cervical spine until cleared
Repeat exam	Check GCS for changes and for signs of impending herniation/deterioration	Change of more than 2 points should prompt further workup
Check glucose	Treat hypoglycemia *and* hyperglycemia	Hyperglycemia is bad for the brain
Control temperature	Maintain between 36°F and 38.3°F	Aggressive cooling: Tylenol, cooling blanket, etc.
Seizure prophylaxis	Give antiepileptic drug if GCS ≤10, acute seizure with injury, or abnormal head CT scan	Phenytoin (Dilantin)/fosphenytoin/levetiracetam
Identify and treat elevated ICP, herniation	Keep head of the bed at 30 degrees; ensure good BP, ventilation, and temperature control; give mannitol 1 gram/kg IV bolus; urgent NS consult	Consider adding hypertonic saline (3% NaCl 250 mL/30 min) for refractory elevations in ICP; monitor BP and electrolytes
Neurosurgery referral/transfer for advanced care	ICP monitoring, ventriculostomy for ICP management, aggressive tiered approach to management, emergency surgery	ICP monitoring and CSF diversion in GCS ≤8

Abbreviations: BP = blood pressure; CSF = cerebrospinal fluid; GCS = Glasgow Coma Scale; ICP = intracranial pressure; MAP = mean arterial pressure; NS = normal saline.

or ICP (**Table 257-8**). Avoid nasotracheal intubation if facial trauma or basilar skull fracture is evident or suspected. Monitor blood pressure throughout the procedure. Preinduction agents such as low-dose succinylcholine, vecuronium, pancuronium, and lidocaine do not improve outcome, but can be used as adjuncts if they do not delay airway control.[32] Maintain in-line cervical spine stabilization during intubation.

Maintain oxygenation and use capnometry to control P_{CO_2} and avoid hyperventilation. Prolonged (>6 hours) hypocapnia causes cerebral vasoconstriction and worsens cerebral ischemia. **Keep oxygen saturation >90, Pa_{O_2} >60, and P_{CO_2} at 35 to 45.**

Circulation Traumatic hypotension leads to ischemia within low flow regions of the injured brain. Ischemia amplifies the neurotoxic cascade and increases cerebral edema. Provide aggressive fluid resuscitation to prevent hypotension and secondary brain injury. **Maintain systolic blood pressure at >90 mm Hg and MAP >80 mm Hg.** A blood pressure within "normal" range may be inadequate to maintain adequate flow and CPP if ICP is increased. **Permissive hypotension worsens outcome in patients with brain injury.**

Isolated head injury rarely produces hypotension, except as a preterminal event. Hypovolemic shock may be seen with polytrauma, massive blood loss from scalp lacerations, or in small children from subgaleal hematoma. If fluid and blood resuscitation is not effective, use vasopressors to preserve cerebral perfusion.

Pain and increased ICP can cause hypertension. Treat pain, and assess for impending herniation (*Cushing reflex*). For management, see discussion within this chapter under "Increased Intracranial Pressure Management" section.

TABLE 257-8 Intubation Agents in Brain Injury

Agent	Comments
Induction agent	
Etomidate, 0.3 milligram/kg IV	May be neuroprotective; may lower intracranial pressure; adrenal suppression unlikely with single use
Propofol 1–3 milligrams/kg IV	Rapid onset and offset; antiseizure properties; can cause hypotension if inadequate fluid resuscitation
Paralytics	
Succinylcholine 1–1.5 milligrams/kg IV	Short acting; avoid in burns, extensive muscle injury, etc.
Rocuronium, 0.6–1.0 milligram/kg IV	Short acting, safe in hyperkalemia

Patient Positioning Raising the head of the bed may improve cerebral blood flow by lowering ICP. However, the interaction between ICP, MAP, and tissue oxygenation is complex and highly variable. Response to position change depends on many factors such as degree of intact autoregulation, brain compliance, and individual patient variability. There is still uncertainty as to whether this procedure is beneficial, but in the setting of suspected elevated ICP, it is currently recommended as a simple maneuver to improve cerebral blood flow. One must ensure that the patient's blood pressure is maintained above the minimum recommended level (MAP 80 mm Hg), because elevation of 30 degrees can drop the mean pressure within the brain by up to 10 to 15 mm Hg and improve CPP (remember CPP = MAP – ICP, so lowering the ICP improves CPP, but lowering MAP in the setting of hypotension could be counterproductive and lower CPP). Elevating the head of the bed to 30 degrees can be safely accomplished even when the spine has not been cleared, as long as neck movement is secured.[33]

Glucose Control Hyperglycemia in the setting of neurologic injury (both stroke and TBI) is associated with worse outcome. Tight hyperglycemic control is recommended in patients with moderate to severe TBI. Insulin drips may be required to achieve adequate control (glucose 100 to 180 milligrams/dL or 5.55 to 9.99 mmol/L).

Temperature Control Elevated temperature is associated with an increased metabolic demand and excessive glutamate release. Elevated temperature elevates ICP and worsens outcome in many neurologic critical care conditions including TBI. Treat fever with the goal of normothermia. The evidence for hypothermia in TBI is not sufficient to recommend its use.

Seizure Treatment and Prophylaxis Seizures after head injury can change the neurologic examination, alter oxygen delivery and cerebral blood flow, and increase ICP. Prolonged seizures can worsen secondary injury. Treat acute seizures with IV lorazepam, and if seizures continue, treat as for status epilepticus. Give prophylactic phenytoin/phosphenytoin if the GCS is ≤10, if the patient has an abnormal head CT scan, or if the patient has had an acute seizure after the injury. The dose is 18 milligrams/kg IV at 25 milligrams/minute. Prophylactic anticonvulsants reduce the occurrence of posttraumatic seizures within the first week. Phenytoin/phosphenytoin is the agent most studied. Levetiracetam can be used, but there are less data supporting its use. Steroids have no role.

Cerebral Herniation Develop a team approach to ICP management between emergency medicine, neurosurgery, intensive care unit, and trauma teams.

Use patient history and physical examination to identify signs and symptoms of impending herniation. Indicators of rising ICP include

severe headache, visual changes, numbness, focal weakness, nausea, vomiting, seizure, change in mental status, lethargy, hypertension, coma, bradycardia, and agonal respirations. Signs of impending transtentorial herniation include unilateral or bilateral pupillary dilation, hemiparesis, motor posturing, and/or progressive neurologic deterioration.

Measure neurologic deterioration by comparing sequential GCS scores. In a patient with a rapidly deteriorating GCS, if time permits, obtain a repeat head CT to identify an expanding intracranial hematoma.

Mannitol and/or hypertonic saline can lower ICP. Mannitol is an osmotic agent that can reduce ICP and improve cerebral blood flow, CPP, and brain metabolism. Mannitol is also a free radical scavenger. It generally has an effect within 30 minutes. Mannitol expands plasma volume and can improve oxygen-carrying capacity. Administer mannitol by repetitive bolus (0.25 to 1 gram/kg), and not by constant infusion. Because no dose-dependent effect is seen with mannitol, some clinicians advocate beginning at the lower range of the suggested dose. Mannitol results in a net intravascular volume loss because of its diuretic effect. Monitor the patient's input and output. Osmotic diuresis is *relatively contraindicated* in hemorrhage and hypotension. However, in the setting of acute herniation, mannitol has been demonstrated to effectively reduce life-threatening elevations of ICP.

Hypertonic saline may be used as an alternative to mannitol in the patient who is not adequately fluid resuscitated or hypotensive. The Brain Trauma Foundation indicates that at this time, data support the primary use of mannitol for the acute treatment of ICP. Most EDs have 3% NaCL available; the dose for adults is 250 mL over 30 minutes. Intensive care units may stock 23.4% sodium chloride solution; the dose for adults is 30 mL over 30 minutes. Monitor serum osmolality and serum sodium.

Mannitol and hypertonic saline may be given serially and in conjunction with one another.

ADVANCED TREATMENT OF BRAIN INJURY

Advanced treatment of brain injury requires invasive and close monitoring (**Table 257-9**).

Cerebral Perfusion Pressure Management **If the GCS is ≤8, arrange for placement of an intracranial bolt or extraventricular drain with monitoring capabilities as soon as possible to monitor ICP and to direct treatment.** Maintain CPP at 55 to 60 mm Hg to adequately perfuse brain tissue.[8] Increasing CPP >70 mm Hg may result in injury to other organs (e.g., acute respiratory distress syndrome from lung tissue trauma).

Consider ICP monitoring for patients with a normal admission brain CT scan if two or more of the following criteria are met: age over 40 years, unilateral or bilateral motor posturing, and systolic blood pressure <90 mm Hg. In addition, provide ICP monitoring in patients undergoing emergency surgery (e.g., orthopedic repair). Management of CPP is essential intraoperatively, where the patient with elevated ICP may experience large shifts in central volume status due to surgical blood loss.

Increased Intracranial Pressure Management An ICP of >20 mm Hg increases morbidity and mortality. Early consultation with neurosurgery for direct ICP monitoring, cerebrospinal fluid diversion, or surgical intervention is highly recommended in moderate and severe TBI. In certain circumstances, an ICP monitor will be placed in the ED by neurosurgery to help guide medical management of ICP, as well as for direct cerebrospinal fluid diversion to lower ICP.

TABLE 257-9 Goal-Directed Therapy of Brain Injury

Goal-Directed Therapy—Suggested Targets		
Pulse oximetry ≥90%	CPP ≥60 mm Hg	Physiologic sodium 135–140 mEq/L
SBP ≥90 mm Hg	ICP <20 mm Hg	INR ≤1.4
MAP ≥80 mm Hg	$PbtO_2$ ≥15 mm Hg	Platelets ≥75 × 10^3/μL
$Paco_2$ 35–45 mm Hg	pH 7.35–7.45	Hemoglobin ≥8 grams/dL
Temperature 36.0–38.3°C	Glucose 80–180 milligrams/dL	

Abbreviations: CPP = cerebral perfusion pressure; ICP = intracranial pressure; MAP = mean arterial pressure; $PbtO_2$ = brain tissue oxygen tension monitoring; SBP = systolic blood pressure.

SPECIFIC HEAD INJURIES

SCALP LACERATIONS

Scalp lacerations can lead to massive blood loss, so control bleeding as rapidly as possible. If direct pressure is not effective, locally infiltrate lidocaine with epinephrine and clamp or ligate bleeding vessels. Before closure, carefully examine wounds to identify foreign bodies, underlying fractures, and galeal lacerations. Large galeal disruptions should be repaired. For discussion of repair of scalp lacerations, see chapter 42, "Face and Scalp Lacerations."

SKULL FRACTURES

Patients who have or are suspected of having a skull fracture require a head CT scan (see Table 257-4). Skull fractures are usually categorized by location (basilar versus skull convexity), pattern (linear, depressed, or comminuted), and whether they are open or closed (**Figures 257-3 and 257-4**). A linear skull fracture with an overlying laceration is an open fracture. Explore wounds gently to avoid driving bone fragments into the brain.

Fractures that cross the middle meningeal artery, a major venous sinus, or linear occipital fractures have high intracerebral complication rates. Patients with skull fractures that are open or depressed, involve a sinus, or are associated with pneumocephalus should be given antibiotics (vancomycin, 1 gram IV, and ceftriaxone, 2 grams IV). A skull fracture that is depressed by more than the thickness of the skull usually requires operative repair.

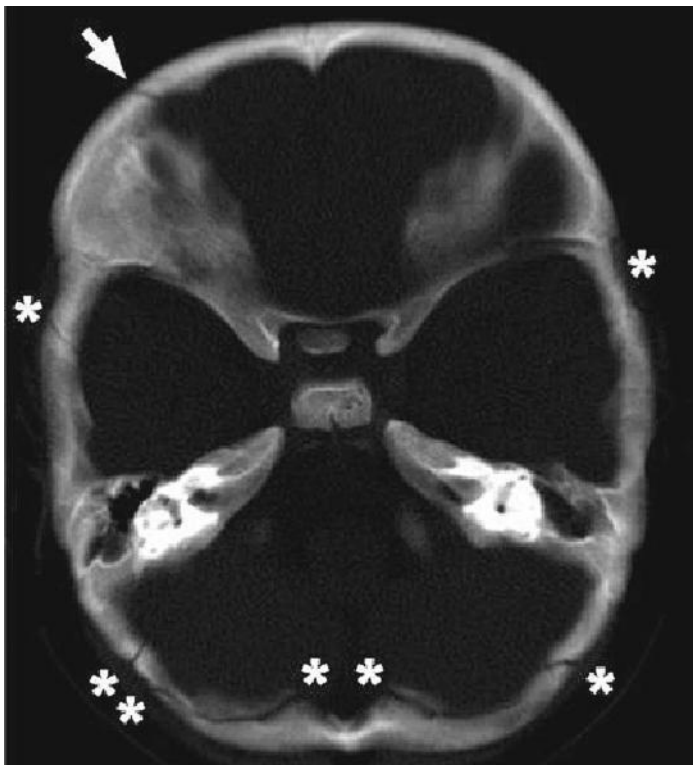

FIGURE 257-3. Linear fracture seen on CT. *Arrow* indicates skull fracture; *asterisks* indicate normal cranial suture lines. I. duPont Hospital for Children, Wilmington, Delaware; Departments of Neurological Surgery and Pediatrics, Thomas Jefferson University, Philadelphia, Pennsylvania.]

BASILAR SKULL FRACTURE AND CEREBROSPINAL FLUID LEAKS

The presence of a basilar skull fracture is a significant risk factor for intracranial injury. The most common basilar skull fracture involves the petrous portion of the temporal bone, the external auditory canal, and the tympanic membrane. It is associated with dural tearing, which often leads to otorrhea or rhinorrhea. Basilar skull fractures may occur anywhere along the skull base, from the cribriform plate through the occipital condyles. Do not place a nasogastric tube through the nares if cribriform plate fracture is suspected; this can lead to direct intracranial injury. **Signs and symptoms associated with basilar skull fractures include cerebrospinal fluid leak, mastoid ecchymosis (Battle sign), periorbital ecchymoses (raccoon eyes), hemotympanum, vertigo, decreased hearing or deafness, and seventh nerve palsy.** Periorbital and mastoid ecchymoses develop gradually over hours after an injury and are often absent in the ED. Cerebrospinal fluid leaks (otorrhea or rhinorrhea) are difficult to diagnose; however, the patient often complains of discharge of clear fluid from the nose or ears. Fluid may be collected and sent for analysis (identification of β transferrin). The β2 transferrin isoform of transferrin is found only in cerebrospinal fluid, and not in blood, mucus, or tears.

Patients with acute cerebrospinal fluid leaks are at risk for meningitis. Antibiotic prophylaxis is often recommended to reduce the incidence of infection.[30] Administration of antibiotics should be done in consultation with the neurosurgeon who will be following the patient. If prophylactic antibiotics are instituted, the drugs selected should have broad coverage with good penetration into the meninges, such as ceftriaxone, 2 grams IV, and vancomycin, 1 gram IV. The head of the patient's bed should be elevated to 30 degrees. A lumbar drain is often placed by the neurosurgical team. Cerebrospinal fluid leaks may require repair by a neurosurgeon or otolaryngologist.

CEREBRAL CONTUSION AND INTRACEREBRAL HEMORRHAGE

Contusions most commonly occur in the subfrontal cortex, in the frontal and temporal lobes, and, occasionally, in the occipital lobes (**Figure 257-5**). They are often associated with subarachnoid hemorrhage. Contusions may occur at the site of the blunt trauma or on the opposite side of the brain, known as a *contrecoup* injury.

Intracerebral hemorrhage can occur days after significant blunt trauma, often at the site of resolving contusions. This complication is more common in patients with coagulopathy. CT scan findings immediately after injury may be normal. Obtain serial CTs if any change in mental status occurs in a patient with coagulopathy until the clot is stable.

SUBARACHNOID HEMORRHAGE

Traumatic subarachnoid hemorrhage results from the disruption of the parenchyma and subarachnoid vessels and presents with blood in the cerebrospinal fluid (**Figure 257-6**). Patients with isolated traumatic

FIGURE 257-5. CT scan demonstrating delayed intraparenchymal hemorrhages from a traumatic contusion. [Image used with permission of Jack Fountain, Jr., MD, Emory University and Grady Memorial Hospital.]

FIGURE 257-6. CT scan demonstrating subarachnoid hemorrhage. *Arrow 1* indicates prepontine cisternal blood, and *arrow 2* identifies blood in the ambient cistern. [Image used with permission of Jack Fountain, Jr., MD, Emory University and Grady Memorial Hospital.]

FIGURE 257-7. Epidural hematoma. Note the convex shape and focal location. [Image used with permission of Jack Fountain, Jr., MD, Emory University and Grady Memorial Hospital.]

subarachnoid hemorrhage may present with headache, photophobia, and meningeal signs. **Traumatic subarachnoid hemorrhage is the most common CT abnormality in patients with moderate to severe TBI.** Patients with early development of traumatic subarachnoid hemorrhage have a threefold higher mortality risk than those without traumatic subarachnoid hemorrhage (42% versus 14%, respectively).[34] Some traumatic subarachnoid hemorrhages can be missed on early CT scans. Generally, CT scans performed 6 to 8 hours after injury are sensitive for detecting traumatic subarachnoid hemorrhage.

EPIDURAL HEMATOMA

An epidural hematoma results when blood collects in the potential space between the skull and the dura mater (**Figure 257-7**). The anatomic relationships of the branches of the middle meningeal artery and the sequelae of fracture and laceration of the artery are shown in Figure 257-2.

Blunt trauma to the temporal or temporoparietal area with an associated skull fracture and middle meningeal arterial disruption is the primary mechanism of injury. Occasionally, trauma to the parieto-occipital region or the posterior fossa causes tears of the venous sinuses with epidural hematomas.

The classic history of an epidural hematoma involves a significant blunt head trauma with loss of consciousness or altered sensorium, followed by a lucid period and subsequent rapid neurologic demise. This clinical presentation occurs in a minority of cases. Traumatic blows to the thin temporal bone over the lateral aspect of the head carry the highest risk (e.g., baseball or pool stick injury). The diagnosis of an epidural hematoma is based on CT scan and physical examination findings. The CT appearance of an epidural hematoma is a biconvex (football-shaped) mass, typically found in the temporal region.

The high-pressure arterial bleeding of an epidural hematoma can lead to herniation within hours after an injury. Early recognition and evacuation reduces morbidity and mortality. Underlying injury of the brain parenchyma is often absent; full recovery may be expected if the hematoma is evacuated prior to herniation or the development of neurologic deficits.

SUBDURAL HEMATOMA

Subdural hematoma is caused by sudden acceleration-deceleration of brain parenchyma with subsequent tearing of the bridging dural veins. This results in hematoma formation between the dura mater and the arachnoid (**Figures 257-8 and 257-9**). Subdural hematoma tends to collect more slowly than epidural hematoma because of its venous origin. However, subdural hematoma is often associated with concurrent brain injury and underlying parenchymal damage. **Brains with extensive atrophy, such as in the elderly or in chronic alcoholics, are more susceptible to the development of acute subdural hematoma.** Even seemingly benign falls from standing position can result in subdural bleeding in the elderly. Children <2 years old are also at increased risk of subdural hematoma.

Traditionally, subdural hematomas have been classified as acute, subacute, or chronic depending on the length of time from onset and occurrence of active hemorrhage. Acute symptoms usually develop within 14 days of the injury. After 2 weeks, the term *chronic subdural hematoma* is used. There is no specific clinical syndrome associated with a subdural hematoma. Acute cases usually present immediately after severe trauma, and often the patient is unconscious. In the elderly or in alcoholics, chronic subdural hematomas may result in vague complaints or mental status changes. Often, there is no recall of injury. On CT scan, acute subdural hematomas are hyperdense (white), crescent-shaped lesions that cross suture lines. Subacute subdural hematomas are isodense and are more difficult to identify. CT scanning with IV contrast or MRI can assist in identifying a subacute subdural hematoma. A chronic subdural hematoma appears hypodense (dark) because the iron in the blood has been metabolized.

FIGURE 257-8. Small subdural hematoma in the right frontotemporal region in an adult. [Image used with permission of Jack Fountain, Jr., MD, Emory University and Grady Memorial Hospital.]

The definitive treatment depends on the type, size, effect on underlying brain parenchyma, and the associated brain injury. Mortality and the need for surgical repair are greater for acute and subacute subdural hematomas. Chronic subdural hematomas can sometimes be managed without surgery depending on the severity of the symptoms. **Table 257-10** compares intracranial injuries.

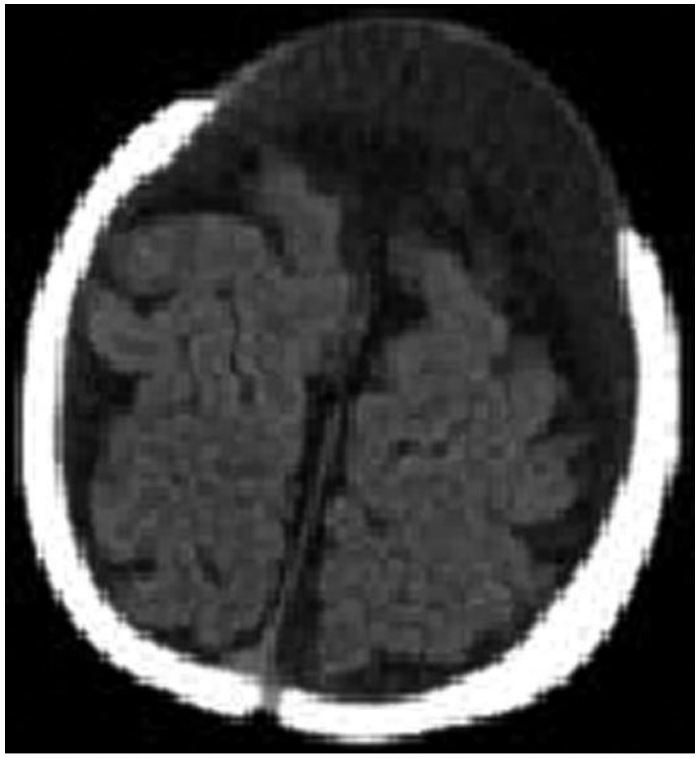
DIFFUSE AXONAL INJURY

Diffuse axonal injury is the disruption of axonal fibers in the white matter and brainstem. Shearing forces on the neurons generated by sudden deceleration cause diffuse axonal injury. The condition is seen after blunt trauma, such as from a motor vehicle crash. In infants, shaken baby syndrome is a well-described cause.[35]

In severe diffuse axonal injury, edema can develop rapidly. The underlying injury can result in devastating and often irreversible neurologic deficits. A CT scan of a patient with diffuse axonal injury may appear normal, but classic CT findings include punctuate hemorrhagic injury along the grey-white junction of the cerebral cortex and within the deep structures of the brain (**Figures 257-10 and 257-11**). Treatment options are very limited, but an attempt should be made to prevent secondary damage by reducing cerebral edema and limiting pathologic increases in ICP.

PENETRATING INJURY

As a bullet passes through the brain, it creates a cavity three to four times larger than its diameter. Direct penetration of the bullet through the brain substance and the transfer of kinetic energy cause the majority of the destruction (**Figure 257-12**). The GCS can be used to predict the prognosis for nonintoxicated patients with a gunshot wound to the brain.



A

B

FIGURE 257-9. **A.** Bifrontal chronic subdural hematoma extending through the anterior fontanelle in a 1-month-old child. **B.** Second image in the same child showing bifrontal chronic subdural hematoma, as well as small, acute intraparenchymal hemorrhage in the posterior fossa.

TABLE 257-10 Comparison of Intracranial Injuries

	Type of Patient	Anatomic Location	CT Findings	Common Cause	Classic Symptoms
Epidural	Young, rare in the elderly and those age <2 y	Potential space between skull and dura mater	Biconvex, football-shaped hematoma	Skull fracture with tear of the middle meningeal artery	Immediate LOC with a "lucid" period prior to deterioration (only occurs in about 20%)
Subdural	More risk in the elderly and alcoholic patients	Space between dura mater and arachnoid	Crescent- or sickle-shaped hematoma	Acceleration-deceleration with tearing of the bridging veins	Acute: rapid LOC, lucid period possible Chronic: altered mental state and behavior with gradual decrease in consciousness
Subarachnoid	Any age group after blunt trauma	Subarachnoid	Blood in the basilar cisterns and hemispheric sulci and fissures	Acceleration-deceleration with tearing of the subarachnoid vessels	Mild, moderate, or severe traumatic brain injury with meningeal signs and symptoms
Contusion/ intracerebral hematoma	Any age group after blunt trauma	Usually anterior temporal or posterior frontal lobe	May be normal initially with delayed bleed	Severe or penetrating trauma; shaken baby syndrome	Symptoms range from normal to LOC

Abbreviation: LOC = loss of consciousness.

Patients with a GCS score of >8 and reactive pupils have a 25% mortality risk, whereas mortality approaches 100% in those with a GCS score of <5. Patients with a penetrating gunshot wound to the brain should be intubated and treated with prophylactic antibiotics, such as vancomycin, 1 gram IV, and ceftriaxone, 2 grams IV.

Stab wounds have very low energy and impart only direct damage to the area contacted by the penetrating object. Patients with penetrating injury require admission, broad-spectrum antibiotics, and operative intervention. **Leave impaled objects in place until controlled surgical removal is facilitated.**

MILD TRAUMATIC BRAIN INJURY

mTBI (often called a concussion) is impairment in brain function without overt hemorrhage or other gross lesions, is caused by an external force, and results in a GCS score of 14 or 15 (also see chapter 110 and **Table 257-3**).[1] The diagnosis is made by a history of any alteration in consciousness at the time or shortly after the inciting event (acceleration-deceleration or blunt force). Alteration in consciousness includes the individual's account of "getting his/her bell rung," "seeing stars," or being dazed or confused as a result of the force. The presence of amnesia further supports the diagnosis and is often associated with more significant injury.

Signs and symptoms such as vomiting, headache, loss of consciousness, focal neurologic deficit, age >65 years, coagulopathy, and/or dangerous mechanism of injury are factors that increase risk of serious injury (see Tables 257-4, 257-5, and 257-6).[26,27,30,36] The presence of alcohol, distracting injuries, and other barriers to obtaining a clear history of the event confound the signs and symptoms of mTBI.

PATHOPHYSIOLOGY

In its mildest form, mTBI is an ionic shift that causes a momentary disruption in function. Symptom recovery is rapid, and the concussive injury results in no obvious structural damage. However, mild insults can also cause a temporary upregulation of ion channels, especially along axons.[37,38] After a single injury, the ion channel density returns to normal over time. Repeated exposure to injury, however, greatly increases the resting number of channels. An increase in the density of ion channels leaves the brain vulnerable to overactivation, neuronal toxicity, and cell death.

In addition to ion channel upregulation, large shifts of balance in ion concentrations may lead to mitochondrial dysfunction and depletion of

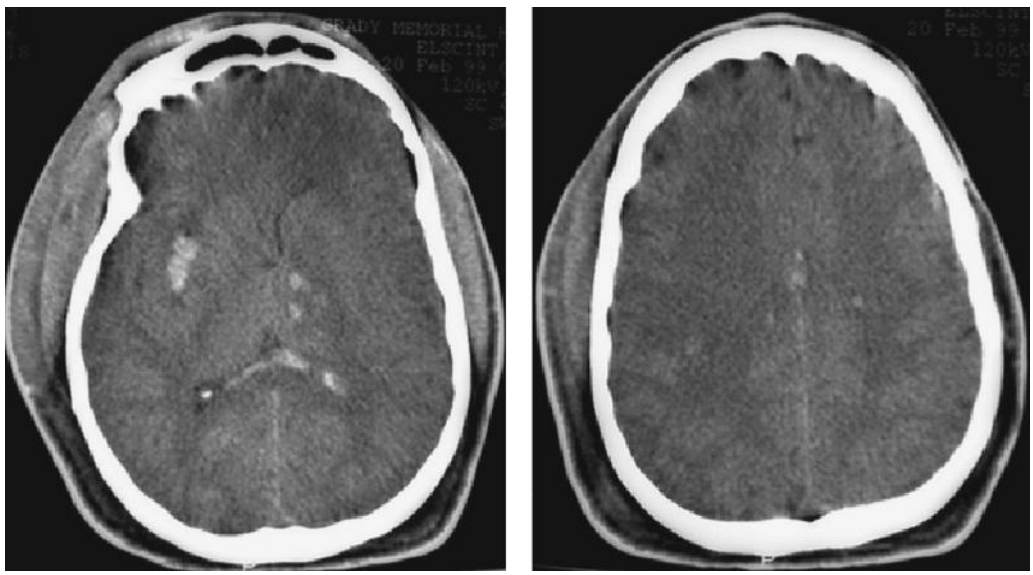


FIGURE 257-10. Diffuse axonal injury with intraventricular blood. [Image used with permission of Jack Fountain, Jr., MD, Emory University and Grady Memorial Hospital.]

FIGURE 257-11. Diffuse axonal injury with loss of the grey matter–white matter interface. [Image used with permission of Daniel Curry, MD, PhD, Texas Children's Hospital and Baylor College of Medicine.]

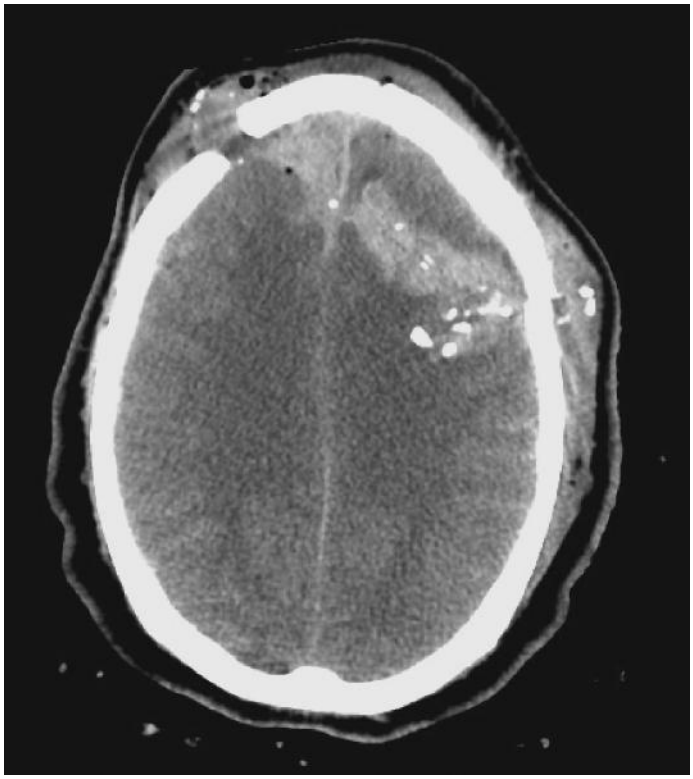

FIGURE 257-12. Gunshot wound traversing through frontal lobes bilaterally; note bone fragments. [Image used with permission of Thomas Egglin, MD, Director of Emergency Radiology and an Associate Professor of Diagnostic Imaging at the Warren Alpert Medical School of Brown University, Providence, RI.]

intracellular energy stores in mTBI.[14,39-41] This state creates a metabolic "mismatch" during which neuronal dysfunction persists until recovery occurs. This pathway is a recognized pattern of injury in moderate/severe TBI and is thought to also play a role in mTBI.

Metabolic insults, electrochemical imbalances (calcium influx and sodium and potassium shifts), and mitochondrial dysfunction also result in damage to axonal transport systems. Structural abnormalities are not always identified on MRI or CT. However, histopathology shows microscopic injury. Indeed, evidence of damage on diffusion tensor imaging has been demonstrated in high school athletes after a single football season, even without clinical signs or symptoms of a concussion.[42,43] Chronic traumatic encephalopathy[44] is hypothesized to occur as a result of repeated exposure to TBI in sports.[45-47]

Repetitive concussions can result in long-term cognitive deficits and structural damage to the brain.[48-51] In extreme cases, when a second concussion occurs prior to recovery from the first, rapid onset of cerebral edema and death can occur, particularly in athletes prematurely returning to play (**second impact syndrome**).[52]

DIAGNOSIS

The physical examination findings in isolated mTBI are often normal. Currently, there are no reliable tests that can confirm the diagnosis of concussion. The GCS lacks the detail to assess the full spectrum of signs and symptoms. Head CT scans are usually normal, and a normal scan only eliminates the concern for an underlying lesion requiring surgery.

Perform a thorough neurologic examination and obtain the GCS. Focal findings suggest potential intracranial pathology or a postictal state. Assess for signs of global impairment, such as confusion, perseveration, or amnesia.[53] Observe gait and test balance. **The most consistent abnormalities in mTBI are subtle impairments in cognitive function (see Table 257-7).** The gold standard written neuropsychological examination is impractical to perform in the ED setting. However, perform some assessment of cognition.

Clinical symptoms (**Table 257-11**) may begin immediately after the insult or may be delayed for days to weeks. Therefore, **the lack of obvious signs and symptoms at the time of evaluation does not exclude mTBI if the historical account is consistent with such injury**. Another complicating factor is that many of the signs and symptoms are nonspecific and overlap with those of other conditions.

The practice of grading concussions is widely employed but is not evidence based. There are >20 different classification systems in existence.[54]

Biomarkers Serum markers specific to neurologic injury may improve future diagnosis and management.[36,55,56]

Of the biomarkers currently under study, S100B (calcium binding protein B antibody) is the only one that is relatively sensitive (94% to 99% sensitive) for detecting the presence of injury, but only under specific conditions. S100B serum levels rise and fall rapidly, so time

TABLE 257-11 Signs and Symptoms of mTBI

Cognitive Symptoms	Physical Signs and Symptoms	Behavioral Changes
Attention difficulties	Headaches	Irritability
Concentration problems	Dizziness	Depression
Amnesia and perseveration	Insomnia	Anxiety
Short-term and long-term memory problems	Fatigue Uneven gait	Sleep disturbances Emotional lability
Orientation problems	Nausea, vomiting	Loss of initiative
Altered processing speed	Blurred vision	Loneliness and helplessness
Altered reaction time Calculation difficulties and problems with executive function	Seizures	Problems related to job, relationship, home, or school management

Note: At 3 months after injury, <30% are symptomatic; at 1 year, 15% are symptomatic.

from injury determines the relevance of a negative finding. S100B is also not currently approved by the U.S. Food and Drug Administration for mTBI. The American College of Emergency Physicians provides the following guidance: "***Level C recommendations.*** *In mTBI patients without significant extracranial injuries and a serum S-100B < 0.1 μg/L measured within 4 hours of injury, consideration can be given to not performing a CT.*"[57]

Cognitive Screening and Psychometrics Cognitive testing in the ED is currently limited to the use of brief memory screens such as the **Mini-Cog** (see Figure 288-2) or the **Quick Confusion Scale** (see Table 286-7). Other tools, primarily developed for sports, such as the Sports Concussion Assessment Tool, the Standardized Assessment for Concussion, and other similar instruments, have not been validated for ED use.

Neuropsychological testing[58-61] consists of a battery of individual tests that evaluate a number of domains required for normal brain function, including memory, attention, concentration, executive function, and reaction time. Several of these tests are used by sports programs to assess recovery from concussion. They are most valuable when baseline scores are available for comparison.

TREATMENT AND DISPOSITION

The primary treatment for mTBI is rest. Make sure the patient avoids aspirin and nonsteroidal anti-inflammatory drugs after acute injury. ED treatment objectives are to identify patients who have intracranial lesions requiring neurosurgical intervention; to admit patients whose condition might deteriorate over time; and for those discharged, to provide instructions for cognitive and physical rest and provide follow-up for reassessment before return to normal activities.

When the patient is safe for discharge, one of the most important "interventions" is to provide thorough concussion discharge instructions. A template is available at http://www.cdc.gov/ncipc/tbi/Physicians_Tool_Kit.htm. Physical and neurologic rest is needed until symptoms abate fully. Discharge the patient to the care of a responsible individual and provide instructions to both the patient and that individual. Patients with mTBI may not comprehend or remember detailed discharge instructions. Have the patient return to the ED for increasing symptoms, headaches, altered mental status, nausea, or vomiting. Refer patients for further evaluation and follow-up care. Patients at an increased risk for reinjury, such as athletes, should undergo a formal graduated return-to-activity program (**Table 257-12**).

Return to Activity Symptoms reflect underlying metabolic dysfunction and are currently the only reliable guide to brain health.[40,54] Return to play or work decisions are based on symptoms and a graduated evaluation program.

Assessments incorporate serial symptom checklists, neuropsychological tests (memory and reaction time assessment), and a balance evaluation (see Table 257-12).[54,62] **Because this type of assessment is not practical in the ED, ED clinicians should not provide definitive return-to-activity directions.**

TABLE 257-12 Return-to-Activity Program

Sports Related	Non–Sports Related
No activity (rest until symptom-free)	No activity (rest until symptom-free)
Light aerobic exercise	Light aerobic exercise
Sport-specific training (noncontact)	Moderate aerobic exercise
Noncontact drills	Return to normal activities
Full-contact drills	
Game play	

Note: Patient must remain asymptomatic for 24 hours between each step. Development of symptoms at any level requires return to the previous symptom-free level.

SPECIAL CONSIDERATIONS

POSTCONCUSSIVE SYNDROME

Patients often report a series of physical, emotional, and cognitive symptoms in the days and weeks after mTBI. The estimated prevalence of postconcussive syndrome varies widely, with about 20% to 40% of patients reporting symptoms at 3 months and about 15% at 1 year.[63,64] The most commonly reported postconcussion symptoms are headache, dizziness, decreased concentration, memory problems, sleep disturbances, irritability, fatigue, visual disturbances, judgment problems, depression, and anxiety.[65] When a cluster of symptoms becomes chronic after mTBI, they are often called **persistent postconcussive symptoms** or **postconcussion syndrome**. Clinical findings at the time of the injury do not reliably predict the development of postconcussive syndrome. Postconcussive syndrome symptoms can overlap those of posttraumatic stress disorder. Neuropsychological testing and use of a symptom checklist are the cornerstones of diagnosis and management. Treatment is symptomatic. Refer patients to a neuropsychologist or mTBI clinic.

RECURRENT CONCUSSIONS

Three or more concussions pose a risk for long-term sequelae, especially in adolescents and young children.[48,49,66] Almost all cases of **second impact syndrome** have occurred in young athletes. **Chronic traumatic encephalopathy**,[44] characterized by early onset of memory loss and depression, is a concern in professional athletes. Pathologically large deposits of tau protein are seen in the brains of deceased chronic traumatic encephalopathy patients.[47] Tau protein deposits have recently been discovered even in youth football players who died from other causes.

SECOND IMPACT SYNDROME

Second impact syndrome is a rare disorder that results in rapid cerebral edema and high mortality (60% to 80%).[52] The pathophysiology and the predictors are not well understood. It is hypothesized that occurrence of a second impact before the brain has reset or recovered from a first mTBI causes a loss of autoregulation and ion imbalance, and leads to rapid cerebral edema. This explanation fits well with the concept of enhanced vulnerability due to metabolic disturbances, energy-demand mismatch, and ion channel upregulation after a concussion.[67,68]

ANTICOAGULATION

Anticoagulants and antiplatelet agents increase the risk of intracranial hemorrhage after injury, especially in the elderly.

Intracranial hemorrhage in patients taking warfarin and who have an elevated INR is associated with a high mortality rate (89%).[69] In general, patients with head trauma, who are taking anticoagulants or antiplatelet agents, should undergo emergent head CT. The OR for the risk of intracranial lesions after mild head injury in patients taking any antiplatelet therapy is 2.6.[70] Clopidogrel seems to be a potent risk factor.[71] The effect of low-dose aspirin (162 mg or less taken daily) on post-head injury bleeding has not been determined.

Patients with intracranial hemorrhage need immediate anticoagulant reversal. Patients taking Warfarin who have an elevated INR are optimally treated with plasma or 4-factor concentrate. See chapters 239, "Thrombotics and Antithrombotics" and 166, "Spontaneous Subarachnoid and Intracerebral Hemorrhage" for further discussion.

A negative initial CT finding in an asymptomatic TBI patient receiving anticoagulation or antiplatelet therapy is reassuring, but delayed hemorrhage may occur and is not easily predicted. [71]

CHAPTER 258

Spine Trauma

Steven Go

INTRODUCTION AND EPIDEMIOLOGY

Trauma to the spine can cause a vertebral spinal column injury, a spinal cord injury, or both. A few studies have tried to estimate the annual incidence of spinal column injury in the general population with results ranging from 11.8 to 64 cases per 100,000,[1,2] but no current figures are available for the U.S. population. In contrast, the estimated annual incidence of spinal cord injury in the United States is 40 cases per million or 12,000 new cases per year, with 81% male victims, a mean age of 42.6 years, and a 67% Caucasian predominance.[3] Since 2010, the leading causes of spinal cord injury are vehicular (37%), falls (29%), and violence (14%). Lifetime costs for spinal cord injury victims vary according to age at time of injury, severity of injury, and socioeconomic status; however, estimates range in millions of dollars per patient.[3]

FUNCTIONAL ANATOMY

VERTEBRAL COLUMN

The vertebral column is composed of 33 vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 fused sacral, and 4 (usually fused) coccygeal. The axial vertebrae (C1 and C2) are anatomically unique in that they are designed for rotary motion. The odontoid (dens) of the axis (C2) is held against the atlas (C1) by the strong transverse ligament. The remaining vertebrae share some common anatomical features (**Figure 258-1**). A typical subaxial vertebra is composed of an anterior body and a posterior vertebral arch. The vertebral arch is comprised of two pedicles, two laminae, and seven processes (one spinous, two transverse, and four articular). These articulations enable the spine to engage in flexion, extension, lateral flexion, rotation, or circumduction (combination of all movements). The orientation of these articular facet joints changes at different levels of the spine and accounts for variations in motion of specific regions of the vertebral column. Due to its inherent flexibility, the cervical spine is the most commonly injured region of the spinal column, with most injuries occurring at the C2 level and from C5 to C7.[4] The second most common region of injury is in the thoracolumbar transition zone.

A series of ligaments serves to maintain alignment of the spinal column. The anterior and posterior longitudinal ligaments run along the vertebral bodies. Surrounding the vertebral arch are the ligamentum flavum and the supraspinous, interspinous, intertransverse, and capsular ligaments. Between adjacent vertebral bodies are the intervertebral disks, consisting of a peripheral annulus fibrosus and a central nucleus pulposus. The intervertebral disks act as shock absorbers to distribute axial load. When compressive forces exceed the absorptive capacity of the disk, the annulus fibrosus ruptures. This allows the nucleus pulposus to protrude into the vertebral canal, and this may result in spinal nerve or spinal cord compression.

SPINAL CORD

The spinal cord is a cylindrical structure that begins at the foramen magnum, where it is continuous with the medulla oblongata of the brain and extends down the spinal canal to the first and second lumbar vertebrae. The spinal cord gives rise to 31 pairs of spinal nerves: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal. Each spinal nerve emerges through the intervertebral foramen corresponding to the appropriate spinal cord level. The lower nerve roots form an array of nerves called the *cauda equina*.

PATHOPHYSIOLOGY

SPINAL COLUMN INJURIES

Given their multiple axes of motion, the bony vertebrae can be injured via several mechanisms and present with a number of different injury patterns (**Table 258-1**).[5-10]

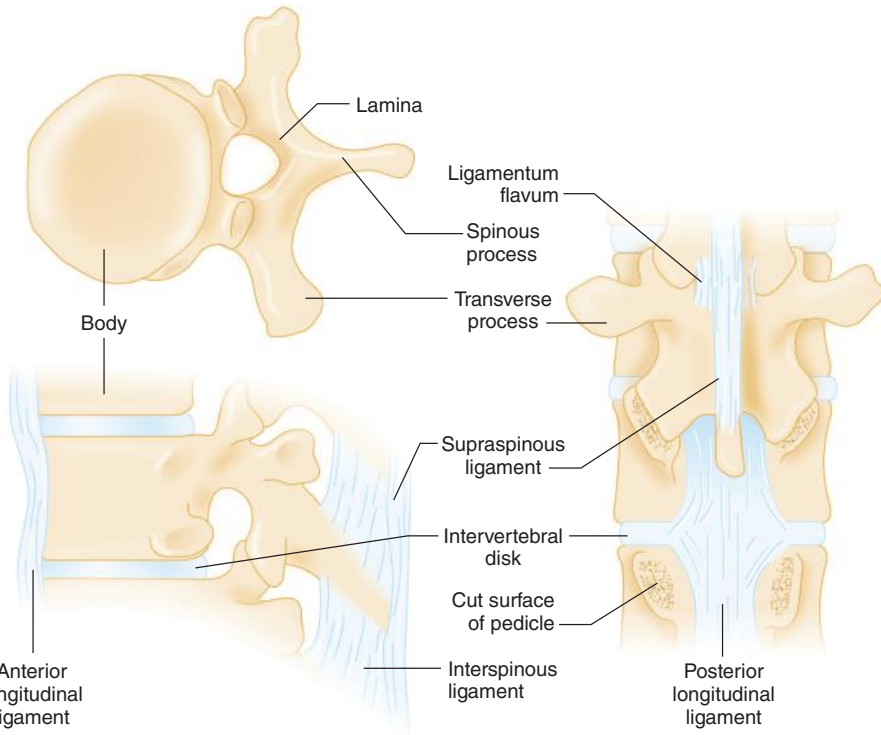

FIGURE 258-1. Vertebral anatomy. Each vertebra consists of a vertebral body and posterior element. Vertebrae are stabilized by an anterior longitudinal ligament, posterior ligament, and interspinous ligament.

TABLE 258-1 Major Spinal Column Injuries

Mechanism of Injury	Injury	Spinal Column Regions Typically Affected	Image	Notes
Flexion	Anterior subluxation (hyperflexion sprain) (usually stable, but depends on the integrity of posterior ligaments)	Cervical	[Photo contributors: Mark Silverberg, MD/Steven Pulitzer, MD. Reproduced with permission from Shah BR, Lucchesi M, Amodio J (eds): *Atlas of Pediatric Emergency Medicine*, 2ed, © 2013, McGraw-Hill Education, New York, NY. Figure 20-57.]	Anterior subluxation produces ligamentous failure and may have no associated fractures. Plain films can be normal. However, significant ligamentous injury can display anterior soft tissue swelling, a widening of the spinous processes at the level of injury ("fanning"), posterior widening of the intervertebral space, and cervical disk space alignment ≥11 degrees between adjacent spaces.
	Atlantoaxial dislocation (unstable)	Cervical	[Used with permission of Jake Block, MD.]	Transverse ligament **rupture** without an associated fracture can occur in older patients from a direct blow to the occiput. Radiographic diagnosis relies on measuring the *predental space*, which is the space between the posterior aspect of the anterior arch of C1 and the anterior border of the odontoid. A predental space of >3 mm on a lateral radiograph (2 mm for CT images) implies damage to the transverse ligament; >5 mm implies rupture of the transverse ligament.
	Bilateral interfacetal dislocation (unstable)	Cervical		Bilateral interfacetal dislocation (*locked facets*) occurs when the articular masses of one vertebra dislocate anteriorly and superiorly from the articular surfaces of the adjacent vertebra below. Disruption of all ligamentous structures occurs. On radiographs, the vertebral body is dislocated anteriorly ≥50% of its width. These injuries usually present with neurologic deficits due to compromise of the intervertebral foramen, unless the dislocation is only partial (*perched facets*).

(*Continued*)

TABLE 258-1 Major Spinal Column Injuries (*Continued*)

Mechanism of Injury	Injury	Spinal Column Regions Typically Affected	Image	Notes
	Simple wedge (compression) fracture (usually stable)	Cervical; TL	[Reproduced with permission from Block J, Jordanov MI, Stack LB, Thurman RJ (eds): *The Atlas of Emergency Radiology*. McGraw-Hill, Inc., 2013. Fig 11-22 Part A.]	Most common thoracic fracture (52%).[5] A vertebral wedge fracture typically involves a fracture of the superior end plate of the vertebral body while sparing the inferior end plate. An isolated simple wedge fracture is stable, but the presence of significant posterior ligamentous disruption can make the injury unstable. A simple wedge fracture is differentiated from a burst fracture by the absence of a vertical fracture of the vertebral body and lack of bulging of the posterior vertebral border.
	Spinous process avulsion (clay shoveler's) fracture (stable)	Cervical	[Reproduced with permission from Block J, Jordanov MI, Stack LB, Thurman RJ (eds): *The Atlas of Emergency Radiology*. McGraw-Hill, Inc., 2013. Fig 11-10 Part A.]	This is an avulsion off the end of one of the lower cervical spinous processes (classically C7). It is thought to be caused by strong muscle contractions pulling on the bone via the ligamentous complex. It is not associated with neurologic compromise.
	Flexion teardrop fracture (highly unstable)	Cervical	[Reproduced with permission from Block J, Jordanov MI, Stack LB, Thurman RJ (eds): *The Atlas of Emergency Radiology*. McGraw-Hill, Inc., 2013. Fig 11-1.]	Extreme hyperflexion causes complete disruption of the spinal ligaments at the level of injury. The "teardrop" is the anteroinferior portion of the vertebral body that is separated and displaced from the vertebral body by the anterior spinal ligament. "Fanning" of the spinous processes may be present, with or without fracture. A sagittal fracture through the vertebral body may be seen on CT. Anterior spinal cord syndrome is associated with this injury

(*Continued*)

TABLE 258-1 Major Spinal Column Injuries (*Continued*)

Mechanism of Injury	Injury	Spinal Column Regions Typically Affected	Image	Notes
Flexion-rotation	Unilateral facet dislocation (stable unless associated with an articular mass fracture)	Cervical	[Reproduced with permission from Simon RR, Sherman Scott C (eds): *Emergency Orthopedics*, 6th ed. McGraw-Hill, Inc., 2011. Fig 9-21B.]	A unilateral facet dislocation occurs when the articular mass and inferior facet on one side of the vertebra are anteriorly dislocated. On a lateral radiograph, the involved vertebral body will be displaced <50% of its width. On the anterior view, the spinous process at the level of the rotation will be pointing toward the side that is dislocated.
	Fracture of lateral mass (can be unstable)	Cervical	 Comminuted fracture of the lateral mass of C4 extending into the right lamina.	Typically presents with severe neck pain and sometimes radicular symptoms. May be associated with Brown-Séquard syndrome or vertebral artery injury; therefore, some experts feel that magnetic resonance angiography should be done in all patients with this lesion.[6] A *pillar fracture* is a type of lateral mass fracture that consists of an isolated vertical or oblique fracture through the lateral mass. The adjacent lamina and pedicle remain intact. The fractured articular mass is displaced posteriorly and may be visible as a double outline on the lateral radiograph.
Flexion-distraction	Anterior compression with associated transverse fracture through vertebral body (unstable)	TL	*Arrow* points to splaying of the posterior elements. [Reproduced with permission from Block J, Jordanov MI, Stack LB, Thurman RJ (eds): *The Atlas of Emergency Radiology*. McGraw-Hill, Inc., 2013. Fig 11-27C.]	These injuries are associated with seatbelt injuries, especially when lap belts alone are used. Radiographic findings include posterior vertebral wall fracture, increased height of the posterior vertebra, and "fanning" of the spinous processes. The **Chance fracture** variant presents with minor anterior vertebral compression and significant distraction of the middle and posterior ligamentous structure. It often occurs from T11 to L2 (TL transition zone). These injuries are often misdiagnosed as an anterior compression fracture. They may require CT to visualize and are often associated with intra-abdominal injuries.

(*Continued*)

TABLE 258-1 Major Spinal Column Injuries (*Continued*)

Mechanism of Injury	Injury	Spinal Column Regions Typically Affected	Image	Notes
Vertical compression	Jefferson burst fracture of atlas (potentially unstable)	Cervical	 [Reproduced with permission from Block J, Jordanov MI, Stack LB, Thurman RJ (eds): *The Atlas of Emergency Radiology*. McGraw-Hill, Inc., 2013. Fig 11-13.]	Vertical compression forces the occipital condyles downward and produces a burst fracture by driving the lateral masses of C1 apart. This is best seen as outward displacement of the lateral masses on the open-mouth odontoid radiograph or on CT. If displacement of both lateral masses (measured as offset from the superior corner of the C2 vertebral body on each side) is >7 mm when added together, rupture of the transverse ligament is likely, and the spine is unstable.
	Burst fracture (unstable)	Cervical; TL	*Arrow* shows posterior displacement of posterior vertebral body cortex. [Reproduced with permission from Block J, Jordanov MI, Stack LB, Thurman RJ (eds): *The Atlas of Emergency Radiology*. McGraw-Hill, Inc., 2013. Fig 11-31B.]	A burst fracture occurs when a vertebra is crushed by an axial load, causing fragments to displace in all directions. The lateral radiograph may show an obvious fracture of the end plates, but sometimes all that is seen is a bowing or disruption of the posterior cortex of the affected vertebra. The anterior radiographic view may show a vertical fracture through the vertebral body and widening of the interpedicular distance. The burst fracture is usually obvious on CT. The spinal cord may be injured if a retropulsed fragment enters the spinal canal.
Extension	Hyperextension dislocation (unstable)	Cervical	[Reproduced with permission from Schwartz DT (ed): *Emergency Radiology: Case Studies*. McGraw-Hill, Inc., 2008. Sect V: Cervical Spine Radiology; Fig 6.]	Extreme hyperextension can cause a complete tear of the anterior longitudinal ligament and intervertebral disk, with disruption of the posterior ligamentous complex. On the lateral radiographic view, the vertebrae may appear normal if the dislocation spontaneously reduces or if the injury is masked by a cervical immobilization collar. **Prevertebral soft tissue swelling may be the only radiographic finding present**. Anterior disk space widening or fracture of the anteroinferior end plate of the vertebral body may occur. Patients usually present with a central cord syndrome.

(*Continued*)

TABLE 258-1 Major Spinal Column Injuries (*Continued*)

Mechanism of Injury	Injury	Spinal Column Regions Typically Affected	Image	Notes
	Hyperextension teardrop fracture or extension corner avulsion fracture (unstable in extension)	Cervical		Hyperextension may cause the anterior longitudinal ligament to avulse a fragment off the anteroinferior corner of the vertebral body. The height of the avulsed fragment usually exceeds its width. This fracture is more common in older patients with osteoporosis.
	Fracture of posterior arch of atlas (stable)	Cervical	 *Arrowhead* indicates the posterior arch fracture. There is also a displaced dens fracture (*arrow*). [Reproduced with permission from Galli, et al: *Emergency Orthopedics: The Spine*. New York, NY: McGraw-Hill;1989]	Fracture occurs from wedging of the posterior arch between the occipital bone and the C2 vertebra. A CT is indicated to rule out an associated Jefferson fracture or a dens fracture.
	Laminar fracture (usually stable)	Cervical	 Bilateral laminar fractures. [Reproduced with permission from Simon RR, Sherman SC (eds): *Emergency Orthopedics*, 6th ed. McGraw-Hill, Inc., 2011. Fig 9-26B.]	Laminar fractures may be associated with spinous process fractures. They may not be evident on plain radiographs and usually require CT for diagnosis.

(*Continued*)

TABLE 258-1 Major Spinal Column Injuries (*Continued*)

Mechanism of Injury	Injury	Spinal Column Regions Typically Affected	Image	Notes
	Traumatic spondylolisthesis (hangman's fracture) (unstable)	Cervical		The hangman's fracture is a fracture of both pedicles of C2, with the anterior displacement of C2 on C3. This was associated with the neck hyperextension from judicial hangings, where the noose knot is placed under the subject's chin and snaps the head backward. Suicidal hangings do not usually cause extreme hyperextension and are not associated with the hangman's fracture. Because the spinal canal at the level of C2 is large, a hangman's fracture does not cause neurologic injury.
Injuries caused by a combination of mechanisms or poorly understood mechanisms	Occipital condyle fractures (usually stable)	Cervical	[Reproduced with permission from Block J, Jordanov MI, Stack LB, Thurman RJ (eds): *The Atlas of Emergency Radiology*. McGraw-Hill, Inc., 2013. Fig 11-11B.]	Occipital condyle fractures are rarely visible on plain radiographs and usually require CT imaging for detection. Presentation is rather variable due to proximity of multiple neurovascular structures.[7] Neurologic impairment is common and usually involves lower cranial nerve deficits and/or limb weakness.
	Atlanto-occipital dissociation (AOD) (highly unstable)	Cervical	[Photo contributors: Konstantinos Agoritsas, MD/Steven Pulitzer, MD. Reproduced with permission from Shah BR, Lucchesi M, Amodio J (eds): *Atlas of Pediatric Emergency Medicine*, 2nd ed. © 2013, McGraw-Hill Education, New York, NY. Fig 20-52.]	Secondary to high-energy impact. Historically, strongly associated with mortality[8]; however, modern patients may survive due to better prehospital care/transport. The classic presentation is paralysis of upper extremities with lack of lower extremity paralysis or weakness (cruciate paralysis).[9] However, presentation can be variable with a common presentation being lower cranial nerve deficits. CT may be required for detection. In radiographs in the normal patient, the distance between the basion and the superior cortex of the dens (basion-dental interval [BDI]) should be ≤10 mm in adults (≤8.5 mm on CT). In addition, the distance from the basion to the posterior border of the body of C2 (basion-atlantal interval [BAI]) should be ≤12 mm anterior displacement or ≤4 mm posterior displacement on a lateral radiograph. If there are abnormalities in both the BDI and BAI, this strongly suggests the existence of AOD.[10]

(*Continued*)

TABLE 258-1 Major Spinal Column Injuries (*Continued*)

Mechanism of Injury	Injury	Spinal Column Regions Typically Affected	Image	Notes
	Odontoid (dens) fractures (type II and III are unstable)	Cervical	Type 1 odontoid fracture. [Reproduced with permission from Block J, Jordanov MI, Stack LB, Thurman RJ (eds): *The Atlas of Emergency Radiology*. McGraw-Hill, Inc., 2013. Fig 11-18.]  Type 2 odontoid fracture. [Reproduced with permission from Block J, Jordanov MI, Stack LB, Thurman RJ (eds): *The Atlas of Emergency Radiology*. McGraw-Hill, Inc., 2013. Fig 11-19C.] Type 3 odontoid fracture. [Reproduced with permission from Block J, Jordanov MI, Stack LB, Thurman RJ (eds): *The Atlas of Emergency Radiology*. McGraw-Hill, Inc., 2013. Fig 11-20C.]	Frequently involves other injuries to the cervical spine and multisystem trauma. Conscious patients will usually describe immediate and severe high cervical pain with muscle spasm. The pain may radiate to the occiput. Neurologic injury is present in 18% to 25% of cases with odontoid fractures, ranging from minimal sensory or motor loss to quadriplegia. Odontoid fractures are classified according to the level of injury. CT can miss odontoid fractures if the fracture line is aligned with the cut of the CT (*en face*).

(*Continued*)

TABLE 258-1 Major Spinal Column Injuries (*Continued*)

Mechanism of Injury	Injury	Spinal Column Regions Typically Affected	Image	Notes
	Translational fracture-dislocation (unstable)	TL	T10-T11 fracture-dislocation.	This is a high-energy disruption of all three columns of spine and is readily apparent both on radiographs and CT. Patients commonly present with severe neurologic findings. These fractures are most often unstable; however, in the absence of destabilizing rib cage fractures, lesions above T7 can be stable.
Sacrum and coccyx fractures	Sacral fracture		 [Reproduced with permission from Block J, Jordanov MI, Stack LB, Thurman RJ (eds): *The Atlas of Emergency Radiology*. McGraw-Hill, Inc., 2013. Fig 8-16A.]	Usually associated with pelvic fracture(s). Transverse fractures through the body can injure the cauda equina. Longitudinal fractures can cause radiculopathies. Central sacral fracture can present with bowel/bladder incontinence.
	Coccyx fracture		[Reproduced with permission from Block J, Jordanov MI, Stack LB, Thurman RJ (eds): *The Atlas of Emergency Radiology*. McGraw-Hill, Inc., 2013. Fig 8-24.]	Coccygeal injuries are usually associated with a direct fall onto the buttocks, with resultant coccyx pain exacerbated by sitting or straining. Localized tenderness can be elicited with coccyx palpation during a rectal exam, but this is not required for diagnosis. Imaging is not needed to diagnose coccygeal fractures. Treatment is symptomatic with analgesics and use of a rubber doughnut pillow.

Abbreviations: C1 = first cervical vertebra; C2 = second cervical vertebra; C3 = third cervical vertebra; C7 = seventh cervical vertebra; T1 = first thoracic vertebra; T7 = seventh thoracic vertebra; TL = thoracolumbar.

The variable anatomic qualities of the regions of the spinal column cause characteristic injury patterns in each region. The exposure and extreme mobility of the **cervical spine (C1-C7)** make it particularly vulnerable to injury, because it is the most flexible and mobile portion of the spinal column. The **cervicothoracic junction (C7-T1)** is one of the **transitional zones** of the spinal column, which are locations where the vertebral morphology changes. This designation is important because transitional zones sustain the greatest amount of stress during motion and are most vulnerable to injury. In contrast to the cervical spine, the **thoracic spine (T1-T10)** is a rigid segment, with its stiffness enhanced by articulation with the rib cage. Therefore, not only is injury to the thoracic spine less common than in other regions, but this also means that the presence of a thoracic vertebral injury indicates the patient was subjected to severe traumatic forces and is at high risk for intrathoracic injuries. Moreover, the spinal canal in the thoracic region is also narrower than in other regions. This increases the risk of cord injury, which is often complete when it occurs. The **thoracolumbar junction (T11-L2)** is a transitional zone between the highly fixed thoracic and relatively mobile lumbar spine. In addition to this change in bone anatomy, the thoracolumbar junction serves as the level of transition from the end of the spinal cord (about L1) to the nerve roots of the cauda equina. Relative to the thoracic spine, the width of the spinal canal in the thoracolumbar region is greater. Therefore, despite a large number of vertebral injuries at the thoracolumbar junction, most do not have neurologic deficits, or, if present, they are partial or incomplete. Relative to the thoracic and thoracolumbar regions, the **lower lumbar spine (L3-L5)** is more mobile. Because of the width of the spinal canal in the lumbar region and the ending of the spinal cord at the L1 level, isolated fractures of the lower lumbar spine rarely injure the spinal cord or result in neurologic injury. The **sacrum** and **coccyx** form the lower portion of the spinal column. The vertebral foramina of the sacrum together form the sacral canal that contains the nerve roots of the lumbar, sacral, and coccygeal spinal nerves and the filum terminale. The coccyx, which articulates with the sacrum, consists of four vertebrae fused together. When neurologic injuries occur, they are usually complete cauda equina lesions or isolated nerve root deficits. **Sacral fractures that involve the central sacral canal can produce bowel or bladder dysfunction.**

FRACTURE STABILITY

Much has been written regarding determining whether or not a particular injury is "stable." Spinal stability is defined as the ability of the spine to limit patterns of displacement under physiologic loads so as not to damage or irritate the spinal cord or nerve roots. Several paradigms have been created, including the Denis column system, which splits the spinal column into anterior, middle, and posterior elements.[11] A spine injury is considered unstable if at least two columns of a particular region are involved. Although this schema and other instability scoring systems have been published,[12-14] determining spinal stability after an acute injury in the ED is particularly difficult. This is because these injuries often occur in the setting of polytrauma, altered mental status, and severe pain, which may result in suboptimal initial imaging. In addition, many EDs lack quick access to emergent MRI to evaluate the spinal ligaments. Therefore, **assume any spine fracture is unstable and maintain appropriate precautions until expert consultation can be obtained from a spine surgeon**.

SPINAL CORD INJURIES

Damage to the spinal cord is the result of two types of injury. First is the **primary injury** from mechanical forces from traumatic impact. This insult sets into motion a series of vascular and chemical processes that lead to **secondary injury**. The initial phase is characterized by hemorrhage into the cord and formation of edema at the injured site and surrounding region. Local spinal cord ischemia ensues secondary to vasospasm and thrombosis of the small arterioles within the gray and white matter. Extension of edema may further compromise blood flow and increase ischemia. A secondary tissue degeneration phase begins within hours of injury. This is associated with neural membrane dysfunction, driven by a pathologic excitation of sodium ion channels, an influx of calcium ions, and the release of glutamine.[15] Cell death ensues from a combination of mechanisms including electrolyte imbalances, cell edema, and the formation and release of oxidative substances.[15]

SPINAL CORD LESIONS

The severity of spinal cord injury determines the prognosis for recovery of function, so it is important to distinguish between complete and incomplete spinal cord injuries. The American Spinal Injury Association defines a **complete neurologic lesion as the absence of sensory and motor function below the level of injury**. This includes loss of function to the level of the lowest sacral segment. In contrast, **a lesion is incomplete if sensory, motor, or both functions are partially present below the neurologic level of injury**. This may consist only of sacral sensation at the anal mucocutaneous junction or voluntary contraction of the external anal sphincter upon digital examination. Complete lesions have a minimal chance of functional motor recovery. Patients with incomplete lesions are expected to have at least some degree of recovery. The differentiation between complete and incomplete spinal cord damage may be complicated by the presence of spinal shock. **Patients in spinal shock lose all reflex activities below the area of injury, and lesions cannot be deemed truly complete until spinal shock has resolved.**

A significant number of descending and ascending tracts have been identified in the spinal cord (**Figure 258-2**). The three most important of these in terms of neuroanatomic localization of cord lesions are the corticospinal tracts, spinothalamic tracts, and dorsal (posterior) columns.

The corticospinal tract is a descending motor pathway. Its fibers originate from the cerebral cortex through the internal capsule and the middle of the crus cerebri. The tract then breaks up into bundles in the pons and finally collects into a discrete bundle, forming the pyramid of the medulla. In the lower medulla, approximately 90% of the fibers cross to the side opposite that of their origin and descend through the spinal cord as the lateral corticospinal tract. These fibers synapse on lower motor neurons in the spinal cord. The 10% of corticospinal fibers that do not cross in the medulla descend in the anterior funiculus of the cervical and upper thoracic cord levels as the ventral corticospinal tract. **Damage to the corticospinal tract neurons (upper motor neurons) in the spinal cord results in ipsilateral clinical findings such as muscle weakness, spasticity, increased deep tendon reflexes, and a Babinski's sign**.

The two major ascending pathways that transmit sensory information are the *spinothalamic tracts* and the *dorsal columns*. The spinothalamic tract transmits pain and temperature sensation. As the axons of the first neurons enter the spinal cord, most ascend one or two levels before entering the dorsal gray matter of the spinal cord, where they synapse with the second neuron of the spinothalamic tract. The second neuron immediately crosses the midline in the anterior commissure of the spinal cord

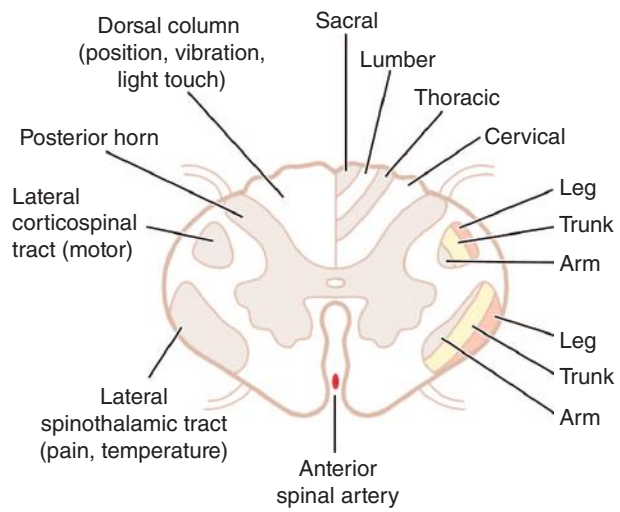

FIGURE 258-2. The anatomy of a cross section of cervical spinal cord. [Reproduced with permission from Simon RR, Sherman SC (eds): *Emergency Orthopedics*, 6th ed. McGraw-Hill, Inc., 2011. Fig 9-5.]

and ascends in the anterolateral funiculus as the lateral spinothalamic tract. **When the spinothalamic tract is damaged, the patient experiences loss of pain and temperature sensation in the contralateral half of the body.** The (pain and temperature) sensory loss begins one or two segments below the level of the damage.

The dorsal columns transmit vibration and proprioceptive information. Neurons enter the spinal cord proximal to pain and temperature neurons. They differ from pain and temperature neurons in that they do not immediately synapse in the spinal cord. Instead, these axons enter the ipsilateral dorsal column and do not synapse until they reach the gracile or cuneate nuclei of the medulla. From these nuclei, fibers cross the midline and ascend in the medial lemniscus to the thalamus. **Injury to one side of the dorsal columns will result in ipsilateral loss of vibration and position sense**. The sensory loss begins at the level of the lesion. Light touch is transmitted through both the spinothalamic tracts and the dorsal columns. Therefore, **light touch is not completely lost unless there is damage to both the spinothalamic tracts and the dorsal columns.**

Each spinal nerve is named for its adjacent vertebral body (see Figure 258-3). In the cervical region, there is an additional pair of spinal nerve roots compared to the number of vertebral bodies. The first seven spinal nerves are named for the first seven cervical vertebrae, each exiting through the intervertebral foramen above its corresponding vertebral body. The spinal nerve exiting below C7, however, is referred to as the C8 spinal nerve, although no eighth cervical vertebra exists. All subsequent nerve roots, beginning with T1, exit below the vertebral body for which they are named.

During fetal development, the downward growth of the vertebral column is greater than that of the spinal cord. Because the adult spinal cord ends as the conus medullaris at the level of the lower border of the first lumbar vertebra, the lumbar and sacral nerve roots must continue inferiorly below the termination of the spinal cord to exit from their respective intervertebral foramina. These nerve roots form the cauda equina. A potential consequence of this arrangement is that injury to a single lower vertebra can involve multiple nerve roots in the cauda equina. For example, an injury at the L3 vertebra can involve the L3 nerve root as well as the lower nerve roots that are progressing to a level caudal to the L3 vertebra.

PREHOSPITAL CARE

The prehospital treatment of patients with spinal injury involves recognition of patients at risk, appropriate immobilization, and triage to an appropriate facility (see chapters 1, "Emergency Medical Services" and 2, "Prehospital Equipment"). Presume that patients with an appropriate traumatic mechanism who have complaints of neck or back pain, tenderness on prehospital exam, neurologic complaints, significant injury above the clavicles, or altered sensorium that precludes accurate evaluation of the spine to have a spinal cord injury, and take appropriate spinal precautions. Transport of the patient to a center that is capable of rapid diagnostics and therapeutics is important to optimize outcome following spinal injury.

Prehospital care for spinal injuries traditionally involves immobilization of the entire spine at the scene with a rigid cervical collar (or similar devices) plus a long backboard. However, there is little evidence that cervical collars and/or long spine boards reduce neurologic injury, spinal instability, or mortality.[16,17] In contrast, cervical collars and long backboards can induce complications such as pressure sores,[18,19] patient discomfort,[20] and respiratory compromise.[21] In light of these data, some experts have recommended retaining the cervical collar but transporting the patient on a gurney with a scoop stretcher[22] or other soft, padded devices[23] to avoid the rigid spine board. Some authors have even proposed abandoning the routine use of cervical collars.[24] Nevertheless, in the absence of controlled data regarding the safety of such measures, current neurosurgery guidelines[25] still recommend usage of the rigid cervical collar and long spine board. In contrast, **spinal immobilization is no longer recommended for fully conscious, neurologically intact patients with isolated *penetrating* neck injury** because collars can delay resuscitation and obscure neck injuries.[26,27]

INITIAL ED STABILIZATION

AIRWAY

ED evaluation of the patient with potential spinal injury should not differ substantially from that of any patient with multiple injuries, with the first priority being the airway. **The higher the level of spinal injury, the more likely is the need for early airway intervention.** For example, unstable spine lesions above C3 can cause immediate respiratory arrest, and lesions affecting C3-C5 can affect the phrenic nerve and diaphragm function. For this reason, some experts recommend that **any patient with an injury at C5 or above should have the airway secured by endotracheal intubation**. Delayed respiratory compromise can occur if spinal cord edema from more caudal lesions progresses rostrally to cause phrenic nerve paralysis. Many patients can initially support ventilatory function using intercostal muscles or abdominal breathing, but they eventually tire and subsequently develop respiratory failure. Therefore, be vigilant for respiratory compromise in patients with high cervical injuries. If safety allows, perform a brief focused neurologic assessment before sedation and intubation.

Maintain in-line spinal stabilization while intubating, because human cadaver studies demonstrate less cervical motion and glottis visualization with in-line stabilization than with cervical collars in place, and movement of an unstable cervical spine can worsen or produce spinal cord injury.[28] Video-assisted intubation improves intubation success over direct laryngoscopy, but manual in-line stabilization is still necessary to minimize cervical extension.[28]

HYPOTENSION

Hypotension in patients with spinal cord injuries may be due to neurogenic shock, blood loss, cardiac injury, tension pneumothorax, or other injuries. Although hypotension and relative bradycardia are classic signs of neurogenic shock, bradycardia can also be associated with intraperitoneal bleeding or prior medication with calcium channel blockers or β-blockers. In one study,[29] 74% of hypotensive patients with penetrating spinal cord injury had major blood loss causing hypotension. Therefore, presume **blood loss as the cause of hypotension in spinal injury patients until proven otherwise.** Hypotension is initially treated with IV crystalloid.

SPINE IMMOBILIZATION

Long spine boards are associated with pressure sores, so remove them as soon as possible. Log rolling is the traditional method for board removal, because it requires only a few staff and allows visualization of the patient's back and performance of a rectal examination. Some experts recommend the "6+ lift and slide maneuver" because it produces less spine motion than log rolling.[30] The 6+ maneuver consists first of unstrapping the patient from the board. Next, one person maintains in-line stabilization at the head, while six others positioned at the chest, pelvis, and lower extremities levels lift the patient as a unit 10 to 20 cm above the board. Another person slides the board out from under the patient, and the patient is then lowered to the bed, maintaining spinal alignment. Disadvantages are the need for many staff members to perform this maneuver and inability to visualize the patient's back.[31]

Hard cervical collars are associated with patient discomfort and pressure sores of the neck.[32] Therefore, promptly clear the cervical spine if possible (see "Clinical Decision Rules in Cervical Spine Imaging" and "Cervical Spine Imaging" below). Do not overtighten the cervical collar on head-injured patients, because jugular venous compression can raise intracranial pressure,[33] although Stifneck® and Miami J® collars may be better than other rigid collars in this regard.[34]

CLINICAL FEATURES

HISTORY

If the patient is able to give a history, focus on key historical points as they pertain to spine injury. Specifically, seek the presence or absence of the

historical elements included in imaging decision rules (see Tables 4,[35] 5,[36] and 6[37]). Evaluate for symptoms of midline spine pain, painful distracting injury, paresthesias, loss of function, change in mental status (including loss of consciousness), or other neurologic symptoms (especially urinary or fecal incontinence or priapism). **Pay particular attention to any symptoms indicating present or impending respiratory compromise, including dyspnea, palpitations, abdominal breathing, and anxiety, which may indicate a high cervical spine injury**.

PHYSICAL EXAMINATION

Once the patient is stabilized and other life-threatening injuries have been excluded or treated, perform a detailed neurologic assessment. An appropriately detailed initial neurologic examination is important to allow for comparison later should the patient deteriorate. Assess the patient's mental status and note any clinical evidence of intoxication. Physical examination should focus on delineating the level of the spinal cord injury (**Figure 258-3**). Document the presence or absence of midline neck or back tenderness. Test motor function for muscle groups (**Table 258-2**). Determine the level of sensory loss (**Figure 258-4**), and investigate proprioception or vibratory function to examine posterior column function. Test for "saddle anesthesia," which is sensory deficit in the region of the buttocks, perineum, and inner aspect of the thighs. Test deep tendon reflexes along with **anogenital reflexes because "sacral sparing" with preservation of anogenital reflexes denotes an incomplete spinal cord level, even if the patient has complete sensory and motor loss.** To test the bulbocavernosus reflex, squeeze the penis to determine whether the anal sphincter simultaneously contracts. Assess rectal tone at the same time. Test the cremasteric reflex by stroking the medial thigh with a blunt instrument. If the scrotum rises, some spinal cord integrity exists. Document rectal tone and sensation around the anus. An "anal wink reflex" (contraction of the anal musculature when the perianal region is stimulated with a pin) indicates some sacral sparing. Conversely, priapism implies a complete spinal cord injury. In 2013, the American Spinal Injury Association published a revised version of the International Standards for Neurological Classification of Spinal Cord Injury.[38] This scoring system is used by spine surgeons to document their initial examination and

TABLE 258-2 Motor Grading System

Grade	Movement
0	No active contraction
1	Trace visible or palpable contraction
2	Movement with gravity eliminated
3	Movement against gravity
4	Movement against gravity plus resistance
5	Normal power

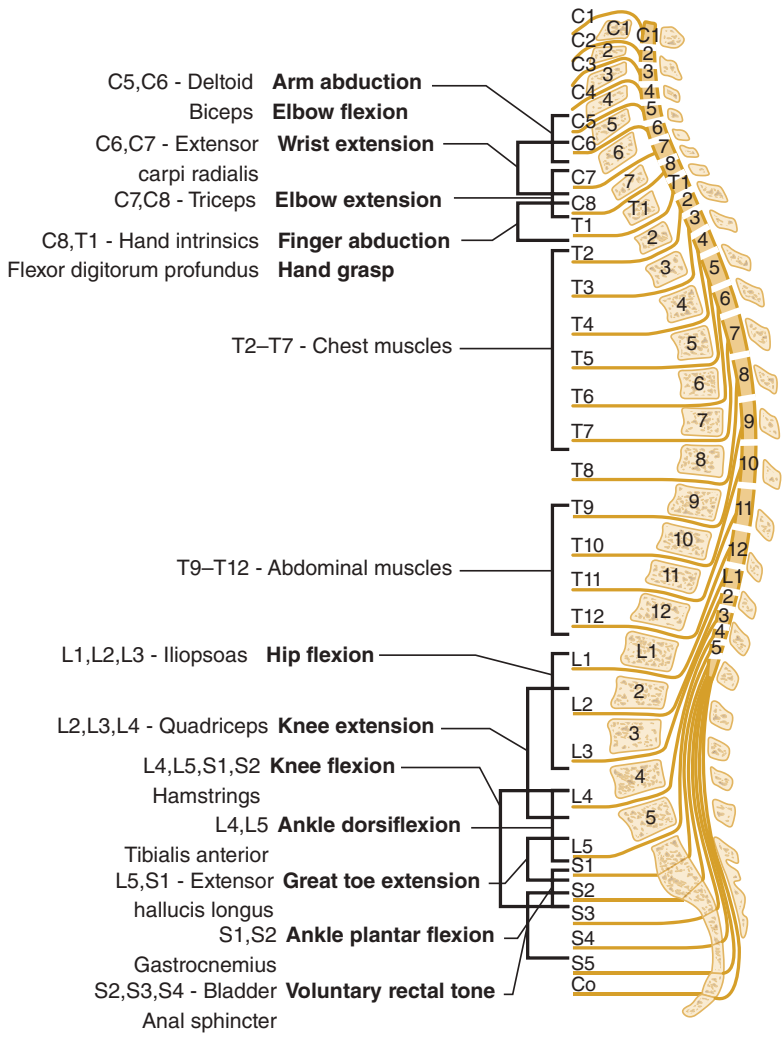

FIGURE 258-3. Spinal cord level. The spinal cord level of injury can be delineated by physical examination, including a detailed neurologic examination.

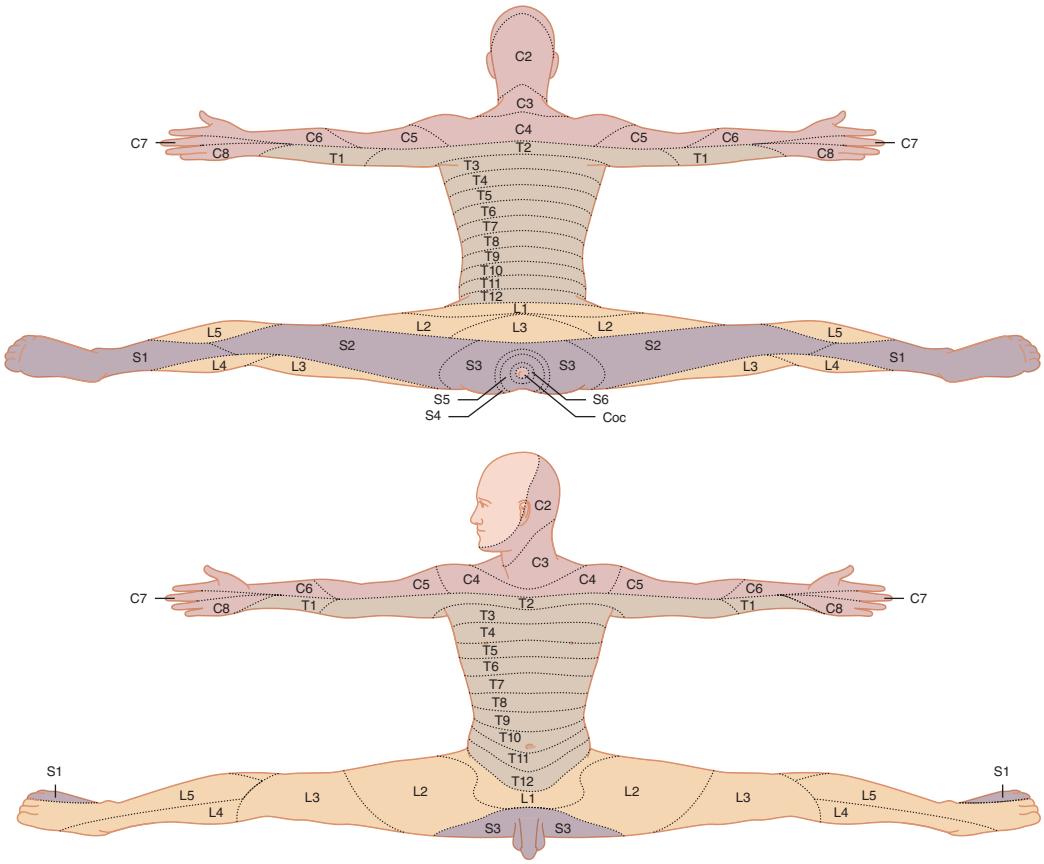

FIGURE 258-4. Dermatomes for sensory examination.

has prognostic value[39]; however, the scale is rather lengthy and is not practical for ED initial assessment.

INCOMPLETE SPINAL CORD SYNDROMES

There are three major incomplete spinal cord syndromes identified by predictable physical examination findings, although overlap in findings may occur (**Table 258-3**).

TABLE 258-3 Four Major Incomplete Spinal Cord Syndromes

Syndrome	Mechanisms	Symptoms	General Prognosis*
Anterior cord	Direct anterior cord compression	Complete paralysis below the lesion with loss of pain and temperature sensation	Poor
	Flexion of cervical spine		
	Thrombosis of anterior spinal artery	Preservation of proprioception and vibratory function	
Central cord	Hyperextension injuries	Quadriparesis—greater in the upper extremities than the lower extremities. Some loss of pain and temperature sensation, also greater in the upper extremities	Good
	Disruption of blood flow to the spinal cord		
	Cervical spinal stenosis		
Brown-Séquard	Transverse hemisection of the spinal cord	Ipsilateral spastic paresis, loss of proprioception and vibratory sensation, and contralateral loss of pain and temperature sensation	Good
	Unilateral cord compression		

*Outcome improves when the effects of secondary injury are prevented or reversed.

ANTERIOR CORD SYNDROME

The anterior cord syndrome results from damage to the corticospinal and spinothalamic pathways, with preservation of posterior column function. **This is manifested by loss of motor function and pain and temperature sensation distal to the lesion. Only vibration, position, and tacticle sensation are preserved.** This syndrome may occur following direct injury to the anterior spinal cord. Flexion of the cervical spine may result in cord contusion or bone injury with secondary cord injury. Alternatively, thrombosis of the anterior spinal artery can cause ischemic injury to the anterior cord. Anterior cord injury can also be produced by an extrinsic mass that is amenable to surgical decompression. The overall prognosis for recovery of function is poor.

CENTRAL CORD SYNDROME

The central cord syndrome is usually seen in older patients with preexisting cervical spondylosis who sustain a hyperextension injury. As named, this injury preferentially involves the central portion of the cord more than the peripheral. The centrally located fibers of the corticospinal and spinothalamic tracts are affected. The neural tracts providing function to the upper extremities are most medial in position compared with the thoracic, lower extremity, and sacral fibers that have a more lateral distribution. Clinically, **patients with a central cord syndrome present with decreased strength and, to a lesser degree, decreased pain and temperature sensation, more in the upper than the lower extremities**. Vibration and position sensation are usually preserved. Spastic paraparesis or spastic quadriparesis can also be seen. The majority will have bowel and bladder control, although this may be impaired in the more severe cases.

BROWN-SÉQUARD SYNDROME

The Brown-Séquard syndrome results from hemisection of the cord. It is manifested by **ipsilateral loss of motor function, proprioception, and vibratory sensation, and contralateral loss of pain and**

temperature sensation. The most common cause of this syndrome is penetrating injury.[40] It can also be caused by lateral cord compression secondary to disk protrusion, hematomas, spine fractures, infections, infarctions, or tumors.

CAUDA EQUINA SYNDROME

Cauda equina syndrome is not a true spinal cord syndrome because the cauda equina is composed entirely of lumbar, sacral, and coccygeal nerve roots; therefore, injuries to this region produce peripheral nerve injuries. **Symptoms and signs may include bowel and/or bladder dysfunction, decreased rectal tone, "saddle anesthesia" (sensory deficit over the perineum, buttocks, and inner thighs), variable motor and sensory loss in the lower extremities, decreased lower extremity reflexes, and sciatica.** Bowel or bladder incontinence is **not** a universal finding, because rectal tone can be spared,[41] and if the patient presents early, the patient's bladder may not yet be full enough to cause overflow incontinence. Careful history and physical examination, including identification of saddle anesthesia,[42] are helpful to suggest the diagnosis, but no one symptom or sign has 100% predictive value for this entity.[42] Therefore, perform an MRI of the lumbosacral spinal cord if clinical suspicion warrants. See the section "Epidural Compression Syndrome" in chapter 279, "Neck and Back Pain," for further discussion of cauda equina syndrome.

NEUROGENIC SHOCK

Neurogenic shock is a type of distributive shock that can occur with CNS or spinal cord injury that probably occurs in less than 20% of spinal cord–injured patients.[43] Loss of peripheral sympathetic innervation results in extreme vasodilatation secondary to loss of sympathetic arterial tone. This causes blood pooling in the distal circulation with resultant hypotension. If the T1 through T4 cord levels are compromised, loss of sympathetic innervation to the heart leaves unopposed vagal parasympathetic cardiac innervation. This results in bradycardia or an absence of reflex tachycardia. In general, **patients with neurogenic shock are warm, peripherally vasodilated, and hypotensive with a relative bradycardia**. Patients tend to tolerate hypotension relatively well, because peripheral oxygen delivery is presumably normal. Loss of sympathetic tone and subsequent inability to redirect blood from the periphery to the core may cause excessive heat loss and hypothermia.

The diagnosis of neurogenic shock is one of exclusion. Certain clues, such as bradycardia and warm, dry skin, may be evident, but **hypotension in the trauma patient can never be presumed to be caused by neurogenic shock until other possible sources of hypotension are excluded**.[29]

SPINAL SHOCK

Spinal shock is **not** neurogenic shock; the two terms have very different meanings and are not interchangeable. **Spinal shock is the temporary loss or depression of spinal reflex activity that occurs below a complete or incomplete spinal cord injury.** The typical presentation involves flaccidity, loss of reflexes, and loss of voluntary movement.[44] The lower the level of the spinal cord injury, the more likely it is that all distal reflexes will be absent. Loss of neurologic function that occurs with spinal shock can cause an incomplete spinal cord injury to mimic a complete cord injury. Therefore, cord lesions cannot be called complete until spinal shock has resolved. The delayed plantar and bulbocavernosus reflexes are among the first to return as spinal shock resolves.[45] The duration of spinal shock is variable; it generally lasts for days to weeks but can persist for months.[46]

DIAGNOSIS

Although spinal column and spinal cord injuries can sometimes be diagnosed clinically, diagnostic imaging is necessary to confirm the diagnosis and direct definitive care. However, judicious use of imaging is desirable to avoid unnecessary costs and ionizing radiation exposure to patients. Therefore, the challenge is identifying the appropriate patients to image and selecting the appropriate imaging modality.

CLINICAL DECISION RULES IN CERVICAL SPINE IMAGING

In some cases, it is obvious who needs cervical spine imaging. For example, patients with head or neck trauma who are not fully alert (Glasgow coma scale score of <15) should undergo imaging of their cervical spine because the frequency of cervical spine injury in association with traumatic brain injury ranges from 1.7% to 8%.[47] However, in less obvious cases, the decision to perform imaging is not quite so clear cut.

An unstructured clinical exam is not adequately sensitive for the detection of cervical spine injuries,[48] so guidelines can assist clinical judgment in deciding whom to image. In alert, stable adult trauma patients who have no neurologic deficits (i.e., low-risk trauma patients), two major clinical decision rules have been defined to avoid unnecessary radiography.

The first decision rule was derived by the **National Emergency X-Radiography Utilization Study (NEXUS)**, which determined that plain cervical spine imaging is unnecessary in patients who lack any one of five clinical criteria (**Table 258-4**).[35] In the study population of 34,069 patients, the NEXUS criteria were 99.6% sensitive (95% confidence interval [CI], 98.6% to 100%) for detecting prospectively defined clinically significant cervical spine injuries, but only 12.9% specific (95% CI, 12.8% to 13.0%), with a negative predictive value of 99.9% (95% CI, 99.8% to 100%). The original NEXUS trial excluded patients >60 years old, but the criteria were subsequently shown to be 100% sensitive (95% CI, 97.1% to 100%) and 14.7% specific (95% CI, 14.6% to 14.7%) for clinically significant injuries in 2943 patients ≥65 years of age.[49] In a subsequent prospective trial (n = 2785) investigating NEXUS's performance in patients ≥65 years of age, NEXUS was only 65.9% sensitive (vs 84.2% in younger patients) for cervical spine injuries detected on CT.[50] However, this trial contained several sources of bias (use of convenience sample, a very high incidence of cervical spine injuries in the elderly group [12.8% vs 4.6% in the previous trial], and every elderly patient included was a trauma team activation). This latter study did not clarify whether the fractures detected on CT were clinically significant or if any intervention was required.

The **Canadian Cervical Spine Rule for Radiography (CCR)** was developed for alert, stable trauma patients to reduce practice variation and inefficiency in the ED use of plain cervical spine radiography.[36] The Canadian rule consists of three assessments, which are asked **in sequential order** (**Table 258-5**).[36] To proceed to the next assessment, the answer to the previous assessment must be "Yes." If the answer to any assessments is "No," then imaging is immediately performed. In the original study sample of 8924 patients, the CCR was 100% sensitive (95% CI, 98% to 100%) and 42.5% specific (95% CI, 40% to 44%) for identifying patients with "clinically important" cervical spine injuries.[36] The CCR has also been validated in both larger hospital-based studies[51] and prehospital studies,[52] but has been criticized for its complexity relative to NEXUS.[53]

There is one published direct prospective comparison of NEXUS and CCR (n = 8283) that reported that CCR was more accurate for detecting cervical spine injury compared to NEXUS, with superior sensitivity (99% vs 91%), specificity (45% vs 37%), positive likelihood ratio (1.81 vs 1.44), and negative likelihood ratio (0.01 vs 0.25).[54] However, some have questioned the methodology of this comparison as being biased in favor of CCR.[55,56] A meta-analysis of 15 studies (79,526 patients) concluded that the CCR appeared to have better diagnostic accuracy than NEXUS[57]; however, the quality of methods of the included studies were termed "modest," and further more rigorous studies were suggested to be done. In both rules, the more subjective parts ("absence of painful distracting injury" and "no evidence of intoxication" for NEXUS; "dangerous

TABLE 258-4 NEXUS Criteria

Absence of midline cervical tenderness
Normal level of alertness and consciousness*
No evidence of intoxication
Absence of focal neurologic deficit
Absence of painful distracting injury†

*Defined as Glasgow coma scale score <15; disorientation to person, place, time, or events; inability to remember three objects at 5 minutes; delayed or inappropriate response to external stimuli.

†Any injury thought "to have the potential to impair the patient's ability to appreciate other injuries."

TABLE 258-5 Canadian Cervical Spine Rule for Radiography: Cervical Spine Imaging Unnecessary in Patients Meeting These Three Criteria

Assessment	Definitions
Assessment #1: There are no high-risk factors that mandate radiography.	High-risk factors include: Age 65 years or older; A dangerous mechanism of injury*; The presence of paresthesias in the extremities
Assessment #2: There are low-risk factors that allow a safe assessment of range of motion.	Low-risk factors include: Simple rear-end motor vehicle crashes; Patient able to sit up in the ED; Patient ambulatory at any time; Delayed onset of neck pain; Absence of midline cervical tenderness
Assessment #3: The patient is able to actively rotate his/her neck (regardless of pain).	Can rotate neck 45 degrees to the left and to the right

*Defined as fall from a height of >3 feet; an axial loading injury; high-speed motor vehicle crash, rollover, or ejection; motorized recreational vehicle or bicycle collision.

mechanism of injury" and assessment of range of motion for CCR) are the most common misinterpretation of the rules, which obviously affects their performance.[57]

Both NEXUS and CCR were developed in an era prior to the routine use of CT as a primary tool to evaluate the cervical spine in blunt trauma patients. Consequently, studies have been done to compare both decision rules using CT scan as the gold standard. In a 2011 study of 2606 blunt trauma patients, NEXUS was found to only be 82.8% sensitive and 45.7% specific for spine injury. Of the 26 missed injuries, 19 patients required further intervention, including 2 who went to the operating room and 1 needing a Halo.[58] The same group compared CCR to CT scan (3201 blunt trauma patients), finding excellent sensitivity of 100% but only 0.60% specificity.[59] Nevertheless, the use of NEXUS has been recommended for use in several national guidelines and trauma societies.[60,61]

In summary, many experts feel that **because both NEXUS and CCR have been widely validated and have demonstrated adequate sensitivity, either rule may be used to determine which low-risk patients should undergo plain or CT cervical spine imaging**.[57]

CERVICAL SPINE IMAGING

Plain Radiography Standard radiography for the identification of bony cervical injury includes three views of the cervical spine: lateral, anterior-posterior, and odontoid. A single lateral cervical spine film will identify only about 90% of injuries to bone and ligaments.[24] The anterior-posterior and open-mouth odontoid views will identify many of the remaining abnormalities. **It is important to image all seven cervical vertebrae, along with the superior border of the first thoracic vertebra**, given the propensity for injuries at the cervical-thoracic junction. Therefore, a "swimmers view" may be necessary to visualize this junction clearly, but this often requires an assistant to pull down the shoulders during the radiograph. The main advantages of plain radiography are that it can be done at the bedside, exposes the patient to only small amounts of ionizing radiation, and has a relatively low cost. One of the main disadvantages of plain films is that they are poor for imaging C1 and C2. In addition, visualization of the entire cervical spine by plain films is often problematic in obese, elderly, or extremely muscular patients, especially with a cervical collar in place.

Cervical Spine CT The practice in many trauma centers is to obtain CT as the initial imaging modality to evaluate the cervical spine. **Multidetector CT is more sensitive and specific than plain radiography for evaluating the cervical spine in trauma patients and can be performed quickly.**[62,63] CT can be used to visualize the entire cervical spine and is particularly useful at the craniocervical and cervicothoracic regions, where the sensitivity of plain films is most limited. In addition, a 3-year retrospective review found that plain radiography did not add any clinically useful information to a cervical spine CT.[64] Furthermore, a cost analysis showed CT to be cost-effective to screen for cervical spine injuries in moderate- to high-risk patients.[65] The Eastern Association for the Surgery of Trauma recommends CT as the primary diagnostic tool for suspected cervical spine injury.[60] In addition, if plain radiography is chosen as the primary imaging modality, a CT should be ordered if an injury is detected or suspected or if the initial plain radiograph is inadequate.

Imaging for Cervical Ligamentous Injury In patients with pure ligamentous injuries, the ligaments are disrupted, but the spine spontaneously reduces to a normal position. The resulting instability risks subsequent neurologic injury if the spine moves. Signs and symptoms include persistent neck pain/midline tenderness, extremity paresthesias, or focal neurologic findings despite normal plain radiographs and/or CT.

Although flexion and extension radiographs have been traditionally used to try to detect ligamentous instability, numerous studies have demonstrated their lack of sensitivity and inefficiency (30% to 80% of flexion and extension radiographs are inadequate), and they provide no further information beyond a CT.[66-70] Therefore, flexion and extension radiographs should not be ordered when more advanced imaging is available.

MRI is the imaging modality of choice if a ligamentous injury is strongly suspected because MRI has excellent sensitivity for soft tissue injuries.[71,72] However, there are practical limitations on its use, including the requirement for the patient to be stable, availability, cost, and patient tolerance for the procedure. If emergent MRI is not feasible, reliable patients with persistent pain but normal CT can be discharged in a firm foam collar with outpatient follow-up in 3 to 5 days. Most patients' symptoms will resolve over a few days. A patient with persistent pain at follow-up will likely require additional imaging. Unreliable patients with severe persistent pain and normal CT images should be considered for an MRI study, although this is rarely indicated as part of the initial investigation. In fact, some data have suggested that newer-generation CTs are sufficient to detect significant injuries without MRI even in obtunded patients.[73,74] However, the results of these studies cannot currently be externally generalized to awake, symptomatic patients.

Thoracic and Lumbar Spine Imaging As of this writing, there are no well-validated clinical decision rules for imaging in possible thoracolumbar spine injuries. However, **Table 258-6** provides practice guidelines for imaging in blunt trauma victims who are suspected of having thoracolumbar injuries.[37,75]

TABLE 258-6 Eastern Association for the Surgery of Trauma Guidelines for Thoracic and Lumbar Imaging after Trauma

Level I (convincingly justifiable based on scientific evidence)	When imaging is deemed necessary, CT scans with axial collimation should be used to screen for and diagnose injury, because CT scans are superior to plain films in identifying thoracolumbar spine fractures.
Level II (reasonably justifiable based on scientific evidence and expert opinion)	Patients with back pain, thoracolumbar spine tenderness on examination, neurologic deficits referable to the thoracolumbar spine, altered mental status, intoxication, distracting injuries, or known or suspected high-energy mechanisms should be screened for thoracolumbar spine injury with CT scan.
	In blunt trauma patients with a known or suspected injury to the cervical spine, or any other region of the spine, thorough evaluation of the entire spine by CT scan should be strongly considered due to a high incidence of spinal injury at multiple levels within this population.
	Patients without complaints of thoracolumbar spine pain who have normal mental status, as well as normal neurologic and physical examinations, may be excluded from thoracolumbar spine injury by clinical examination alone, without radiographic imaging, provided that there is no suspicion of high-energy mechanism or intoxication with alcohol or drugs.
Level III (supported by available data, but scientific evidence lacking)	MRI should be considered in consultation with the spine service for CT findings suggestive of neurologic involvement and of gross neurologic deficits.

Abbreviation: CT = multidetector CT.

As with the cervical spine, CT has largely supplanted plain radiography in the imaging of thoracic and lumbar injuries with significant blunt trauma. CT scanning is indicated in almost all patients with proven bony spinal injury, subluxations, neurologic deficits (but no apparent abnormalities on plain films), or severe neck or back pain (with normal plain films) and when the thoracic and lumbar spine should be examined to define the anatomy of a fracture and the extent of impingement on the spinal canal. Rather than obtaining separate plain radiographs or dedicated CT images, the thoracic and abdominal CT scans obtained to evaluate the multiple trauma patient can be used to reconstruct images of the thoracic and lumbar spine, although some authors have suggested that spinal image reconstruction is not necessary because the spine can be seen on the visceral CT scans.[76,77] CT can reveal the anatomy of an osseous injury, grade the extent of spinal canal impingement by bone fragments, and assess the stability of an injury. If an associated spinal cord or nerve root injury is suspected, MRI is the imaging study of choice.

It is less clear how to screen for thoracolumbar injuries in patients who have less severe mechanisms of injuries. Although it has been shown repeatedly that CT is more sensitive for thoracolumbar injuries in severely injured patients,[37] there has been no prospective controlled comparison between plain radiography and CT in more mildly injured patients. Nevertheless, some published guidelines suggest CT should be considered the standard screening modality for thoracolumbar injuries.[37]

Spinal Cord and Neural Tissue Imaging MRI is not as sensitive as CT for detecting or delineating bone injuries but is superb at defining neural, muscular, and soft tissue injury. **MRI is the diagnostic test of choice for describing the anatomy of nerve injury. Entities such as herniated disks or spinal cord contusions can also be delineated on MRI.** MRI is indicated in patients with neurologic findings with no clear explanation after plain films and/or CT scanning. If the patient is stable and MRI is unavailable, transfer to a tertiary care facility with MRI capabilities is appropriate.

Concurrent Spine Injury Imaging The determination of a spinal column injury at one level should prompt imaging of the entire remainder of the spine with CT because approximately 20% of patients with a spine fracture in one segment will have a noncontiguous second fracture at another segment.[78,79]

Spine Imaging in Obtunded Patients While experts recommend that all obtunded patients with significant blunt trauma should have their entire spine imaged, consensus does not yet exist on what imaging is necessary to clear the spine in obtunded patients. Specifically, **it is controversial whether a negative CT of the spine is adequate or if a subsequent MRI needs to be done**,[80] although at this writing, the trend in the literature suggests that a negative CT is sufficient.[73,74] In the absence of definitive data, maintain spinal precautions in the obtunded trauma patient in the ED, and defer any spine clearance to local expert consultants.

TREATMENT AND DISPOSITION OF SPINAL COLUMN INJURIES

The goals of treatment are to prevent secondary injury, alleviate cord compression, and establish spinal stability. Maintain spinal immobilization and keep movement to a minimum. **Obtain emergent consultation with a spine surgeon (neurosurgeon or orthopedic surgeon depending on the particular facility) on all spinal column fractures or ligamentous injuries, regardless of neurologic compromise**.

CERVICAL SPINE FRACTURES

The majority of cervical spinal fractures will require admission for definitive treatment or for the care of associated injuries. Until transfer of care to a surgeon, spine precautions should be maintained, associated injuries stabilized, and the patient carefully monitored for respiratory or neurologic deterioration.

THORACIC AND LUMBAR SPINE FRACTURES

Thoracolumbar fractures are also high risk for associated spinal cord or other traumatic injuries, such as aortic, intrathoracic, or intra-abdominal visceral injuries. Although many of these injuries will require admission, there are two types of thoracolumbar factures that may be amenable to outpatient therapy.

Compression fractures, also known as "wedge" or "anterior" compression fractures, comprised approximately 52% of thoracolumbar fractures in one published series.[81] These fractures occur as a result of a hyperflexion during an axial load that crushes the anterior portion of the vertebra. If the percentage of loss of vertebral height is <40%, the patient may be a candidate for outpatient therapy, and this should be discussed on a case-by-case basis by the spine surgeon. However, if the loss of vertebral height is ≥50% or if the angle between the damaged vertebra and the rest of the spinal column is >25% to 30%, the compression fracture is generally considered unstable.

In addition, make certain that an apparent compression fracture seen on plain radiographs is not a **burst fracture**, which is a compression-type fracture that involves the posterior half of the vertebrae. Burst fractures may result in retropulsed fragments that can impinge on the spinal canal and cause neurologic injury. In two studies, the incidence of misdiagnosis of burst fractures on plain radiographs ranged from 20% to 23%.[82,83] Another fracture that is sometimes misdiagnosed as a wedge compression fracture on plain radiograph is the **Chance fracture**. This fracture occurs via a flexion-distraction mechanism and involves minor anterior vertebral compression and significant distraction of the middle and posterior ligamentous structures. Typical radiographic findings reveal a transverse fracture lucency in the vertebral body, an increased height of the posterior vertebral body, fracture of the posterior wall of the vertebral body, and posterior opening of the disk space. Finally, minor to moderate trauma can cause **pathologic fractures** secondary to preexisting neoplastic, infectious, or osteoporotic processes in the spine. Because the above mentioned fractures can be easily misdiagnosed with plain radiography alone, **some experts recommend that compression fractures of the thoracolumbar spine on plain radiographs be further evaluated with CT**.[84]

If, after a thorough evaluation, a stable wedge compression fracture with no neurologic compromise is diagnosed, the patient may be treated as an outpatient with analgesia, heat, massage, rest, and appropriate follow-up for consideration of physical therapy.

SACRUM AND COCCYX FRACTURES

Injuries of the sacral spine and nerve roots are very unusual. When they occur, they are frequently associated with fractures of the pelvis. In general, transverse fractures through the body are most significant in that they cause injury to part or all of the cauda equina. Longitudinal fractures may cause radiculopathy. **Sacral fractures that involve the central sacral canal can produce bowel or bladder dysfunction.**

One notable exception to the need for emergent consultation is an **isolated coccyx fracture.** Coccygeal injuries are usually associated with a direct fall onto the buttocks, with resultant coccyx pain exacerbated by sitting or straining. Imaging is not needed to diagnose coccygeal fractures. Treatment is symptomatic with analgesics and use of a rubber doughnut pillow.

SPECIAL CONSIDERATIONS

CORTICOSTEROIDS

High-dose methylprednisolone remains a controversial treatment in acute blunt spinal cord injury and should not be given routinely. The major neuroprotective mechanism by which high-dose methylprednisolone is believed to work is in its inhibition of free radical–induced lipid peroxidation. Other proposed beneficial actions include its ability to increase levels of spinal cord blood flow, increase extracellular calcium, and prevent loss of potassium from injured cord tissue. Methylprednisolone is advocated in preference to other steroids because it crosses cell membranes more rapidly and completely.

In the 1990s, the National Acute Spinal Cord Injury Study (NASCIS) group published three prospective, double-blind studies to evaluate the efficacy of methylprednisolone in blunt spinal cord injury: NASCIS I, II, and III.[85-87] NASCIS I compared high-dose methylprednisolone and a lower-dose methylprednisolone regimen (n = 330). NASCIS I showed no evidence in recovery of function between the groups. NASCIS II compared a higher dose of methylprednisolone (**Table 258-7**), naloxone, and

TABLE 258-7	The National Acute Spinal Cord Injury Study II High-Dose Methylprednisolone Protocol
Indications	Blunt trauma Neurologic deficit referable to the spinal cord Treatment must be started within 8 h of injury
Treatment	Methylprednisolone, 30 milligrams/kg IV bolus over 15 min Followed by a 45-min pause Methylprednisolone, 5.4 milligrams/kg/h IV is then infused for 23 h

placebo (n = 427). This trial was also negative, but based on post hoc subgroup analysis, NASCIS II showed modest improvements in motor function when steroids were administered within 8 hours of injury. NASCIS III compared high-dose methylprednisolone for 24 hours, high-dose methylprednisolone for 48 hours, and tirilazad mesylate for 24 hours (n = 499). NASCIS III was also a negative trial, but post hoc analysis found that patients who received the 48-hour methylprednisolone regimen within 3 to 8 hours of their injury showed motor improvement. In all three trials, patients who received high-dose methylprednisolone and longer duration protocols were more likely to develop complications such as severe sepsis, severe pneumonia, wound infection and delayed healing, pulmonary embolism and deep vein thrombosis, GI bleeding, and death. A recent Cochrane systematic review (written by the lead author of the NASCIS trials) essentially confirmed the conclusions of NASCIS II and III that high-dose methylprednisolone was beneficial when administered within 8 hours of injury, but these patients were also more likely to develop complications.[88] The systematic review also recommended that more randomized trials be done urgently.

The results of the NASCIS clinical trials have been criticized as not providing sufficient clinical evidence to support the use of steroids in acute spinal cord injury. Examples of bias cited include the use of post hoc subgroup analysis, the artificiality of the 3- and 8-hour time limits, and a difference in the severity of injury in particular treatment groups. Reassessment, meta-analysis, and studies by other authors have questioned the validity of the NASCIS trials and the effectiveness of high-dose steroid therapy in these patients.[89-91] Consequently, the 2013 updated guidelines for the management of acute spinal cord injuries endorsed by the American Association of Neurological Surgeons and the Congress of Neurological Surgeons stated that "there is no consistent or compelling medical evidence of any class to justify the administration of methylprednisolone for acute spinal cord injury," and that "methylprednisolone should not be routinely used in the treatment of patients with acute spinal cord injury."[92] Moreover, the U.S. Food and Drug Administration has not approved corticosteroids for acute spinal cord injury.[93]

Nevertheless, the use of methylprednisolone persists in some centers. Therefore, given the continued controversy over its use,[94,95] **the decision to start corticosteroids should only be made in conjunction with the surgeon who will ultimately be caring for the patient, and *not* given routinely**.

It is important to realize that the NASCIS trial protocol was evaluated only in patients with **blunt** spinal cord injury, while penetrating injuries were excluded from these studies. In fact, **high-dose methylprednisolone therapy has not been found to be efficacious in penetrating spinal cord injury**.[96] In addition, because corticosteroids worsen outcomes in brain-injured patients, they should be avoided in this population as well.[97]

CARDIOVASCULAR COMPLICATIONS

If neurogenic shock is present, initiate an infusion of IV crystalloid to correct this relative hypovolemia. **If IV fluids are not adequate to maintain organ perfusion, positive inotropic pressor agents may be beneficial adjuncts to improve cardiac output and raise perfusion pressure.** In terms of target systolic blood pressure and mean arterial pressure, the evidence in the literature is limited at best. However, it has been recommended that systolic blood pressure should be kept greater than 90 mm Hg, with the mean arterial pressure kept at 85 to 90 mm Hg.[98] The aggressive use of fluids in neurogenic shock should be performed with careful monitoring, because there is danger of excessive fluid replacement, resulting in heart failure and pulmonary edema. There is no definitive evidence that any particular vasopressor is superior to another for this indication.[99]

Bradycardia, when present, usually occurs within the first few hours or days after spinal cord injury because of a predominance of vagal tone to the heart. In cases of hemodynamically significant bradycardia, atropine may be needed. Rare occurrences of atrioventricular conduction block with significant bradycardia require a pacemaker.

PENETRATING INJURY

Penetrating injuries to the neck are discussed in chapter 260, "Trauma to the Neck." For spinal gunshot wounds with a transabdominal or transintestinal trajectory, administer prophylactic broad-spectrum IV antibiotics in the ED. **Corticosteroids are contraindicated in patients with any type of penetrating spinal injuries,** and emergent consultation with a spine surgeon is indicated.

Acknowledgments: The author gratefully acknowledges the prior contributions of Bonny J. Baron, Kevin J. McSherry, James L. Larson, Jr., and Thomas M. Scalea, the authors of this chapter in the previous edition. The author would also like to thank Lawrence R. Ricci, DO, for his invaluable assistance with locating images.

CHAPTER 259

Trauma to the Face

John Bailitz
Tarlan Hedayati

INTRODUCTION AND EPIDEMIOLOGY

Assaults, motor vehicle crashes, falls, sports, and gunshot wounds account for the majority of facial fractures (in descending order of incidence), with motor vehicle crashes and gunshot wounds resulting in a higher severity of injury.[1] The lack of a seat belt or airbag increases the risk of facial fractures and panfacial fracture.[2] The most common fractures are to the nasal bone, followed by orbital floor, zygomaticomaxillary, maxillary sinuses, and mandibular ramus.[1] Mechanisms and injury patterns vary with geography. In the urban setting, penetrating trauma and assaults result in midface and zygomatic fractures. In the rural setting, motor vehicle crashes and recreational injuries result in fractures of the mandible and nose. Males are more frequently affected than females, but domestic violence and elder and child abuse must always be considered in any patient presenting with facial trauma. The majority of abused women and children will have injuries to the head, face, and neck.[3,4]

PATHOPHYSIOLOGY

The facial skeleton is designed to create effective mastication. Vertical and horizontal buttresses are formed by bony arches joined at suture lines. Stronger vertical buttresses are formed by the zygomaticomaxillary buttress laterally and the frontal process of the maxilla medially. Weaker horizontal buttresses are formed by the superior orbital rims, orbital floor, and hard palate. The orbit itself is comprised of seven different bones, with the inferior and medial walls being particularly fragile. Therefore, frontal, lateral, and oblique forces often result in facial fractures.

The identification of facial injury and the restoration of normal appearance, sight, mastication, smell, and sensation are all essential

tasks,[5] but the principal focus should be on protecting the patient's airway during the primary survey and the other initial considerations described in **Table 259-1**.

Up to 44% of patients with severe maxillofacial trauma require endotracheal intubation due to mechanical disruption or massive hemorrhage into the airway.[6] The incidence of associated injury to the brain, orbit, cervical spine, and lungs is directly related to the mechanism of injury and severity of facial fractures.[6-8] Evaluate facial injuries as part of the secondary survey only after managing life-threatening injuries. Because up to 6% of patients with maxillofacial trauma will develop vision loss, a detailed eye examination is essential, especially in patients with high-energy mechanisms, orbital fractures, significant head injury, and abnormal pupillary findings.[8,9]

CLINICAL FEATURES

The mechanism of injury helps estimate the extent of injury. Exact details of motor vehicle crashes and assaults are often incomplete due to associated traumatic brain injury, intoxication, or other factors. Always address the possibility of abuse. When reported mechanisms do not match the injury, ask patients, especially women and the elderly, about interpersonal violence. Contact pediatricians and local child protective services when considering child abuse. It is better to report all suspected abuse than allow violence to continue and escalate. Obtain history of allergies, medications (especially cardiovascular and antithrombotic agents), comorbidities, tetanus immunization status, and time of last meal from the trauma patient or other available sources.

The secondary survey begins with three screening questions to help localize injuries while simultaneously examining the patient from the upper to the lower face. Important clinical findings in facial trauma are presented in **Table 259-2**.

(1) How is your vision? Any patient with visual complaints or evidence of periorbital injury requires a thorough eye examination. (2) Is your face numb? Ask this question while checking for anesthesia of the forehead, lower eyelid, cheek and upper lip, or chin, suggesting injury to the supraorbital, infraorbital, or mental nerves. (3) Do your teeth fit together normally? Malocclusion typically occurs in patients with mandibular or maxillary fractures. Pain and tenderness near the ear indicate mandibular condyle injury. With zygomaticomaxillary complex fractures, patients often report pain over the cheek and trismus from masseter spasm or mechanical impingement of either the temporalis muscle or coronoid process of the mandible.

Inspect the face from the front, sides, feet, and above to detect subtle asymmetry in facial structure from zygomatic, orbital, and Le Fort injuries (**Figures 259-1 to 259-3**). Palpate the entire orbital rim for tenderness and step-off deformities, which suggest fracture, and for crepitus, which suggests sinus involvement.

Examine the eyes before significant swelling occurs, or use lid retractors to better inspect the globe. Begin with corrected visual acuity using a wall, pocket, or phone app Snellen eye chart, name tag, or finger counting. In patients with loss of visual acuity, note light perception and color perception. **Loss of vision implies injury to the optic nerve or globe.** Subconjunctival hemorrhage and bloody chemosis occur with orbital fractures.

TABLE 259-1 Initial Considerations in Facial Trauma

Primary survey
Airway—endotracheal intubation for mechanical disruption or severe hemorrhage.
Circulation—early packing of nasal and oral cavity. Apply direct pressure to external wounds. Avoid blind clamping.
Evaluate and manage emergent life-threatening conditions before facial injuries.
Secondary survey
Early meticulous facial and ocular examinations.
History
Mechanism predicts severity of facial and associated brain, cervical spine, and pulmonary injury.
Screen for abuse, especially in women, children, and elders.

TABLE 259-2 Important Clinical Issues in Facial Trauma

History
How is your vision?
Do any parts of your face feel numb?
Does your bite feel normal?
Inspection
Lateral view for dish face with Le Fort III fractures.
Frontal view for donkey face with Le Fort II or III fractures.
Bird's eye view for exophthalmos with retrobulbar hematoma.
Worm's view for enophthalmos with blow-out fractures or flattening of malar prominence with zygomatic arch fractures.
Raccoon eyes (bilateral orbital ecchymosis) and Battle's sign (mastoid ecchymosis) typically develop over several hours, suggesting basilar skull fracture.
Palpation
Palpating the entire face will detect the majority of fractures.
Intraoral palpation of the zygomatic arch, palpating lateral to posterior maxillary molars to distinguish bony from soft tissue injury.
Assess for Le Fort fractures by gently rocking the hard palate with one hand while stabilizing the forehead with the other.
Eye
Examine early before swelling of lids, or use retractors. Document visual acuity. Systematically examine the eye from front to back. Specifically, check the pupil for teardrop sign pointing to globe rupture; hyphema; and swinging flashlight test for afferent papillary defect.
Fat through wound indicates orbital septal perforation.
Check intraocular pressure for evidence of orbital compartment syndrome only in absence of globe injury.
Nose
Crepitus over any facial sinus suggests sinus fracture.
Nasal septal hematoma appears as blue, boggy swelling on nasal septum.
Cerebrospinal fluid leak.
Ears
Auricular hematoma.
Hemotympanum.
Cerebrospinal fluid leak.
Oral
Jaw deviation due to mandible dislocation or condyle fracture. Malocclusion occurs in mandible, zygomatic, and Le Fort fractures.
Missing or injured tooth.
Lacerations and mucosal ecchymosis suggest mandible fracture.
Place finger in external ear while the patient gently opens and closes jaw to detect condyle fractures.
Tongue blade test: Patient without fracture can bite down on a tongue blade enough to break blade twisted by examiner.

Assess extraocular motion and pupils. **Binocular double vision suggests entrapment of the extraocular muscles, whereas monocular double vision suggests lens dislocation.** Limitation on upward gaze occurs with fractures of the inferior and medial orbital wall from entrapment or injury to the inferior rectus, inferior oblique, or oculomotor nerve (**Figure 259-4**). Examine the pupils for shape, position, symmetry, and reactivity. Teardrop-shaped pupil indicates globe injury. Note the distance between the medial canthi; normal is the width of the patient's globe. **Telecanthus, widening of this distance with normal interpupillary distance, occurs with naso-orbito-ethmoid injuries.** Widening of the interpupillary distance, or hypertelorism, results from a "blow-out" injury to the orbits, often resulting in blindness.

Check the swinging flashlight test for evidence of an afferent papillary defect (Marcus Gunn pupil) (see chapter 241, "Eye Emergencies"). With normal function, the swinging light results in brief dilation during movement followed by constriction when the light is directly over the eye. With injury to the optic nerve or retina, the affected pupil will not constrict

FIGURE 259-1. Zygomatic arch fracture. Note flattening of the right malar eminence on bird's eye. [Reproduced with permission from Knoop K, Stack L, Storrow A, Thurman RJ: *Atlas of Emergency Medicine,* 3rd ed. © 2010, McGraw-Hill, New York.]

FIGURE 259-3. Le Fort III fracture has a classic dish face deformity on lateral view. [Reproduced with permission from Knoop K, Stack L, Storrow A, Thurman RJ: *Atlas of Emergency Medicine,* 3rd ed. © 2010, McGraw-Hill, New York.]

until the light is again moved to the unaffected eye. The test is sensitive but not specific for optic nerve injury because an afferent papillary defect may result from pathology anywhere along the visual pathway.

Finish the physical examination of the eye by completing funduscopic, slit-lamp, and fluorescein examinations, as well as checking intraocular pressures when indicated. Flashes of light and floaters may be reported in patients with retinal detachments and vitreous hemorrhage. Foreign-body sensation and photophobia suggest corneal abrasions. Check for hyphema after having the patient sit upright for several minutes. In patients without evidence of globe rupture, check intraocular pressure in patients with significant exophthalmos, afferent nerve defects, or other evidence of retrobulbar hematoma.

Check carefully for globe injury with any penetrating injury to the periorbital area. Consult ophthalmology for suspected hyphema or vitreous hemorrhage. Fat herniating through the wound suggests an injury through the orbital septum. Through-and-through injuries, tarsal plate injuries, and injuries to the medial quadrant involving the lacrimal duct require repair by an ophthalmologist.

Begin the examination of the nose by checking for deformity from multiple angles while asking the patient about prior nose injury. Check for tenderness, crepitus, septal hematoma, and cerebrospinal fluid rhinorrhea. A septal hematoma appears as a blue, boggy, and tender area of swelling along the nasal septum (**Figure 259-5**). Incision and evacuation are required to prevent destruction of cartilage resulting in a saddle nose deformity. Ensure that simple nasal fractures are not associated with complex naso-orbito-ethmoid injuries. Perform the bimanual nasal palpation test with tenderness over the medial canthus. Begin by anesthetizing the nose. Then insert a cotton tip applicator inside the nose along the lateral nasal wall to the area behind the medial orbital wall and canthus. Palpate the area of the medial canthus externally with the opposite hand to check for movement from fracture of the medial wall of the orbit. Obtain a CT scan for suspected injury to the medial canthus or when telecanthus is present. Isolated nasal fractures and septal hematoma evacuation are reviewed in chapter 244, "Nose and Sinuses."

FIGURE 259-2. Traumatic exophthalmos. Note significant right exophthalmos on bird's eye view due to retrobulbar hematoma. [Reproduced with permission from Knoop K, Stack L, Storrow A, Thurman RJ: *Atlas of Emergency Medicine,* 3rd ed. © 2010, McGraw-Hill, New York.]

FIGURE 259-4. Orbital blow-out fracture causes limitation of upward gaze due to entrapment of inferior rectus.

FIGURE 259-5. Septal hematoma presenting as a grapelike mass on left nasal septum. [Reproduced with permission from Knoop K, Stack L, Storrow A, Thurman RJ: *Atlas of Emergency Medicine,* 3rd ed. © 2010, McGraw-Hill, New York.]

Classic tests for cerebrospinal fluid rhinorrhea are not accurate in distinguishing cerebrospinal fluid from serous nasal discharge in the presence of nasal bleeding. The double ring or halo sign occurs when clear cerebrospinal fluid diffuses past blood when dropped on a paper towel. Trauma-related serous nasal discharge will also diffuse past blood. The glucose test is likewise not reliable. Nasal discharge does not contain glucose, whereas cerebrospinal fluid does. Bleeding may create a false-positive glucose test.

Begin the inspection of the ear by checking the mastoid process for Battle's sign (suggesting a basilar skull fracture) and the ear for auricular hematoma. Incision and drainage are required to prevent destruction of cartilage resulting in a cauliflower deformity. Traumatic injury to the ear, including auricular hematoma evacuation, is reviewed in chapter 242, "Ear Disorders." Check the external auditory canal for lacerations, cerebrospinal fluid leak (temporal bone or middle cranial fossa injury), and hematotympanum (a purple and often bulging tympanic membrane). Insert a finger into the external auditory canal and ask the patient to gently open and close the mouth to check for a mandibular condyle fracture.

Inspect the jaw for deviation resulting from a fracture or dislocation. Malocclusion occurs in mandibular fractures, Le Fort fractures, and zygomatic fractures. Check the mouth carefully for missing or subluxed teeth, fractures of the alveolar ridge, sublingual hematoma, or breaks in the oral mucosa (**Figure 259-6**). Be sure to inspect the tongue for lacerations that may result in significant swelling later on. The tongue blade test has been reported to be 96% sensitive in identifying clinically significant mandibular fracture injuries in facial trauma patients.[10-12] The patient without a mandible fracture bites down forcefully enough on a tongue blade to allow the physician to snap the tongue blade with a twisting motion. Patients who open the mouth and cannot break the blade require further imaging. The tongue blade test is best used in conjunction with other clinical findings because test sensitivity may be as low as 85%.[12]

FIGURE 259-6. Open mandible fracture with a fracture line through gingiva into oral cavity. [Reproduced with permission from Knoop K, Stack L, Storrow A, Thurman RJ: *Atlas of Emergency Medicine,* 3rd ed. © 2010, McGraw-Hill, New York.]

DIAGNOSIS

IMAGING

Noncontrast CT is the imaging modality of choice. Plain radiographs remain helpful when CT is not available or to exclude injury in the low-risk patient. Recommendations for imaging based on level of injury and clinical findings are summarized in **Table 259-3**.

Subtle fractures of the frontal bone require head CT with bone windows for optimal evaluation. Because fracture of the frontal bones requires a significant force, head CT is also required to evaluate for associated traumatic brain injury. With involvement of the supraorbital ridge, include a facial CT with axial and coronal sections to better define often complex orbital fracture anatomy.

The Waters' view safely replaces the multiple views in traditional facial series for midfacial fractures.[13,14] One study suggested that at least two views be obtained due to recalculated sensitivities as low as 87% and the lack of comparison of the Waters' view to CT.[15] Not included in this analysis was a study of 730 patients demonstrating a sensitivity of 100% for Waters' view read by emergency physicians versus facial series read by specialists.[16]

Head CT has been reported to be 90% sensitive in excluding injury found on facial CT. **An additional Waters' view is unnecessary with a low clinical suspicion for facial fracture in patients undergoing a head CT for suspected traumatic brain injury.**[17] Using this strategy avoids additional radiation from unnecessary Waters' view or facial CT, and prevents additional trips to CT after cervical spine clearance required for facial CT coronal positioning.

Facial CT with coronal and axial sections is the imaging study of choice for patients with an abnormal Waters' view or as the initial study with significant clinical findings.[16] Computer-generated three-dimensional reconstructions are helpful to better identify complex fractures but do not add additional information in minimally displaced fractures.[18] Head and cervical spine CT scans are recommended in addition to facial CT in patients with high-energy mechanisms or significant clinical findings.

Panorex (orthopantomogram) remains the imaging study of choice for mandible fractures. However, mandible CT is 92% to 100% sensitive

TABLE 259-3 Recommendations for Imaging Based on Level of Injury and Clinical Findings

Level	Low Suspicion	Significant Clinical Findings	Additional Considerations
Frontal bone	Head CT	Head CT (skull windows)	Facial CT with orbital involvement.
			Cervical spine CT with significant clinical findings.
Midface	Waters' view	Face CT with coronal and axial sections; head CT as strong force causes midface fractures	Coronal face sections require cervical spine clearance for positioning.
			Computer-generated, three-dimensional reconstructions with complex injuries.
			Head CT can replace Waters' view.
Mandible	Panorex (orthopantomogram)	Mandible CT	Facial CT detects mandible fractures.

for detecting injury compared with 70% to 86% for Panorex in adults and children and has become the "gold standard" for diagnosing mandible fractures.[19,20] Mandible CT is easier to interpret with less interphysician variability compared with Panorex.[21] Mandible CT scans may miss fractures of the dental root.[19] Panorex is not often available in the ED, requires an upright patient, and may miss mandibular condyle fractures. Mandible CT is recommended in patients requiring head CT to evaluate for traumatic brain injury or when a Panorex is not available. The traditional mandible series (including posterior-anterior, Towne's view, and lateral oblique view) remains an option when Panorex and CT are not available.

TREATMENT

AIRWAY MANAGEMENT

During the primary survey of facial trauma patients, aggressively protect the airway from hemorrhage and mechanical obstruction. Significant hemorrhage into the airway can result from mandible and midfacial fractures. Loss of mechanical support resulting in airway obstruction can occur with bilateral posterior mandible fractures. Significant edema of the soft palate may result from midfacial injuries. Furthermore, the patient is often unable to maintain the damaged airway due to concomitant traumatic brain injury, intoxication, or other life-threatening injuries.

Reposition the airway as needed with a jaw thrust, or head tilt and chin lift after cervical spine clearance. Grasp an obstructing tongue with gauze, a towel clip, or suture, to pull anteriorly and out of the airway with mandible fractures. Remove avulsed teeth and foreign bodies. Use nasal trumpets very carefully to avoid worsening of the injury or intracranial placement in severe midfacial injuries. Bag-mask ventilation often requires a two-person technique because of loss of normal facial bony structures and the need to suction the airway secondary to significant hemorrhage. When the cervical spine has been clinically cleared, allow the alert patient without significant associated injury to remain in an upright position of comfort, with suction in hand, to better handle bleeding and secretions.

Each patient's unique clinical presentation and the physician's experience dictate the best method for establishing a definitive airway. Rapid-sequence intubation is the preferred method of airway management in trauma. The presence of mandible fractures occasionally makes intubation easier than expected. However, always plan for the difficult airway in patients with facial trauma. **To prevent the "can't intubate/can't oxygenate" failed airway, do not administer paralytics unless a patient can be bagged effectively or alternative airway devices or plans are in place.**

Awake intubation with sedation and local airway anesthesia may allow the emergency physician to quickly determine how difficult orotracheal intubation will be while preserving airway reflexes.[22] Etomidate and ketamine both provide sedation with preservation of respiratory drive. When oral endotracheal intubation appears more straightforward than expected on direct laryngoscopy, the endotracheal tube may be placed or paralytics administered followed by orotracheal intubation. When endotracheal intubation appears more difficult or impossible, primary cricothyrotomy or alternative airway management techniques may be performed (see chapters 22, "Basic Cardiopulmonary Resuscitation," 108, "Resuscitation of Neonates," and 109, "Resuscitation of Children").

The best approach to the difficult trauma airway involves planning ahead by having equipment ready for oral endotracheal intubation as well as the neck prepared and a cricothyrotomy kit ready. A laryngeal mask airway device may be a temporizing measure but does not protect the airway from aspiration of stomach contents and may not be possible with injuries involving the pharynx. Fiberoptic devices are an excellent option in the rare case when time, a lack of significant hemorrhage, and an experienced operator are present. Avoid nasal intubation to prevent worsening of injury, hemorrhage, or intracranial placement.[8]

HEMORRHAGE

Significant hemorrhage with severe midfacial or mandible injury can obstruct the airway and make attempts at intubation difficult. The blood supply to the face originates primarily from the sphenopalatine and greater palatine branches of the external carotid artery. Extensive anastomoses occur in the nasal cavity with the anterior and posterior ethmoidal branches of the internal carotid artery. Control posterior nasal epistaxis early with nasal tampon, dual balloon device, or traditional Foley catheter placement with anterior layered gauze packing. Be careful to avoid intracranial placement of nasal packing in severe midfacial fractures. After intubation, oral packing may be needed in a patient with significant mid- and lower facial bleeding. Reduction of significantly displaced nasal fractures and Le Fort injuries may be needed (although rarely) to stop arterial bleeding. Life-threatening hemorrhage can occur in up to 10% of patients with midface fractures.[23] With significant persistent bleeding, immediate operative intervention is required for ligation of injured vessels or better reduction of fractures. Arterial embolization may also be effective in controlling bleeding from branches of the external carotid artery but is associated with a small risk of stroke and other complications.[24] To date, there are no reports describing the use of tranexamic acid for control of massive bleeding from facial injury in the ED.

SPECIFIC FACIAL FRACTURES

FRONTAL BONE FRACTURES

Frontal bone fractures are uncommon injuries resulting from high-energy mechanisms such as unrestrained motor vehicle crashes or assaults with blunt objects. The significant amount of force needed to fracture the thick frontal bone likewise increases the immediate risk of traumatic brain injury, additional facial fractures, and cervical spine injury. Concomitant craniofacial injuries are present in 56% to 87% of patients with frontal sinus fractures.[25] Severe frontal fractures may extend to the temporal bones and require a hearing and facial nerve function evaluation. Otorrhea in this setting is a cerebrospinal fluid leak until proven otherwise.[26] Ocular injuries can occur in up to 25% of patients with frontal bone fractures. The most common finding is an afferent pupillary defect, occurring in about 10% of patients.[27]

Lacerations typically overlie frontal sinus fractures. Careful exploration is needed to identify all fractures. Crepitus is frequently palpable with any sinus fracture. In cases of suspected fracture, obtain a head CT to evaluate the anterior and posterior tables as well as the underlying intracranial structures (**Figures 259-7 and 259-8**).

Because the dura is adherent to the posterior table, operative repair of through-and-through frontal sinus fractures is necessary to prevent pneumocephalus, cerebrospinal fluid leak, and infection. Consider rhinorrhea in any patient with a frontal bone fracture to be a cerebrospinal

FIGURE 259-7. Forehead laceration overlying a frontal sinus fracture. [Reproduced with permission from Knoop K, Stack L, Storrow A, Thurman RJ: *Atlas of Emergency Medicine,* 3rd ed. © 2010, McGraw-Hill, New York.]

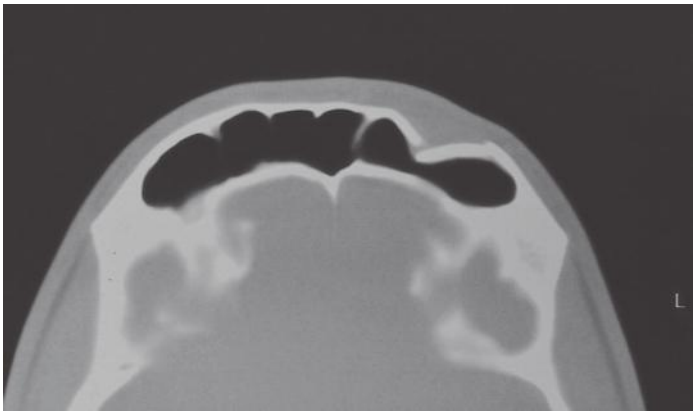

FIGURE 259-8. Frontal sinus fracture from patient in Figure 259-7. CT demonstrating fracture of the anterior table of the frontal sinus. [Reproduced with permission from Knoop K, Stack L, Storrow A, Thurman RJ: *Atlas of Emergency Medicine,* 3rd ed. © 2010, McGraw-Hill, New York.]

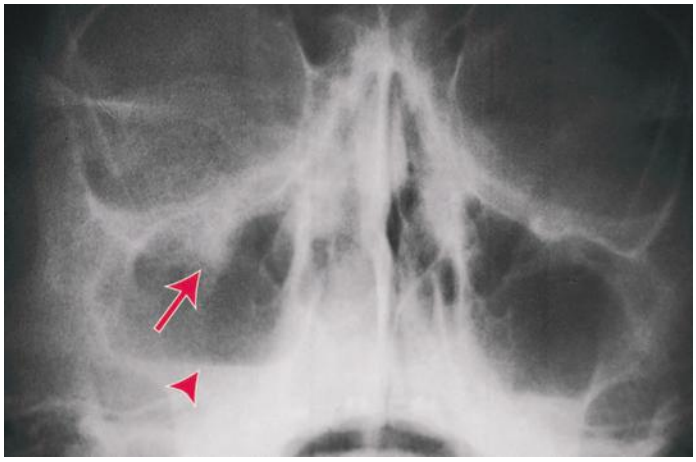

FIGURE 259-10. Blow-out fracture. Waters' view with teardrop sign (*arrow*) and fluid in right maxillary sinus (*arrowhead*). [Reproduced with permission from Knoop K, Stack L, Storrow A: *Atlas of Emergency Medicine,* 2nd ed. © 2002, McGraw-Hill, New York.]

fluid leak until proven otherwise.[26] Mucopyoceles, collections of pus that develop as a result from nasal ducts blocked by fracture, and cranial empyema can result. Oral antibiotics, such as first-generation cephalosporins or amoxicillin clavulanate, are recommended with any sinus fracture. The patient with an isolated anterior table fracture may be discharged with nasal and oral decongestants and appropriate follow-up with a facial surgeon (otolaryngologist, plastic surgeon, or ophthalmology). Admit patients with depressed fractures for IV antibiotics and operative repair.

ORBITAL FRACTURES

The orbit is traditionally thought of as a four-walled structure. It is made up of the frontal bone superiorly, the zygoma and sphenoid bones laterally, the zygoma and maxilla inferiorly, and the thin-walled lamina papyracea of the ethmoid bone medially. There are two categories of orbital fractures: pure, blow-out fractures and unpure, orbital fractures. The pure orbital blow-out fracture involves only the orbital walls and occurs when an object of small diameter strikes the globe without causing an orbital ridge or rim fracture. Force transmitted through the fluid-filled globe results in a fracture of the weaker inferior or medial orbital walls. Adipose tissue, the inferior rectus, or the inferior oblique can then herniate and become entrapped within the maxillary or ethmoid sinus (**Figure 259-9**). Lateral, inferior, and superior orbital ridge fractures typically occur with other facial fractures. **Significant force applied to the nasal bridge can result in naso-orbito-ethmoid fractures that are often accompanied by injury to the lacrimal duct, dural tears, and traumatic brain injury.**

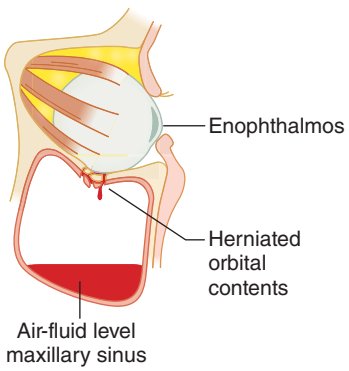

FIGURE 259-9. Blow-out fracture findings, including fluid in the maxillary sinus, herniated fat or muscle, and delayed enophthalmos, occur with orbital floor fracture. [Reproduced with permission from Scaletta TA, Schaider JJ: *Emergency Management of Trauma,* 2nd ed. © 2001, McGraw-Hill, Inc., New York.]

Several key physical examination findings suggest orbital fracture. Enophthalmos occurs with herniation of globe contents before significant edema. Carefully palpate the entire orbital rim to detect any step-off deformity or crepitus. Infraorbital anesthesia often occurs with fracture of the orbital floor. Diplopia on upward gaze occurs with entrapment of the inferior rectus, inferior oblique, or orbital fat, or from injury of muscles or the oculomotor nerve. Naso-orbito-ethmoid fractures result in pain on eye movement, traumatic telecanthus, epiphora (tears spilling over the lower lid), and cerebrospinal fluid leak.[28]

Radiographic findings consistent with orbital fracture are seen in **Figure 259-10**. Additional findings include air-fluid levels or opacification of the maxillary sinus. Obtain a facial or orbital CT with axial and coronal sections to plan surgical management in patients with positive findings on a Waters' view or as the initial study in patients with significant clinical findings (**Figure 259-11**).

The patient with an isolated orbital fracture requires treatment with oral amoxicillin-clavulanate to treat sinus pathogens, decongestants, and instructions to avoid nose blowing until the defect has been repaired. Specialty consultation before discharge is important because controversy continues regarding the best time and indications for operative repair. Repair may be delayed 1 to 2 weeks in adults, whereas children require a shorter time for follow-up and repair. Naso-orbito-ethmoid fractures require admission for specialty consultation with facial surgery and neurosurgery.

Emergent ophthalmology consultation is required for associated ocular injury. **Retrobulbar hematoma or malignant orbital emphysema may create an ocular compartment syndrome, resulting in an acute ischemic optic neuropathy (Figure 259-12).** Physical examination findings include exophthalmos, decreasing visual acuity, and increased intraocular pressure. Emergency lateral canthotomy reduces ocular pressure and ischemia. Orbital fissure syndrome results from a fracture of the orbit involving the superior orbital fissure with injury to the oculomotor and ophthalmic divisions of the trigeminal nerve. Physical examination findings include paralysis of extraocular motions, ptosis, and periorbital anesthesia. Orbital apex syndrome occurs when the optic nerve is also involved, resulting in the preceding physical examination findings and diminished visual acuity.

ZYGOMA FRACTURES

The prominent location of the zygoma results in frequent fractures. Zygomatic arch fractures occur when an anterior and lateral force is applied typically from a fist or blunt object. **The less common zygomaticomaxillary (or "tripod") fracture results classically from a**

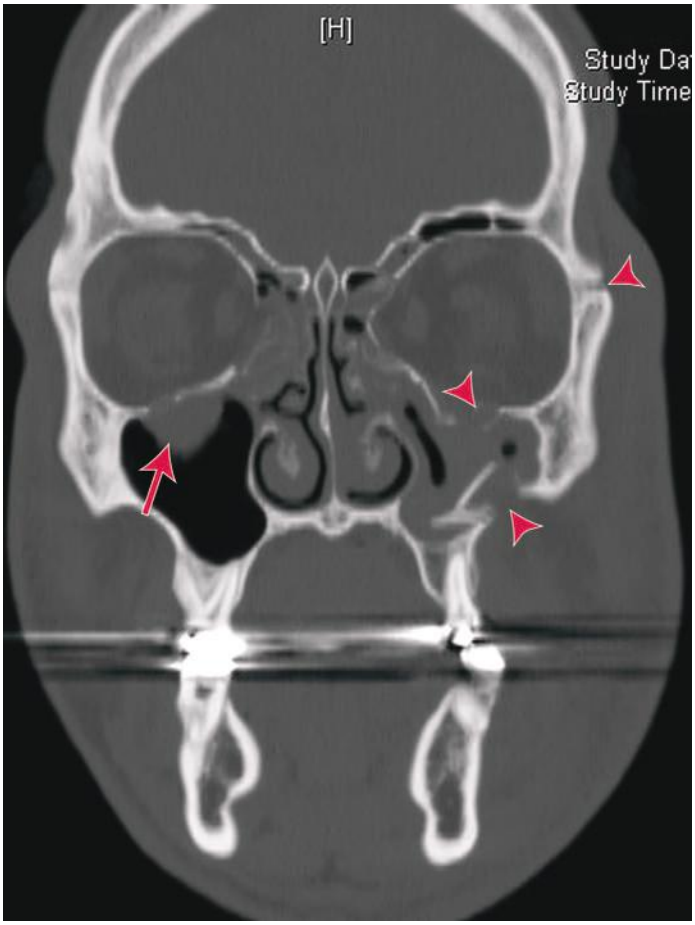

FIGURE 259-11. Left zygomatic maxillary complex and right blow-out fractures. Disruption of zygomatic frontal suture and maxillary sinus on left (*arrowheads*) with herniation of orbital contents into maxillary sinus on the right (*arrow*) on face CT coronal section.

FIGURE 259-12. Retrobulbar hematoma. CT of patient in Figure 259-2 demonstrates right retrobulbar hematoma. [Reproduced with permission from Knoop K, Stack L, Storrow A, Thurman RJ: *Atlas of Emergency Medicine, 3rd ed.* © 2010, McGraw-Hill, New York.]

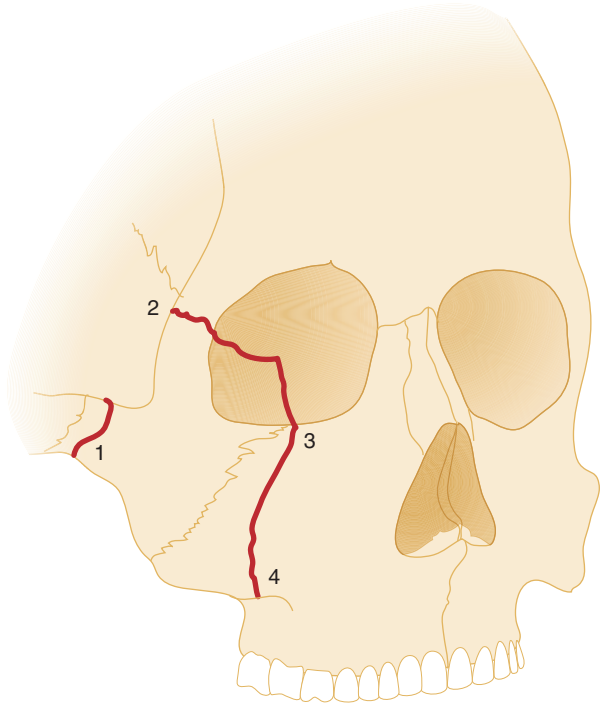

FIGURE 259-13. Tripod fracture locations. Zygomatic arch fracture (*1*), lateral orbital rim fracture (*2*), inferior orbital rim fracture (*3*), and lateral wall of maxillary sinus fracture (*4*). high-energy deceleration injury with disruption of the zygomaticofrontal suture, zygomaticotemporal junction, and infraorbital rim (Figures 259-13 and **259-14).** Because the zygoma forms the inferior and lateral walls of the orbit and superior and lateral roof of the maxillary sinus, zygomaticomaxillary fractures are considered orbital and sinus fractures.

On physical examination, flattening of the malar eminence will be noted in the absence of often significant swelling (Figure 259-1). The eye may appear to tilt as the lateral canthus is pulled inferiorly, often with a large lateral subconjunctival hemorrhage. Trismus results from masseter spasm or mechanical impingement of either the temporalis muscle or coronoid process of the mandible. Place a finger adjacent to the maxillary molars and palpate the posterior surface of the arch for tenderness or loss of the space compared to the uninjured side. Diplopia, infraorbital anesthesia, and crepitus occur with significant orbital and sinus involvement. Facial CT is needed to define the extent of the injury.

Patients with isolated temporal arch fractures can be discharged with appropriate medications and follow-up. Patients with zygomaticomaxillary fractures with any loss of vision or significant displacement require admission for IV antibiotics and operative repair.

MIDFACIAL FRACTURES

Midfacial fractures can be caused by motor vehicle crashes, sports, assault, and falls due to seizures or intoxication or in the elderly. The incidence of midfacial fractures in motor vehicle crashes has declined significantly due to improvements in vehicle restraint systems.[29] Fractures of the maxilla require a significant force such as an unrestrained motor vehicle crash patient whose face strikes the dashboard or the severely battered patient.

Le Fort injuries often present dramatically, with significant hemorrhage, early swelling, bilateral orbital ecchymosis, and cerebrospinal fluid leaks in Le Fort II and III injuries. Each pattern results in a unique movement of the midface while gently rocking the hard palate with one hand and stabilizing the forehead with the other hand (**Figure 259-15**).

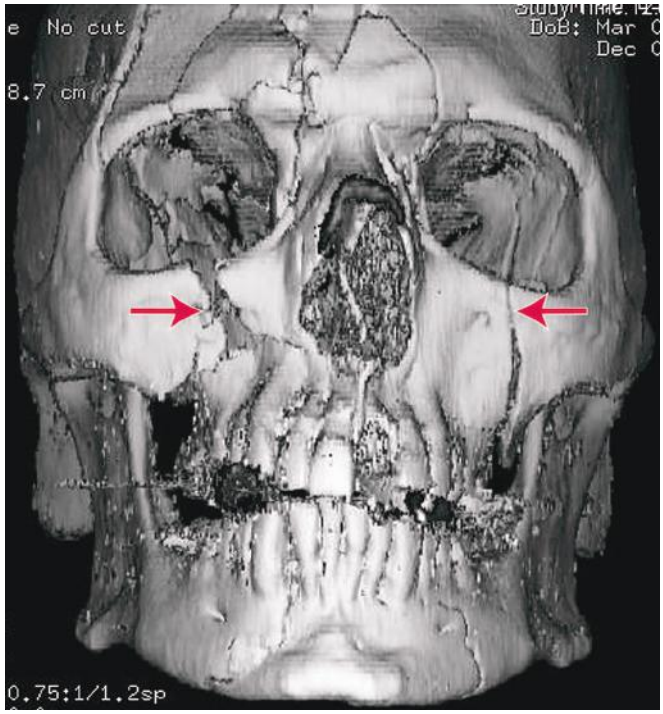

FIGURE 259-16. Bilateral Le Fort II fractures. Face CT with three-dimensional reconstructions demonstrating bilateral Le Fort II in a panfacial fracture patient (*arrows*).

Le Fort I is a transverse fracture separating the body of the maxilla from the pterygoid plate and nasal septum. Only the hard palate and teeth move, similar to a loose upper denture. **Le Fort II** is a pyramidal fracture through the central maxilla and hard palate. Movement of the hard palate and nose occurs, but not the eyes (**Figure 259-16**). **Le Fort III** is craniofacial dysjunction when the entire face is separated from the skull from fractures of the frontozygomatic suture line, across the orbit and through the base of the nose and ethmoids. The entire face shifts with the globes held in place only by the optic nerve. A **Le Fort IV** fracture includes characteristics of the Le Fort III and also involves the frontal bone. CT scan of the face with coronal and axial slices with three-dimensional reconstructions best defines these complex injuries.

Patients with Le Fort injuries often present with significant hemorrhage, requiring airway protection and nasal packing. Oral packing is often required for control of fractures involving the hard palate. Le Fort injuries require admission for management of significant associated injuries, IV antibiotics, and surgical repair.

MANDIBLE FRACTURES

Mandible fractures are the second most common facial fracture after nasal fractures. Assaults, motor vehicle crashes, and falls are the most commonly reported mechanisms.[30] One large trauma center reported 36% of fractures in the region of the angle, followed by 21% in body, and 17% in the parasymphyseal region.[31] Always look for multiple mandibular fractures with one injury at the site of impact and a second subtle injury on the opposite side of the ring. In fact, a mandibular fracture should be considered bilateral until proven otherwise. Comminuted mandible fractures could result in upper airway obstruction due to the tongue being unsupported anteriorly. Presume an open fracture until a thorough intraoral examination determines otherwise. Fractures are classified as either favorable or unfavorable, depending on whether the musculature reduces or opens the fracture.

Patients with mandible fractures usually complain of malocclusion with pain worsened by attempted movement. On inspection, the mandible may appear widened or displaced to one side. Patients may present with trismus due to pain and swelling. Palpation reveals loss of the smooth counters of the mandible, tenderness, and anesthesia in the

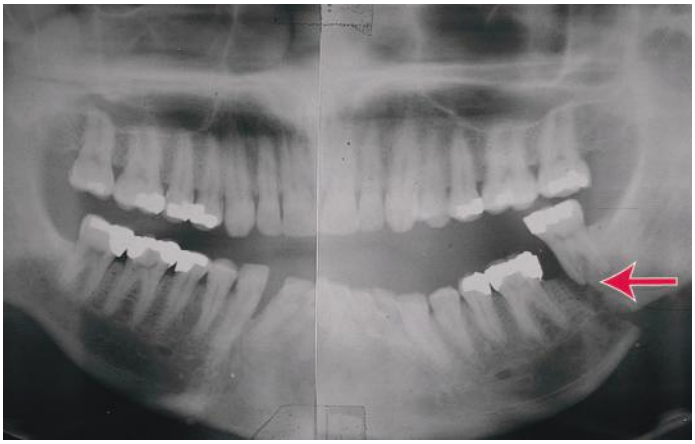

FIGURE 259-17. Mandible fracture. Panoramic view demonstrating an unfavorable mandibular fracture with obvious misalignment (*arrow*) due to the distracting forces of the masseter muscle. distribution of the proximal inferior alveolar or distal mental nerve. **A careful intraoral examination is important to exclude small breaks in the mucosa seen with open fractures, sublingual hematoma or ecchymosis, and dental or alveolar ridge fractures and to identify missing teeth.** Examine the ears for evidence of tympanic membrane perforation, hematotympanum, or evidence of condyle displacement. Place a finger into the external auditory canal and ask the patient to open and close the mouth to palpate for injury to the condyle.

Panorex remains the initial imaging study in patients with a low clinical suspicion of injury (**Figure 259-17**). Order mandible or face CT with coronal and axial sections in patients suspected of having condyle fractures, complex fractures, or multiple facial fractures (**Figure 259-18**). A chest radiograph is necessary in the unconscious patient with missing teeth to exclude aspiration of the missing teeth.

In the patient with a stable airway, placement of a Barton's bandage, an ace wrap over the top of the head and underneath the mandible, will stabilize the fracture and help relieve pain. Administer pain control and antibiotics, such as penicillin G 2 to 4 million units IV (or clindamycin, 600 to 900 milligrams, in penicillin-allergic patients), for open fractures. Although studies question the utility of antibiotics, given the overwhelming number of potentially virulent oral anaerobes contaminating open mandible fractures, antibiotics remain a logical therapeutic agent.[32,33] Patients with closed fractures may be given urgent outpatient follow-up. Open fractures require admission for operative repair.

PEDIATRIC CONSIDERATIONS

Facial fractures in the pediatric population are typically due to falls, bicycle accidents, pedestrian accidents, and transport accidents. The nasal bones and mandible are most commonly fractured.[34] Several unique considerations must be made in the initial management of the pediatric patient with facial trauma. Cricothyrotomy is contraindicated in patients <8 years old because the cricothyroid membrane is not developed until age 8 and should be avoided in those between 9 and 12 years of age. In children with severe midfacial injury in whom oral endotracheal intubation is not possible, laryngeal mask airway placement or needle cricothyrotomy serves as a temporizing measure pending emergency tracheostomy. Facial trauma in children should always prompt the consideration of child abuse.

Skull development predisposes children to certain facial and associated injuries while making others less likely. The child's high center of gravity, relatively poor balance, explorative nature, and prominent forehead make the child more susceptible to frontal bone impact and underlying brain injury. Cervical spine injury in children occurs at higher levels and more often without bony radiographic injury (spinal cord injury without radiologic abnormality). The maxillary sinuses do not

begin developing until age 6 years old, which reduces the incidence of midfacial fractures compared with adults.

The pliable pediatric orbital floor is more likely to bend and crack, forming a small "trapdoor" through which muscle and fat become entrapped and potentially ischemic.[35] Pediatric mandible fractures are more likely to be incomplete fractures and more irregular secondary to the underlying developing teeth.[36] Rapid bone remodeling in children with callous formation begins within 1 week and makes delayed reduction difficult. Children with mandible fractures require prompt diagnosis and 1- to 2-day referral to a pediatric facial surgeon to prevent long-term problems with asymmetrical facial growth, cosmetic deformities, and difficulty with mastication.[37]

CHAPTER 260

Trauma to the Neck

Ashley S. Bean

INTRODUCTION

The human neck contains numerous vital structures. Both blunt and penetrating injuries can damage structures from many organ systems. The challenge is to treat immediate, life-threatening complications of neck injury, such as airway compromise and hemorrhage, and also to recognize subtle signs of serious pathology.

ANATOMY

The neck is anatomically defined by triangles, zones, and fascial planes. Each sternocleidomastoid muscle separates the neck into two descriptive triangles, anterior and posterior (**Figure 260-1**). The posterior triangle is bordered by the anterior surface of the trapezius, posterior surface of the sternocleidomastoid muscle, and the middle third of the clavicle. The anterior triangle is formed by the borders of the sternocleidomastoid muscle, inferior mandible, and midline of the neck. Most vital structures are contained within the anterior triangle.

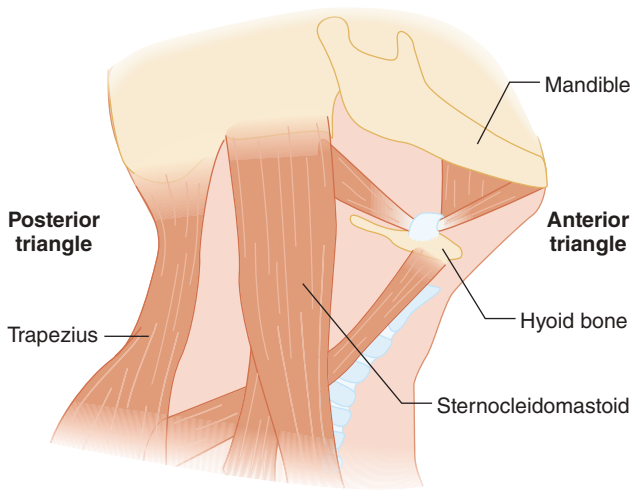

FIGURE 260-1. Triangles of the neck.

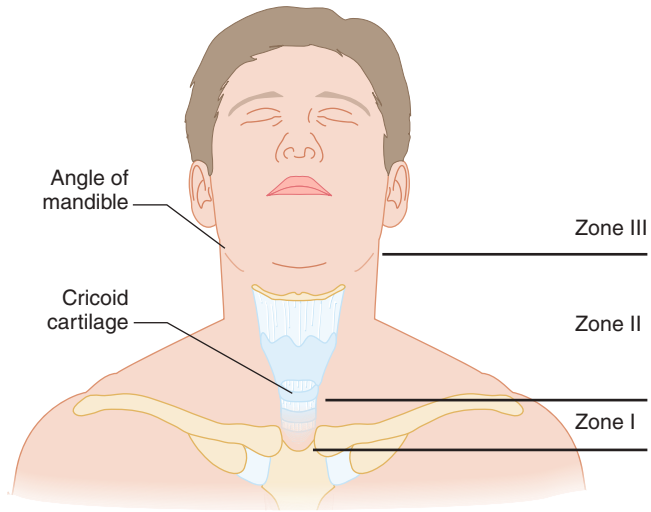

FIGURE 260-2. Zones of the neck.

The anterior triangle is further subdivided into three horizontal zones (**Figure 260-2**), which have historically determined whether a patient undergoes mandatory surgical exploration or further diagnostic evaluation.[1] Using this classification system, the index of suspicion for injury to a particular structure is dictated by the zone (**Table 260-1**). **Classically, zone II injuries undergo surgical exploration; zone I and III wounds undergo further evaluation.** This zone-based approach assumes a direct correlation between the site of the external wound and damage to deep structures; however, the trajectory of the penetrating object can be difficult to determine clinically, and nearly half traverse multiple zones.[2-4]

Finally, the neck is divided into fascial planes (**Figure 260-3**). The platysma is a thin muscle that stretches from the facial muscles to the thorax, demarcating superficial from deep wounds. **Wounds that do not penetrate the platysma are not life threatening.** The platysma muscle is enclosed within superficial fascia anteriorly and deep fascia posteriorly. The deep fascia is comprised of the investing, pretracheal, and prevertebral fascia and the carotid sheath.[5] These fascial layers compartmentalize neck structures and, thus, can prevent exsanguination by confining hematomas. Conversely, increased pressure from expanding hematoma or edema can compromise the airway. Further,

TABLE 260-1 Anatomic Zone and Structures of the Anterior Neck

Neck Zone	Anatomic Boundaries	Structures
Zone 1	Clavicles to the cricoid cartilage	Proximal carotid vertebral arteries Major thoracic vessels Superior mediastinum Lungs Esophagus Trachea Thoracic duct Spinal cord
Zone 2	Cricoid cartilage to the angle of the mandible	Carotid and vertebral arteries Jugular veins Esophagus Trachea Larynx Spinal cord
Zone 3	Angle of the mandible and the base of the skull	Distal carotid and vertebral arteries Pharynx Spinal cord

the layers can serve as a conduit for infection tracking from the neck into the mediastinum.[6]

INITIAL MANAGEMENT OF NECK INJURIES

The initial management of neck trauma follows the Advanced Trauma Life Support Guidelines with the systematic Airway, Breathing, Circulation, and Disability approach. Perform a primary survey to identify and treat immediate life-threatening injuries, followed by a secondary survey to discover further injuries.[7]

AIRWAY

Many patients with neck trauma have signs and symptoms of airway compromise.[8] Patients with shock, airway obstruction, impending airway collapse, or altered mental status require immediate airway control (**Table 260-2**). Although there is disagreement about the timing of definitive airway management in less emergent patients, airway anatomic distortion can progress rapidly. Promptly intubate any patient at risk for airway compromise (**Table 260-3**).[9] **Assume a difficult airway in a patient with neck trauma.** Keep all your adjuncts to intubation, as well as a secondary means of securing the airway, readily available.

Rapid-sequence orotracheal intubation is the preferred modality for securing the airway in patients with neck trauma and is successful in 98% of patients.[10,11] When bag-mask ventilation proves difficult due to airway distortion or physical characteristics, perform an awake, orotracheal intubation using a sedative without a paralytic. Anticipate difficulty with bag-mask ventilation in patients with facial hair precluding a seal; unstable mid-facial fractures; airway obstruction from blood, vomitus, or expanding hematoma; subcutaneous emphysema; or an open laryngeal injury that allows external passage of air.[6]

Video laryngoscope–guided intubation[12] and endotracheal intubation over a fiberoptic bronchoscope are useful techniques to secure the airway.[10,13,14]

The laryngeal mask airway is a bridging device but is contraindicated in patients with significant airway distortion. Even if effective, the laryngeal mask airway is only a temporary method for ventilating trauma patients, not a definitive airway.[7]

A surgical cricothyrotomy, or needle-cricothyrotomy if the patient is younger than 8 years of age, is generally the last step in the failed airway management. Patients with neck trauma are at increased risked for requiring a surgical cricothyrotomy due to disruption of the laryngotracheal anatomy.[13] Although there are no absolute contraindications to cricothyrotomy, relative contraindications include suspected or known tracheal transection, fractured larynx, or laryngotracheal disruption with retraction of the distal segment into the mediastinum. Tracheal transection can occur in patients with a "clothesline injury." In such patients, pharmacologic paralysis may cause loss of muscle tone with disruption of the proximal and distal tracheal segments.[6] If the patient has an open laryngeal disruption, you can perform direct intubation through the wound into the distal segment.[11] If other airway techniques are unsuccessful, however, tracheostomy is indicated.[10]

BREATHING

Pneumothorax and hemothorax are present in up to 20% of patients with penetrating neck trauma.[15] Auscultate for the presence or absence of breath sounds during the primary survey. Suspect tension pneumothorax

in patients with unilateral breath sounds, hypotension, and respiratory distress, and treat with needle decompression and/or placement of a thoracostomy tube.[6] Provide continuous pulse oximetry monitoring and supplemental oxygen.

CIRCULATION

Exsanguination is the proximate cause of death in most penetrating neck injury victims,[8] and massive bleeding from trauma kills more rapidly than an unstable airway. Control hemorrhage by applying direct pressure to bleeding wounds. Be careful not to simultaneously occlude both carotid arteries or obstruct the patient's airway. Do not blindly clamp vessels in the ED because this practice can lead to cerebral ischemia or nerve injury.[6] If life-threatening hemorrhage is not controlled by simple pressure, you can insert a Foley catheter into the wound tract and inflate the balloon until bleeding stops or you encounter resistance.[16] Animal model and anecdotal tactical medicine experience suggests that topical hemostatic static agents may improve the survival of patients with bleeding not controlled by pressure. Although the ideal hemostatic agent has not been identified, hemostatic dressings combined with direct pressure appear to decrease blood loss and increase patient survival.[17] Hemostatic dressings may benefit patients with uncontrolled bleeding who need transfer to another hospital for definitive care. Patients with uncontrolled hemorrhage despite these attempts require immediate surgery.[18] If subclavian vessels are involved, uncontrolled hemorrhage in zone I injuries may require emergent thoracotomy.[19]

DISABILITY

Unstable cervical spine injury is uncommon in awake, neurologically intact patients with an **isolated penetrating neck injury**.[20] Vertebral fractures and spinal cord injury are exceedingly rare in patients with isolated stab wounds to the neck.[21] Therefore, cervical collar placement may, in fact, be detrimental by obscuring the injury and increasing the difficulty of hemorrhage control and intubation.[20] Cervical collars should not be maintained at the expense of monitoring the injury or life-saving procedures.

Spinal cord damage is more likely from gunshot wounds, and cord damage is sustained at the time of injury. Deficits, which are usually permanent, should be evident at time of presentation unless the patient has an altered sensorium. Place a cervical collar on patients with a neurologic deficit or altered mental status precluding exam, after checking the neck to identify any penetrating injuries, vascular thrills or bruits, or bleeding or hematoma.[22,23]

However, patients with blunt neck trauma frequently have cervical spine fractures, so maintain cervical spine immobilization in such injuries.[24]

INITIAL RADIOLOGIC EVALUATION

Although conventional radiographs of the chest and neck may suggest a variety of pathologies in the patient with neck trauma (**Table 260-4**),[7,18,25,26] most patients with penetrating or blunt neck trauma will require advanced imaging in the form of multidetector CT angiography (MDCTA), MRI, or magnetic resonance angiography. Obtain a chest radiograph to evaluate for pneumothorax and hemothorax in patients with neck trauma because there is a high incidence of these thoracic complications. In addition, pneumothorax and hemothorax can be detected rapidly by bedside ultrasound.[27] Do not delay transfer of patients between hospitals or to the operating room to obtain conventional radiographs of the neck.

DIAGNOSIS AND TREATMENT

Any wound deep to the platysma raises concern for damage to the vital structures of the neck. Simple diagnostic maneuvers add valuable information to the physical exam. Instruct awake and cooperative patients to cough (to check for hemoptysis), to swallow saliva (to assess for dysphagia from esophageal injury), and to speak (to evaluate for laryngeal fracture).[6] **In patients with penetrating neck trauma, a careful, structured physical exam is more than 95% sensitive for detecting clinically significant vascular and aerodigestive injuries.**[23] The physical exam is most accurate for identifying arterial injuries; conversely, esophageal and venous injuries may be missed. Assess the patient for "hard" and "soft" signs of injury (**Table 260-5**).[15,28] **Nine out of 10 patients with hard signs will have an injury requiring repair and should be rapidly transferred to the operating room or angiography suite.** If your institution does not have the requisite surgical or diagnostic capabilities readily available, transfer to an appropriate hospital. Presence of soft signs increases suspicion of structural damage and indicates the need for additional diagnostic evaluation; however, only a minority of patients with soft signs will have a clinically significant injury.[15,29-31]

PENETRATING NECK INJURY

Although penetrating neck wounds account for only 1% of traumatic injuries, the mortality rate is as high as 10%.[8] Gunshot wounds and stab wounds are the predominant mechanisms of injury, whereas flying debris and sharp object impalement are less frequent causes.[8,18,32] Patients often have significant concurrent wounds to the head, chest, or abdomen.[8,18,28,32]

Gunshot wounds are more likely than stab wounds to cause vascular and aerodigestive system damage. Transcervical gunshot wounds have at least a 70% chance of substantial associated injuries.[28,33] **Vascular injuries are the most common cervical injury and the leading cause of death from penetrating neck trauma.**[18] The remainder of associated neck injuries are split among spinal cord, aerodigestive tract, and peripheral nerve injuries.[15,28,32]

There is no debate regarding the treatment of unstable patients with clear evidence of vascular or aerodigestive injury—this group of patients should undergo invasive intervention.[2,8,29,32] Controversy arises in two areas concerning the management of stable patients:

1. Should all zone II injuries undergo mandatory exploration?
2. Should all zone I and III injuries undergo a specific, extensive battery of diagnostic testing?

GENERAL TREATMENT OPTIONS

Mandatory Operative Exploration Historically, all zone II injuries were surgically explored. This aggressive practice began during World War II as a response to a high incidence of missed injuries and mortality, but selective management is generally recommended today to minimize unnecessary surgery.[34] Zone II is the most commonly injured area and is easily accessed surgically.[29,32] Exposure and vascular control are more difficult for zone I and III injures, so most patients with zone I and III injuries undergo angiography and endoscopy to determine the need for operative intervention.[35]

Selective Management The movement toward selective management rather than mandatory exploration began in response to the high rate of negative neck explorations. Furthermore, advocates of a more conservative methodology cite the sensitivity of physical exam in detecting clinically significant injuries. Contrarians maintain concerns about missed lethal injuries when relying solely on the clinical exam.[36,37] Less invasive, selective protocols, which mandate rapidly obtained angiography, esophagography, and panendoscopy, have radically decreased nontherapeutic neck operations without increasing morbidity and mortality; however, the yield of angiography and endoscopic studies in asymptomatic patients is exceedingly low.[8,15,38]

No-Zone Targeted Diagnostic Workup A new iteration in selective management has evolved with the addition of information gleaned from MDCTA to the diagnostic process. MDCTA now permits fast, reliable information about injuries in all neck zones. Furthermore, physical examination plus MDCTA is up to 100% sensitive and 97.5% specific for detecting significant vascular or aerodigestive injury. Perhaps more importantly, the negative predictive value for arterial injury is 98% to 100%.[39,40] Unlike angiography, MDCTA also allows assessment of the aerodigestive tracts and the cervical spine.[5]

In addition to defining specific injuries, MDCTA can determine if the wound track approximates important structures. Wounds with a trajectory not concerning for injury do not need further invasive (angiographic or endoscopic) workup. Conversely, trajectories in close proximity to vital structures should prompt a targeted diagnostic workup.[4] Disadvantages of MDCTA include exposure to ionizing radiation, use of iodinated IV contrast, and image artifacts due to motion or metallic foreign bodies.[41] Furthermore, patients cannot undergo angiography, either for diagnosis or intervention, directly after MDCTA due to iodinated contrast exposure.[3]

A penetrating neck trauma protocol (**Figure 260-4**) that combines a -structured physical exam and MDCTA dramatically reduces formal neck explorations.[2,42] In this scheme, the zone of injury has little impact on the management of the patient because the neck is considered to be a single unit. Per this protocol (see Figure 260-4), symptomatic patients with hard signs of neck injury undergo emergent operative or angiographic intervention. Symptomatic patients with only soft signs of injury are at intermediate risk and should undergo MDCTA. Further diagnostic testing can be guided by MDCTA findings. Symptomatic patients with an indeterminate MDCTA artifact should undergo traditional testing.[2,6,18,43]

Although patients who are asymptomatic are at low risk for injury, it is unclear what their diagnostic algorithm should entail. Options include observation and/or targeted diagnostic testing including MDCTA. Specific concern for digestive tract injuries can be addressed via esophagoscopy or esophagram; potential laryngotracheal injuries can be evaluated with endoscopy. Trauma centers with a high volume of penetrating neck injuries may opt to observe patients with serial physical exams in lieu of advanced diagnostic testing. Hospitals that infrequently manage penetrating neck injuries may be more likely to order adjunctive screening testing.[29,44]

PENETRATING VASCULAR INJURIES

Vascular injuries are present in up to 40% of patients with penetrating neck trauma and are the most commonly associated cervical injury in this population. Arterial injuries, which predominately involve the carotid artery, account for 45% of penetrating neck vascular trauma and are the most frequent cause of death.[8,15,19,32] The morbidity and mortality of vascular injuries are related both to exsanguination and neurologic complications.[5] For instance, **carotid artery injury** leads to stroke in 15% of patients and death in up to 22%. **Venous injuries** are discovered in up to 20% of patients with penetrating neck wounds.[32] Signs of venous injury are often subtle and difficult to identify by physical exam; however, most asymptomatic venous injuries do not require repair.[30]

The overwhelming majority of patients with hard signs of vascular injury (Table 260-5) will require operative intervention. In contrast, while up to one quarter of patients with soft signs of vascular injury will have a vascular abnormality identified at angiography, only 3% of these patients will require vascular repair.[15]

Diagnosis Several imaging modalities are useful during the evaluation of vascular neck trauma (**Table 260-6**). Although angiography remains the gold standard for investigating penetrating neck vascular injuries, **MDCTA is now the first-line imaging modality**.[5] Angiography continues to be useful, however, in specific circumstances. MDCTA findings that are inconclusive or incongruent with the patient's clinical exam should be refined by angiography.[45] In addition, stable patients with injuries suitable for endovascular repair may undergo definitive angiographic intervention.[5]

Disadvantages of **angiography** include its inability to provide a comprehensive evaluation of nonvascular neck structures, limited availability, and mobilization of additional personnel.[3] Potential complications include contrast-induced nephropathy, puncture site hematoma, thrombosis, embolism, vascular spasm, ischemia, and arterial dissection.[32]

The advent of CT angiography and improvements in multidetector CT technology have revolutionized the diagnosis and treatment of penetrating neck injuries. MDCTA images the vascular, aerodigestive, and osseous structures of the neck. Furthermore, MDCTA is sensitive for the detection of injury, can be rapidly performed, and is noninvasive, accurate, and widely available.[3]

Color flow Doppler US is highly sensitive for detecting clinically important vascular injuries. Advantages of US include its portability, noninvasive nature, lack of ionizing radiation, and relatively decreased capital expense. Disadvantages include the inability to scan through subcutaneous emphysema, hematoma, marked operator variability, and limited availability. Additionally, US cannot penetrate bone and is thus unable to image intrathoracic or intracranial vessels.[3,26] Finally, it cannot evaluate the aerodigestive structures of the neck.[3]

MRI or MRI angiography in patients with metallic projectiles is contraindicated due to concern for ferromagnetic material.[5] Furthermore, the role of MRI in the diagnosis of aerodigestive injuries has not been evaluated. Thus, MRI cannot be used to comprehensively evaluate neck structures.[3] MRI may play a select role in the evaluation of nonprojectile penetrating trauma, which involves the cervical spine.[46]

Treatment Treatment of vascular injuries depends on the vessel involved and accessibility of the lesion. Options vary from observation to surgical repair to angiographic embolization or stenting. Patients with

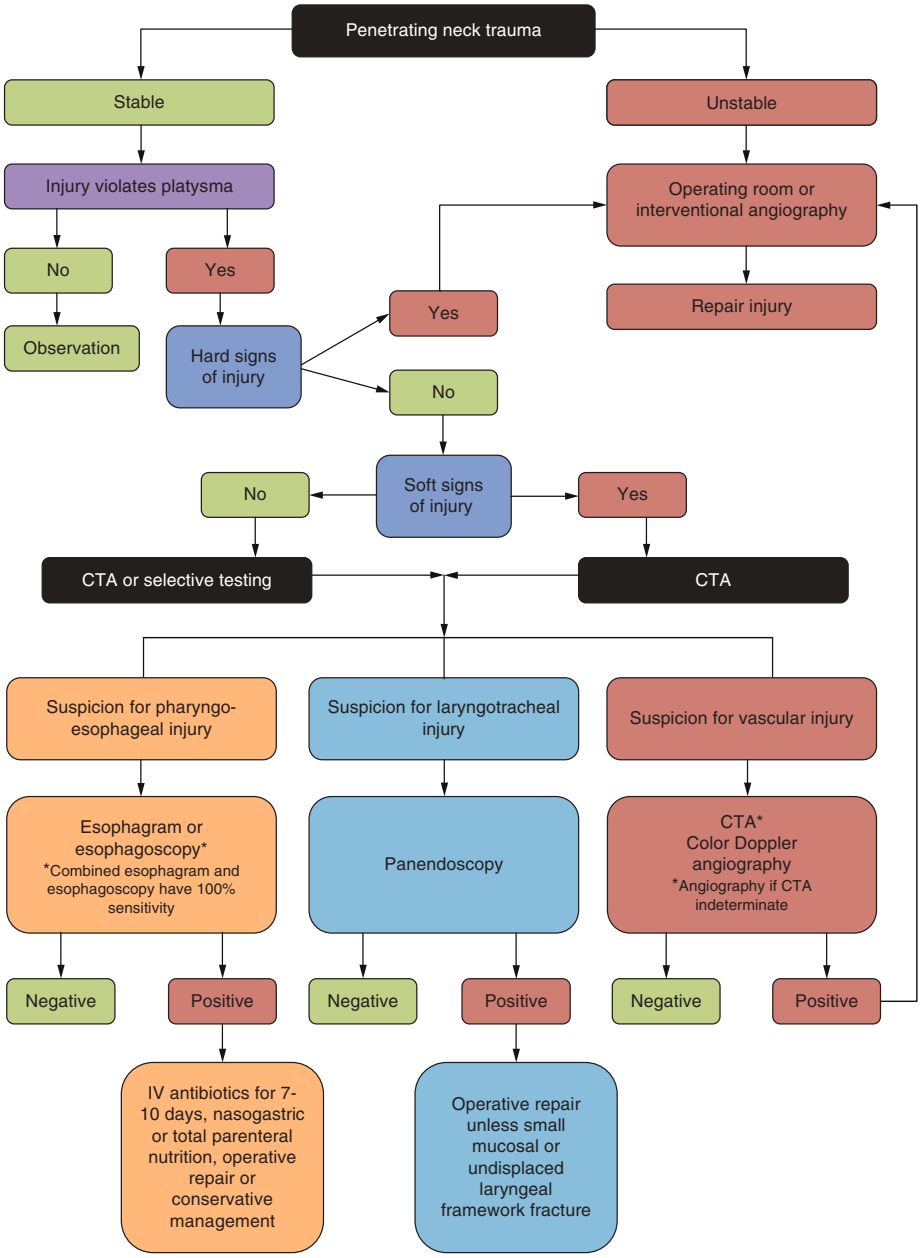

FIGURE 260-4. Penetrating neck trauma protocol.

carotid artery injuries that are asymptomatic, low-velocity injuries, or small intimal tears or pseudoaneurysms may not need repair if they have intact distal circulation and reliable surgical follow-up.[6]

BLUNT NECK INJURY

Blunt neck trauma comprises only 5% of traumatic injuries to the neck. Road traffic accidents are the most common cause of blunt neck trauma. Other causes of blunt neck injury include assault, pedestrians struck by vehicles, falls, and hanging.[47] While vascular injury occurs in approximately 1% of patients with blunt neck trauma,[48] cervical aerodigestive injuries are rare. As with penetrating neck trauma, patients with blunt neck injury frequently have significant associated injuries.[49] In contrast, airway occlusion rather than hemorrhage is the most rapidly fatal injury.[6]

BLUNT CAROTID AND VERTEBRAL DISSECTION

The mortality rate of symptomatic blunt cerebral vascular injury approaches 60%.[48] However, most patients with blunt cerebral vascular injury are initially asymptomatic and do not develop neurologic symptoms for hours to days.[49] Fortunately, angiographic screening of certain asymptomatic patients for blunt cerebral vascular injury can increase the likelihood of diagnosis 10-fold.[48] Moreover, early identification and treatment of blunt cerebral vascular injury significantly reduce the rate of stroke and death.[49] Numerous screening criteria can be used to increase blunt cerebral vascular injury detection in asymptomatic patients (**Table 260-7**).[24,50,51] Unfortunately, 20% of blunt cerebral vascular injuries occur without any established risk factor.[52]

The mechanism of injury for blunt cerebral vascular injury is cervical hyperextension and rotation or hyperextension during rapid deceleration, which can result in intimal dissections, thromboses, pseudoaneurysms, fistulas, and transections.[52] Intimal tears expose subendothelial collagen that acts as a substrate for platelet aggregation. The subsequent thrombus can embolize, cause stenosis, or create critical vessel occlusions. Furthermore, tears can provide a pathway for dissection.[53]

Diagnosis Diagnostic four-vessel cerebral angiography is the gold standard for the diagnosis of blunt cerebral vascular injury.[51] Unfortunately, MDCTA has a low sensitivity for the detection of blunt cerebral vascular injury. Even when scanners with 16 or more slices are used and the images are interpreted by a neuroradiologist, sensitivity of MDCTA

TABLE 260-6 Vascular Evaluation of Penetrating Neck Trauma

Imaging Modality	Advantages	Disadvantages
Catheter angiography	Gold standard Both diagnostic and therapeutic Access to zone I and III injuries where surgical repair is difficult	Invasive Expensive Labor intensive Requires skilled operators
Helical CT angiography	Readily available Fast Minimally invasive Visualization of missile trajectory High-resolution images of vascular, aerodigestive, and bone structures with single study	Only diagnostic, not therapeutic Requires IV contrast Image quality affected by technique of contrast injection Metallic streak artifact may obscure findings Limited evaluation of low zone I and high zone III injuries May miss small intimal flaps, pseudoaneurysms, and arteriovenous fistulas
Duplex ultrasonography	Noninvasive Inexpensive No contrast medium	Highly operator dependent Limited view of zones I and III Obscured by subcutaneous emphysema and hematomas May miss small lesions

remains less than 80%. However, because MDCTA has excellent specificity (97%), patients with blunt cerebral vascular injury identified by MDCTA do not require confirmatory angiographic evaluations.[54]

US has a low sensitivity for blunt cerebral vascular injury and should not be used as a screening test.[51]

Although MRI has been gaining acceptance in the evaluation of blunt cerebral vascular injury, the sensitivity and specificity of this imaging modality are lower than those of diagnostic four-vessel cerebral angiography. Therefore, do not use MRI as the sole screening study for blunt cerebral vascular injury.[51]

Treatment Antithrombotic agents (aspirin, clopidogrel, or heparin) and operative or interventional angiographic repair are blunt cerebral vascular injury treatment options. Specific therapy is determined by a grading scale (**Table 260-8**).[51,55]

TABLE 260-7 Compiled Screening Criteria for Blunt Cerebral Vascular Injury

- Signs and symptoms
  - Arterial hemorrhage from nose, neck, or mouth
  - Cervical bruit in patients <50 y old
  - Expanding cervical hematoma
  - Focal neurologic deficit: transient ischemic attack, hemiparesis, vertebrobasilar symptoms, Horner's syndrome
  - Stroke on secondary CT
  - Neurologic deficit unexplained by head CT
- Risk factors for blunt cerebral vascular injury
  - High-energy transfer mechanism and one of the following:
    - Facial fractures: Le Fort II or III fracture, mandible fracture, frontal skull fracture, orbital fracture
    - Cervical spine fracture patterns: subluxation, fractures extending into the transverse foramen, fractures of C1–C3
    - Any basilar skull fracture or occipital condyle fracture
    - Petrous bone fracture
    - Diffuse axonal injury with Glasgow Coma Scale score ≤8
    - Concurrent traumatic brain and thoracic injuries
    - Neck hanging with anoxic brain injury
    - Clothesline type injury with significant swelling, pain, or altered mental status

TABLE 260-8 Blunt Carotid and Vertebral Artery Injury Grading Scale

Grade	Description	Treatment
Grade I	Luminal irregularity or dissection with <25% luminal narrowing	Antithrombotic agent
Grade II	Dissection or intramural hematoma with ≥25% luminal narrowing, intraluminal thrombus, or raised intimal flap	Antithrombotic agent or surgical repair if accessible
Grade III	Pseudoaneurysm	Antithrombotic agent or surgical repair if accessible
Grade IV	Occlusion	Antithrombotic agent or surgical repair if accessible
Grade V	Transection with free extravasation	Surgical repair if accessible Balloon occlusion or embolization

UPPER AIRWAY AND ESOPHAGEAL INJURIES FROM BLUNT AND PENETRATING TRAUMA

LARYNGOTRACHEAL INJURIES

Penetrating neck trauma causes laryngotracheal injury in 2% to 5% of penetrating trauma patients and has a 2% to 15% mortality rate.[2,15,32] **Significant laryngotracheal injuries should be detected by physical exam.** Patients with hard signs of laryngotracheal injuries (see Table 260-5) need urgent airway control and operative intervention. Soft signs of laryngotracheal injury (see Table 260-5) are present in approximately 18% of patients with penetrating neck injury, but only 15% of these patients will have a laryngotracheal injury diagnosed.[15]

Blunt laryngotracheal injuries occur in less than 0.5% of blunt trauma patients.[56] The majority of blunt laryngotracheal trauma is caused by car collisions. Such injuries are rare because the larynx is protected by the mandible and supported by muscles that deflect most external forces.[57] **Patients with laryngotracheal injuries due to blunt trauma may have a quiescent phase with progressively increasing subclinical airway edema or hematoma that can result in delayed airway obstruction.**[58]

Diagnosis Evaluate patients with a history of significant anterior neck trauma[59] or signs and symptoms of a laryngotracheal injury[57,58,60] with flexible fiberoptic laryngoscopy to define airway patency and the extent of intraluminal injury. CT imaging is critical in patients with suspected laryngotracheal injury without airway compromise and can impart information that influences management.[61]

Treatment Treatment of laryngotracheal injuries is based on the classification system developed by Schaefer and Brown (**Table 260-9**).[62] Patients with grade I and II injuries can be managed medically; grade III, IV, and V injuries typically require operative intervention.[63]

PHARYNGOESOPHAGEAL INJURIES

Up to 9% of patients with **penetrating neck trauma** have pharyngoesophageal injuries.[28] Whereas laryngotracheal injuries are usually apparent, **pharyngoesophageal injuries typically have more subtle**

TABLE 260-9 Laryngeal Injury Grading Scale

Grade I	Minor endolaryngeal hematoma without detectable fracture
Grade II	Edema, hematoma, minor mucosal disruption without exposed cartilage, nondisplaced fractures
Grade III	Massive edema, mucosal disruption, exposed cartilage, vocal fold immobility, displaced fracture
Grade IV	Grade III with two or more fracture lines or massive trauma to laryngeal mucosa
Grade V	Complete laryngotracheal separation

signs resulting in diagnostic delays. In fact, there are no hard signs of pharyngoesophageal injury. Deaths from esophageal injury are usually due to mediastinitis and sepsis.[32] Soft signs and symptoms (see Table 260-5)[26] that portend injury may be present and signal the need for further evaluation.[28] Also suspect this injury if the trajectory of the bullet visualized by CT is in close proximity to the pharynx or esophagus.[5] Finally, in patients receiving conventional soft tissue neck radiographs, prevertebral air is suggestive of a pharyngoesophageal injury.[18]

Pharyngoesophageal injuries are exceedingly rare in patients with blunt neck trauma. Between 1970 and 2003, 11 cases of cervical digestive tract injury due to blunt forces were reported.[64] **Suspect esophageal injury in patients with a history of a sudden acceleration or deceleration event in which the neck was extended.** In this scenario, injuries occur as the esophagus is forced against the spine. However, the low incidence of injuries coupled with their subtle clinical presentation can lead to a delay in diagnosis, leading to morbidity and mortality. In patients with blunt trauma, the signs and symptoms of pharyngoesophageal injury are much more likely to result from laryngotracheal pathology.[6]

Diagnosis Patients with hard signs of vascular or laryngotracheal injuries should undergo intraoperative endoscopy if a pharyngoesophageal injury is identified or suspected during exploration. Symptomatic patients who do not meet criteria for neck exploration can be evaluated by either direct esophagoscopy or swallowing studies.[8] Esophagoscopy is more sensitive for detecting esophageal injuries with the added benefit of quantifying the size and extent of the injury. It can be performed intraoperatively and on unstable or intubated patients. The combination of these two studies achieves 100% sensitivity for detecting these injuries.[65]

Patients who are asymptomatic can be evaluated for digestive tract injuries with multidetector CT. Patients without evidence of injury by multidetector CT should either be observed or, if a high suspicion for injury exists, undergo direct esophagoscopy or swallowing studies using a water-soluble agent.[8]

Treatment Give patients with pharyngoesophageal injuries IV antibiotics and either parenteral or enteral nutrition via a nasogastric tube. Small pharyngeal perforations may be managed medically, whereas pharyngeal perforations larger than 2 cm and esophageal perforations require surgical repair.[28]

STRANGULATION

Strangulation is one form of blunt neck trauma. Mechanisms include hanging, postural strangulation, ligature strangulation, and manual strangulation.[66] Accidental, homicidal, and suicidal strangulations are frequent causes of death. In fact, 10% of violent deaths in the United States are due to strangulation,[25] and hanging is the second most common means of suicide death in the United States.[67] Accidental strangulation is more frequent in children, but also occurs in adults whose clothing or hair becomes entangled in machinery or who participate in the paraphilia of erotic asphyxiation.[66,68] In all forms of strangulation, death is ultimately due to cerebral anoxia and ischemia; obstruction of cerebral venous return rather than acute airway compromise is postulated to be the most common pathophysiologic mechanism of death.[6]

CLINICAL FEATURES

Although airway compromise is envisioned by most people to be the cause of strangulation deaths, **the major pathologic mechanism is neck vessel occlusion rather than airway obstruction**. There are numerous case reports of people with functioning tracheostomies committing suicide by hanging or strangulation. Only limited pressure is needed for venous compression. If both external and internal jugular veins are simultaneously occluded, cerebral vascular congestion, edema, and unconsciousness result.[66] Next, loss of muscle tone allows arterial compression with subsequent cerebral anoxia. Airway obstruction and carotid body reflex–mediated cardiac dysrhythmia are minor mechanisms of death in strangled patients.[69]

In addition to cerebral anoxia, strangulation injuries include laryngotracheal fractures, cervical spine fractures, pharyngeal lacerations, and carotid artery injuries.[70] Although hyoid bone fractures are classically associated with strangulation, they are found in a minority of these patients—even those with fatal injuries. Furthermore, with the exception of judicial hangings, cervical spine and cord injuries are not frequently seen in patients who survive strangling.[66] Carotid artery dissection is a rare complication, but should be suspected in a patient with a lateralizing neurologic exam or bruising or tenderness over the carotid artery. Moreover, consider unreported strangulation in young patients with acute neurologic deficits or a spontaneous carotid artery dissection.[69]

Physical signs of strangulation include petechiae and neck contusions; however, half of victims have no visible signs of neck trauma, and two thirds are asymptomatic.[25] In fact, patients with extensive laryngeal injury may have few external signs.[71] In those who are symptomatic, the most common complaints are neck pain, voice changes, swallowing difficulty, and breathing problems. Any of these symptoms can signal impending airway compromise and should be investigated.[69]

Patients presenting in cardiac arrest have a dismal prognosis.[66] Conversely, recovery of patients with neurologic symptoms is unpredictable. Patients with severe neurologic symptoms, such as a Glasgow Coma Score of 3, may recover without sequelae, whereas patients with normal initial exams may progressively deteriorate.[68] Most in-hospital, post-strangulation deaths occur due to laryngeal or pulmonary edema or cerebral anoxia.[66]

Perhaps the most difficult task in caring for strangled patients is evaluating the "walking and talking" victim who lacks physical signs of strangulation. Victims may be under the influence of alcohol or drugs or be hyperventilating. Physicians may be tempted to ascribe symptoms to anxiety and to discount the patient's story.[25] Furthermore, there is a subset of seemingly asymptomatic patients who die after developing delayed cerebral or pulmonary edema.[71]

DIAGNOSIS

The evaluation of patients with suspected strangulation is multifaceted and may involve radiologic imaging or endoscopy. Although pulmonary edema, aspiration pneumonia, larynx or hyoid bone fractures, or tracheal deviation caused by edema or hematoma may be visible on chest radiography, CT and MRI can provide more detailed information of soft tissue neck structures. Radiologically demonstrated intramuscular hemorrhage or edema, swelling of the platysma, subcutaneous bleeding, and hemorrhagic lymph nodes are indicative of strangulation injury.[25,72] To exclude carotid dissection, carotid artery imaging should be performed on patients with neurologic deficits discordant with brain CT findings.[25] Finally, patients with symptoms of laryngeal tracheal injury such as dyspnea, dysphonia, aphonia, or odynophagia should undergo laryngobronchoscopy, which may reveal petechiae, edema, or vocal cord paralysis.[25]

TREATMENT AND DISPOSITION

Unconscious patients and those with progressive symptoms such as odynophagia, hoarseness, neurologic changes, or dyspnea require aggressive respiratory management including intubation. Patients with pulmonary edema may benefit from positive end-expiratory pressure ventilation. Furthermore, patients may develop cerebral edema, requiring strategies to reduce intracranial pressure or seizure prophylaxis. Observe asymptomatic patients for delayed respiratory and neurologic dysfunction.[68]

Addressing the numerous psychosocial issues that are typically present in strangled victims is a critical element of their overall coordinated treatment plan. Victims of domestic violence may need social services. Only 5% of strangled domestic violence victims seek medical attention within 2 days of the strangulation.[73] Such patients are at high risk for subsequent harm and death from the same abuser.[25] Survivors are also at risk for posttraumatic stress disorder.[6] Patients who have attempted suicide require psychiatric evaluation. Hangings are often one component of a complex suicide attempt. When suicide is suspected, evaluate

patients for other methods of self-harm such as wrist lacerations, self-stabbing, gunshot wounds, or ingestions.[68]

SPECIAL CONSIDERATIONS

CHILDREN

Children with blunt or penetrating trauma are susceptible to the same mechanisms and injuries as adults. Additional mechanisms of injury seen in childhood include child abuse, playground trauma, and handlebar injuries during bike falls.[74]

The initial management and indications for emergent intervention for children with penetrating neck trauma mirror those of adults. Children are at higher risk for complications from angiography, endoscopy, and ionizing radiation. Thus, the need for an extensive workup in the asymptomatic child must be critically evaluated.[75]

Children have the same incidence of injury and ischemic sequelae of blunt cerebral vascular injury. The 40% rate of ischemic symptom development in untreated children with blunt cerebral vascular injury is reduced to nearly zero when treatment is initiated during the quiescent phase.[76]

Children have certain anatomic characteristics that protect them from laryngeal injury. In addition to being more flexible, the larynx is located in a higher, more protected position.[77] Conversely, there are features that predispose children to developing symptomatic airway edema. During childhood, the diameter of the larynx is smaller and its mucosa is more loosely attached, allowing edema and hematomas to progress. Therefore, children are more likely to present with respiratory distress.[36]

As with adults, pharyngoesophageal injuries are rare and often have a subtle, delayed presentation. Maintain a high index of suspicion for these injuries.[78]

ANTICOAGULATED OR MASSIVELY BLEEDING PATIENTS

Correct coagulopathy in patients with neck trauma who are taking anticoagulants. See Table 166-5 for suggested protocols for anticoagulant reversal. The exception to this recommendation is for patients with blunt cerebral vascular trauma, because the majority of these injuries are treated with antithrombotic agents.

Finally, resuscitate massively bleeding patients with blood products in ratios as outlined by a **massive transfusion protocol**.[79] Also, consider administering tranexamic acid to bleeding trauma patients. The **CRASH-2 trial** demonstrated that this antifibrinolytic significantly reduces deaths from traumatic bleeding when given within 3 hours of the inciting injury.[80]

CHAPTER 261

Pulmonary Trauma

David Jones
Anna Nelson
O. John Ma

INTRODUCTION AND EPIDEMIOLOGY

Blunt thoracic injuries account for up to one fourth of all injury-related deaths.[1] The mechanism of injury and severity of tissue damage predict the clinical course and outcome.[2] Injuries that do not violate the pleura usually can be managed with conservative measures, such as wound management or observation. **Penetrating injuries** that violate the pleura typically result in pneumothorax, with an accompanying hemothorax in most cases. Treatment is generally supportive care after tube thoracostomy.

Blunt trauma produces damage by direct injury, compression, and forces of acceleration or deceleration. Patients with significant blunt injury may require intubation and mechanical ventilation and invasive procedures such as tube thoracostomy. In general, victims of penetrating injuries who survive to reach the hospital often have better outcomes than those who have sustained blunt injuries. Blunt chest trauma from blast injuries is discussed in chapter 7, "Bomb, Blast, and Crush Injuries." Penetrating chest injuries in the "cardiac box" (see Figure 262-1), an area bounded by the sternal notch, xiphoid process, and nipples, should be presumed cardiac or great vessel injuries until proven otherwise.

CLINICAL FEATURES

HISTORY

The most frequent symptoms of thoracic trauma are chest pain and shortness of breath. The pain is most often localized to the involved area of the chest wall, but sometimes it is referred to the abdomen, neck, shoulder, back, or arms. Dyspnea and tachypnea are nonspecific findings and may also be caused by blood loss or pain from other injuries or by anxiety.

PHYSICAL EXAMINATION

Rapidly perform the physical examination during the primary and secondary surveys to detect life-threatening injuries.

Inspect the chest wall for contusions, abrasions, and other signs of trauma, including a "seat belt sign" that can indicate deceleration or vascular injury. Examine the chest for signs of paradoxical segments or flail chest, intrathoracic bleeding, and open chest wounds. The patient must be making a reasonable ventilatory effort to demonstrate these injuries.

Distended neck veins may indicate the presence of pericardial tamponade, tension pneumothorax, cardiac failure, or air embolism; however, in the setting of hypovolemia, this sign may be absent. If the face and neck are cyanotic and/or swollen, then suspect severe injury to the superior mediastinum with occlusion or compression of the superior vena cava. Subcutaneous emphysema from a torn bronchus or laceration of the lung can also cause severe swelling of the neck and face.

A scaphoid abdomen may indicate a diaphragmatic injury with herniation of abdominal contents into the chest. Excessive abdominal movement during breathing may indicate chest wall damage that might not otherwise be apparent.

Breath sounds are most readily heard in the axillae. Unilaterally decreased breath sounds may indicate the presence of hemothorax or pneumothorax. If the patient has an endotracheal tube in place, assess the depth of the tube for mainstem bronchus intubation (the usual depth is no more than three times the inner diameter of the endotracheal tube—23 cm in adult males and 21 cm in adult females) before performing tube thoracostomy in these patients. Persistent decreased breath sounds on one side may also be due to a bronchial foreign body or ruptured bronchus. The presence of bowel sounds in the thorax usually indicates a diaphragmatic injury.

Palpate the neck to determine whether the trachea is midline or displaced. Palpation of the chest wall may reveal areas of localized tenderness or crepitus due to fractured ribs or subcutaneous emphysema. Localized and consistent tenderness over ribs should be attributed to rib fractures, even in the absence of findings on conventional chest radiography. Severe localized tenderness, crepitus, or a mobile segment of the sternum may be the only objective evidence of a sternal fracture. Palpation of the chest with the patient coughing or straining may detect abnormal motion of an unstable portion of the chest wall better than visual inspection.

Sensitivity of physical examination findings is not high enough to rule in or out common thoracic injuries. A study of hemodynamically stable chest trauma patients showed that the sensitivity of auscultation for the detection of a hemopneumothorax is only 50%.[3] Consider patient symptoms, vital signs, and physical examination findings together to detect significant injuries in stable chest trauma patients and to guide further investigation with imaging.

IMAGING

CHEST RADIOGRAPH

Plain chest radiographs are helpful to screen for abnormal mediastinal contours, hemothorax, pneumothorax, pulmonary contusions, diaphragmatic injury, and osseous trauma. Mark penetrating surface wounds before imaging. Most chest radiographs are initially taken in the supine position at the bedside due to concern for occult spinal cord injuries and to facilitate resuscitation. **Chest radiographs frequently underestimate the severity and extent of chest trauma and may fail to detect an injury.** Up to 50% of blunt chest trauma patients with normal initial chest radiography have multiple injuries on CT; however, some of these occult injuries do not change management or outcome.[4-8] Chest x-ray is obtained to identify findings such as pneumothorax, hemothorax, aortic or great vessel injury, multiple rib fractures, sternal fracture, diaphragmatic rupture, and pulmonary contusions or lacerations. The National Emergency X-Radiography Utilization Study (NEXUS) Chest Rules were developed in a manner similar to NEXUS Cervical Spine Imaging rules to identify patients with **blunt chest trauma** with very low risk of thoracic injury. The rules were developed and validated in a convenience sample of 9905 patients >14 years old. If all of the NEXUS Chest criteria were absent, chest imaging (plain radiography or CT) could be omitted (**Table 261-1**). Patients in this cohort were not evaluated with bedside US, and decision for plain chest radiography or chest CT was left to the discretion of the caring physician. Sensitivity and specificity were 98.8% and 13.3%, respectively, for thoracic injury. Only about half of the study group underwent CT, limiting any conclusions about plain radiography versus CT in patients with blunt chest trauma.

ULTRASOUND

Bedside US can quickly diagnose pneumothorax, hemothorax, and pericardial tamponade as part of the FAST examination. In trained hands, US has a greater sensitivity and equal specificity for detecting hemothorax in patients with chest trauma compared with chest radiography.[9] Likewise, the sensitivity of US for detecting pneumothorax approaches 92%, with near 100% specificity (as compared with 50% to 80% sensitivity and 90% specificity for chest radiographs)[10]; thus, US appears to have greater "diagnostic performance" than clinical exam and chest radiograph together.[11] **US in the ED can detect occult pneumothorax as accurately as CT.**[12] In addition, US has also been found helpful for describing small, medium, or large pneumothoraces with good agreement with CT (**Figure 261-1**).[13]

COMPUTED TOMOGRAPHY

CT can detect major and occult injuries and identify the need for additional interventions, but may demonstrate incidental findings that require follow-up and do not change acute care.[8] CT is more sensitive for detecting pulmonary contusion and hemothorax than plain radiography.[4] For penetrating lung injury, if the clinical condition allows, CT is performed to identify the extent of injury and involvement of the heart or great vessels.

TABLE 261-1 NEXUS Rules for Chest Radiography

Blunt trauma in patients >14 y old in whom chest imaging is considered to exclude intrathoracic injury	Presence of 1 or more criteria: cannot exclude intrathoracic injury and obtain chest imaging
	Age >60 y old
	Rapid deceleration: fall >20 ft (>6 m); motor vehicle crash >40 mph (>64 km/h)
	Chest pain
	Intoxication
	Abnormal alertness or abnormal mental status
	Distracting painful Injury
	Tenderness to chest wall palpation

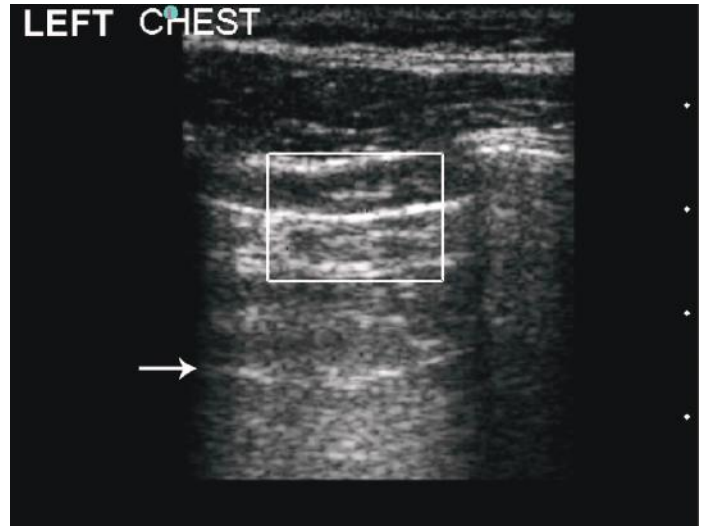

FIGURE 261-1. Pneumothorax (7.5–10 MHz). Power Doppler is activated and the gain adjusted correctly by comparison with the normal right hemithorax. The patient's left hemithorax showed a negative pleural sliding sign, no comet tail artifacts, and no power Doppler signal at the pleural interface. The specificity for pneumothorax is improved when an A-line is also visible (*arrow*). [Reproduced with permission from Ma OJ, Mateer JR, Reardon RF, Joing S (eds): *Emergency Ultrasound,* 3rd ed. McGraw-Hill, Inc., 2014. Fig 5-26, p. 82.]

OTHER DIAGNOSTIC STUDIES

Thoracic trauma often requires a contrast esophagogram to diagnose esophageal injury. **Water-soluble contrast is preferred over barium-containing contrast in patients with high suspicion for esophageal rupture.** Barium swallow imaging has fewer false positives, but may cause mediastinitis if there is leakage of contrast out of the esophagus.

In selected cases, such as in penetrating wounds of the chest or lower neck, bronchoscopy or esophagoscopy may be indicated to exclude an injury to the aerodigestive tract. Such studies may be deferred until the patient is resuscitated and hemodynamically stable.

GENERAL TREATMENT

INITIAL RESUSCITATION

Perform initial resuscitation and airway management according to established principles (see chapter 254, "Trauma in Adults"). If the patient is making little or no respiratory effort, consider CNS dysfunction due to head trauma, intoxication, or spinal cord injury. In patients with respiratory effort but with little or no air movement, suspect upper airway obstruction. Absent or abnormal breath sounds may indicate flail chest, hemopneumothorax, diaphragmatic injury, or parenchymal lung damage. Although each of these has unique therapies, respiratory distress that is not immediately relieved by specific intervention should prompt intubation and ventilation. Suspect, diagnose, and treat specific life-threatening pulmonary injuries during the primary survey. These include tension pneumothorax, massive hemothorax, and open pneumothorax.

VENTILATORY SUPPORT

The management of chest trauma patients with respiratory instability is challenging. Hypoxia and hypoventilation are two preventable causes of mortality; therefore, **maintaining adequate oxygenation and ventilation in the acute chest trauma patient is essential**. Monitor all trauma patients by continuous noninvasive pulse oximetry to assure adequate oxygen saturation. In patients with severe chest trauma or respiratory compromise, an arterial blood gas is helpful to monitor metabolic status and adequate oxygenation and ventilation. Metabolic acidosis with insufficient respiratory compensation is an indication for ventilatory

TABLE 261-2 Considerations for Early Ventilatory Assistance after Thoracic Trauma

Altered mental status
Hypovolemic shock
Multiple injuries
Multiple blood transfusions
Elderly patient
Preexisting pulmonary disease
Respiratory rate >30–35 breaths/min
Vital capacity <10–15 mL/kg
Negative inspiratory force <25–30 cm H_2O

support. Ventilatory support is indicated in chest trauma patients who continue to exhibit impaired ventilation despite measures to relieve chest wall pain and evacuate hemopneumothorax (**Table 261-2**).

CARDIAC ARREST ASSOCIATED WITH ENDOTRACHEAL INTUBATION

Decompensation leading to cardiac arrest may occur during or after endotracheal intubation for reasons related to the initial injury or the procedure (**Table 261-3**). If the patient has poor venous return due to hypovolemia, hyperventilation may increase intrathoracic pressure and decrease venous return to the heart. In the hypovolemic patient, the resultant reduction in cardiac output can lead to cardiac arrest. Ventilate hypovolemic patients with tidal volumes of no more than 5 to 8 mL/kg and at rates not exceeding 10 to 14 times per minute. Excessive hyperventilation can also cause severe alkalosis, which shifts the oxyhemoglobin saturation curve to the left, impairing oxygen unloading at the tissue level. **In the presence of pulmonary injury or preexisting bullous disease, vigorous positive-pressure ventilation can lead to tension pneumothorax, further reducing venous return.**

Unexplained bradycardia associated with assisted ventilation should prompt immediate verification of proper endotracheal tube position and exclusion of esophageal tube placement, as well as evaluation for tension pneumothorax.

LIFE-THREATENING PULMONARY INJURIES

TENSION PNEUMOTHORAX

Diagnose tension pneumothorax clinically, before the chest x-ray is obtained. Although the classic presentation includes distended neck veins, hypotension or evidence of hypoperfusion, diminished or absent breath sounds on the affected side, and tracheal deviation to the contralateral side (**Figure 261-2**), one or more of these elements may be absent in the presence of hypovolemia. **Perform immediate needle decompression.**

NEEDLE DECOMPRESSION

The most common approach to needle decompression is to introduce a 14-gauge IV needle and catheter into the pleural space in the midclavicular line just above the rib at the second intercostal space (**Figure 261-3**). An anterior midclavicular approach is important because this is the shortest distance from the skin to the pleura, avoids the internal mammary vessels that are located approximately 3 cm lateral to the sternal border, and avoids mediastinal vessels.[14-16] A standard needle and catheter may not be long enough for decompression, as the mean chest wall thickness in the United States is 4.5 cm.[15] An alternative site is the fourth to fifth intercostal space at the anterior axillary line.[16] A rush of air exiting the pleural space may be audible and is diagnostic of a pneumothorax. Needle depression converts the tension pneumothorax into an open pneumothorax; needle decompression is a temporizing measure and should be followed promptly with tube thoracostomy. If the patient's hemodynamics fail to improve following decompression, consider other causes of hypoperfusion, including pericardial tamponade.

TABLE 261-3 Potential Causes of Cardiac Arrest after Endotracheal Intubation

Inadequate preoxygenation
Esophageal intubation
Intubation of the right or left mainstem bronchus
Tension pneumothorax
Systemic air embolism
Decreased venous return due to excessive ventilatory rate or pressures
Vasovagal response

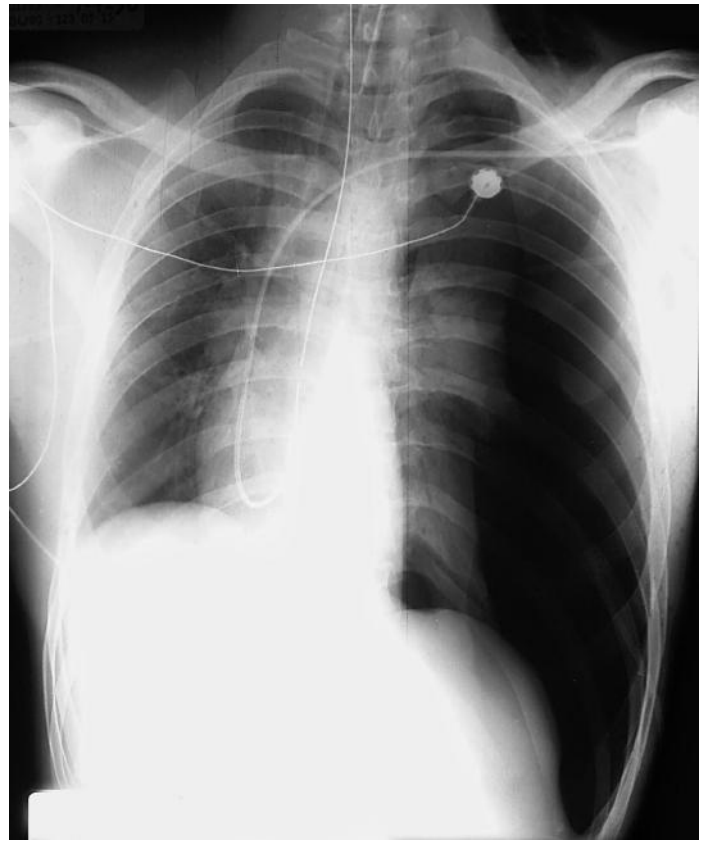

FIGURE 261-2. Tension pneumothorax. Supine chest radiograph of a tension pneumothorax. Note the deviation of the trachea and shifting of the mediastinal contents to the right. Tension pneumothorax should normally be diagnosed prior to chest radiograph. MASSIVE HEMOTHORAX

Common causes of massive hemothorax include injury to the lung parenchyma, intercostal arteries, or internal mammary arteries. Each hemithorax can hold 40% of a patient's circulating blood volume. A massive hemothorax is defined in the adult as at least 1500 mL. Massive hemothorax is life threatening by three mechanisms. First, acute hypovolemia does not allow for sufficient preload to sustain left ventricular function and adequate cardiac output. Second, the collapsed lung results in hypoxia by creating alveolar hypoventilation, ventilation–perfusion mismatch, and anatomic shunting. Third, the hydrostatic pressure of the hemothorax compresses the vena cava and the pulmonary parenchyma, further impairing preload and raising pulmonary vascular resistance, respectively. Although the clinical signs and symptoms of hemothorax in the chest trauma patient can vary, suggestive findings include decreased or absent breath sounds and no chest movement with respiratory effort.

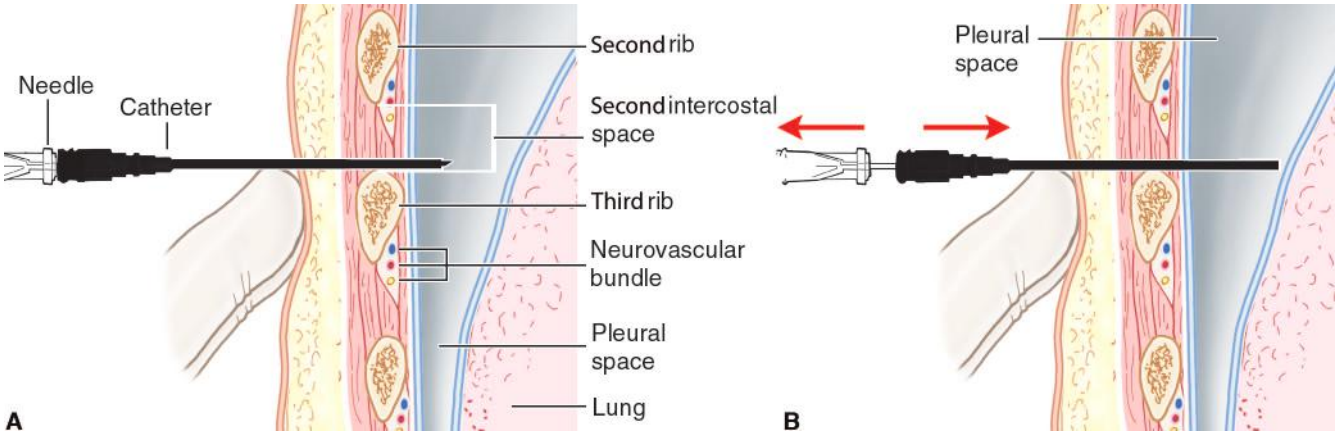

FIGURE 261-3. Decompression of a tension pneumothorax with a catheter-over-the-needle. **A.** The catheter-over-the-needle is inserted through the second intercostal space and into the pleural cavity. **B.** The catheter is advanced while the needle is removed. [Reproduced with permission from Reichman EF (ed): *Emergency Medicine Procedures*, 2nd ed. © 2013. McGraw-Hill Education, New York, NY. Fig 38-2A&B.]

The diagnosis is made by plain chest radiography when complete opacification of a hemithorax is observed. As an alternative to chest radiography in the unstable patient, point-of-care US may reveal a layer of fluid between the chest wall and lung (**Figure 261-4**). Lung collapse, due to intubation of the contralateral mainstem bronchus, can mimic the appearance of hemothorax; always verify proper endotracheal tube placement. Treatment is tube thoracostomy and replacement of blood products as clinically indicated.

OPEN PNEUMOTHORAX

Open pneumothorax is a communication between the pleural space and surrounding atmospheric pressure. This is sometimes referred to as a "sucking chest wound," but also may be due to small rents in the parietal pleura or small air passages without an obvious penetrating injury. Respiratory distress is due to lung collapse and subsequent inability to ventilate the affected lung. Air entry and breath sounds are often diminished on the affected side, and chest wall motion can be impaired. The initial therapeutic maneuver to treat a sucking chest wound is to cover the wound with a three-sided dressing such that air can exit but not enter the chest. Avoid complete occlusion, as this may convert the injury into a tension pneumothorax. Do not insert a chest tube through the trauma wound, as it is likely to follow the missile or knife tract into the lung or diaphragm.

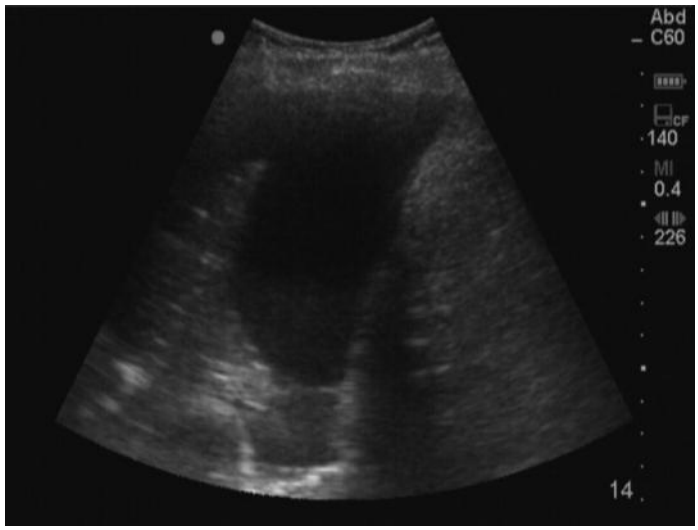

FIGURE 261-4. Hemothorax. US can evaluate for pleural fluid, which usually represents hemothorax. This is a view of the lung, diaphragm, and spleen. Pleural fluid (hemothorax) can be seen superior to the diaphragm.

SYSTEMIC AIR EMBOLISM

Systemic air embolism is an acute complication of severe chest trauma and presents with disastrous circulatory and cerebral complications. Patients with penetrating chest wounds who require positive-pressure ventilation are at risk for developing air embolus. High ventilatory pressures, especially >50 cm H_2O, may force air from an injured bronchus into an adjacent injured vessel. Air embolus may lead to severe dysrhythmias or CNS deficits. Patients presenting with hemoptysis in the setting of penetrating chest trauma are at particular risk for this serious complication.

If systemic air embolism is suspected or diagnosed, place the patient in a flat supine position with 100% oxygen applied, which may decrease air bubble size by displacing nitrogen and promoting resorption of the embolus. **There is no evidence to support the theoretical benefit of the Trendelenburg (head down) position in arterial air embolism.** Hyperbaric oxygen therapy, if available, helps to decrease size and increase resorption of air bubbles. Airway management of patients at risk for systemic air embolism should include maneuvers that can selectively ventilate each lung. In unilateral lung injury, isolating and ventilating the uninjured lung can, in theory, be used to prevent systemic air embolism. In the event of circulatory collapse, treatment begins with cardiopulmonary resuscitation protocols and an immediate thoracotomy to clamp the injured area of lung. This is followed by air aspiration from the heart and ascending aorta.[17,18] Open cardiac massage with clamping of the ascending aorta may help push air through the coronary arteries. Initiate cardiopulmonary bypass promptly, if available.

TUBE THORACOSTOMY

Evacuate large hemothoraces or hemopneumothoraces as rapidly as possible to decrease their negative effects on ventilation and perfusion. Double-check clinical and radiographic findings to make sure you are placing the chest tube on the proper side of the patient. Historically, a 24F or 28F (8.0 or 9.3 mm) chest tube was recommended for a simple pneumothorax and a >32F (>10.7 mm) chest tube for a suspected hemothorax. One study suggests there are no differences in efficacy of drainage, complication rate, pain, or need for additional procedures when using small or large chest tubes.[19]

INSERTION SITE

Perform tube thoracostomy for treatment of traumatic pneumothorax or hemothorax in the anterior axillary line at the level of the nipple in men or inframammary crease in women (corresponding to the fifth intercostal space) just behind the lateral edge of the pectoralis major.

Make an oblique skin incision at least 1 to 2 cm **below** the interspace through which the tube will be placed. Insert a large clamp through the skin incision and into the muscles in the next higher intercostal space, just **above** the rib, thus avoiding the neurovascular bundle (**Figure 261-5**). The resulting oblique tunnel through the subcutaneous tissue and intercostal muscles usually closes promptly after the chest tube is removed, thereby reducing the chances of recurrent pneumothorax.

Once the clamp is pushed through the internal intercostal fascia, open it to enlarge the hole to at least 2.0 cm. Insert a finger along the top of the clamp through the hole to verify the position within the thorax and to verify that the lung is not adhering to the chest wall (**Figure 261-6**).

CHEST TUBE INSERTION

Advance the tube at least until the last side hole is 2.5 to 5.0 cm (1 to 2 inches) inside the chest wall. For a pneumothorax, direct the tube toward the apex, away from the hilum and mediastinum. For a hemothorax, direct the tube posteriorly and laterally. However, do not reposition any tube position that functions effectively unless indicated by abnormal or suboptimal placement identified on the chest radiograph. In general, do not clamp the chest tube for any reason. Any continuing air leakage can rapidly collapse the lung or cause a tension pneumothorax. Importantly, loss of vital signs and clinical deterioration after chest tube placement may indicate exsanguinating injury and loss of the protective vascular tamponade effect as the hemothorax is evacuated. In this circumstance, clamp the chest tube and transport the patient directly to the operating room for an emergency thoracotomy.

CONNECT TO SUCTION

Attach the open end of the tube to a combination fluid-collection water-seal suction device, with 20 to 30 cm H_2O of suction. If a significant hemothorax is known to be present or if a large amount of blood starts to drain immediately, consider collecting the blood in a heparinized autotransfusion device so that it can be returned to the patient.

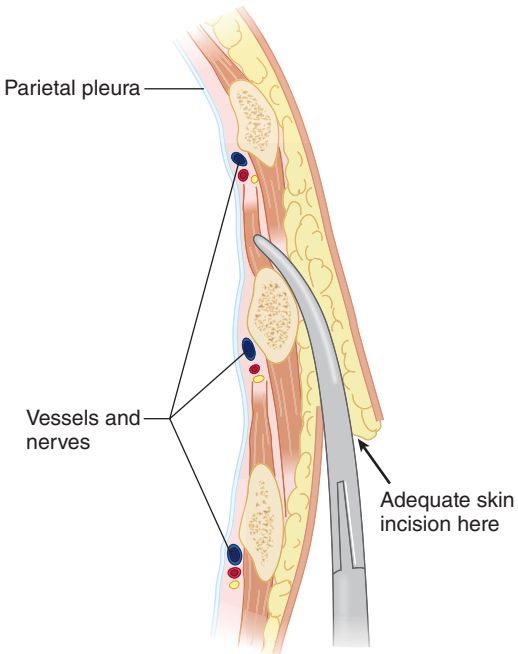

FIGURE 261-5. Chest tube insertion. The clamp is inserted through the incision and is tunneled up to the next intercostal space.

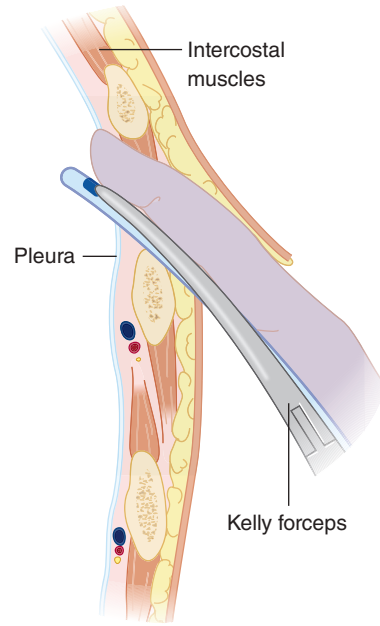

FIGURE 261-6. Chest tube insertion. Using the finger as a guide, place the tip of the clamp into the pleural cavity just above the rib to avoid intercostal vessels and nerves.

DOCUMENT TUBE PLACEMENT AND FUNCTION

Check the intrathoracic position of the chest tube and of its last hole and the amount of air or fluid remaining in the pleural cavity with a portable chest radiograph as soon as possible after the tube is inserted. Serial chest auscultation, chest radiographs, and careful recording of the volume of blood loss and the amount of air leakage are important guides to the functioning of chest tubes. If a chest tube becomes blocked and a significant pneumothorax or hemothorax is still present, replace the tube or place a second chest tube on the affected side. Irrigating an occluded chest tube or passing a Fogarty catheter through it in an effort to reestablish its patency is not advised.

Leave chest tubes in place on suction at least 24 hours after all air leaks have stopped (if placed for a simple pneumothorax) or until drainage is serous and <200 mL/24 h (if placed for hemothorax).[20] However, in intubated patients, maintain chest tubes throughout mechanical ventilation to prevent sudden development of a new pneumothorax.

The use of prophylactic broad-spectrum antibiotics in patients who require tube thoracostomy for a traumatic hemothorax or pneumothorax remains controversial.[21-23] Whether or not antibiotics are given, adhere to protocols for the placement, maintenance, and early removal of chest tubes to decrease the risk of infection.

SPECIFIC LUNG INJURIES

PULMONARY CONTUSION

Pulmonary contusions, defined as direct injury to the lung resulting in both hemorrhage and edema in the absence of a pulmonary laceration, are a source of severe morbidity and mortality following penetrating and blunt trauma. CT has shown this entity to be much more prevalent than previously recognized.[4] The most common cause of pulmonary contusions is a compression-decompression injury to the chest, such as seen in high-speed motor vehicle crashes.

FIGURE 261-7. Pulmonary contusion. **A.** Chest radiograph shows pulmonary contusion from blunt chest trauma, along with 9th and 10th rib fractures. **B.** CT shows pulmonary contusions on the anterior part of the right lung and a sternal fracture with mediastinal hematoma.

There are two stages in the pathophysiology of pulmonary contusions. First, there is direct injury to lung parenchyma. Second, resuscitative measures, particularly IV crystalloid fluid administration directed at restoring intravascular volume loss due to hemorrhage, can precipitate cardiopulmonary decompensation. Fluid resuscitation in the setting of unilateral pulmonary contusion can cause extravasation of fluid into the contralateral (uninjured) lung. Increased capillary hydrostatic pressures result in leakage of blood and fluid into the interstitium and alveoli. Unfortunately, the process is self-perpetuating; as each proximate segment of lung sees the full force of the right heart activity, it becomes functionally congested and contused, and the process continues to the next uninjured segment of lung. This process results in increased intrapulmonary shunting and resistance to airflow, decreased lung elasticity, and increased work of breathing, leading to hypoxia, hypercarbia, and respiratory acidosis. Cardiopulmonary decompensation may quickly ensue.

Chest pain, tachypnea, chest wall contusions, and hypoxia suggest underlying pulmonary contusion. Physical examination may reveal decreased or coarse breath sounds over the affected lung field. Chest radiograph and CT may show patchy, ground-glass opacities in mild or moderate contusion and widespread consolidation in severe contusion.[5] Contusions are found in nonsegmental areas of the lung and across pleural fissures. Radiographic findings of pulmonary contusion may mimic those associated with aspiration pneumonia and fat embolism, but these entities are typically not seen for 12 to 24 hours and usually have a segmental distribution. **Areas of lung opacification on chest imaging within 6 hours of blunt trauma are usually considered diagnostic of pulmonary contusion (Figure 261-7).** CT is more sensitive for the detection of pulmonary contusions than plain radiographs, with as many as 70% of pulmonary contusions not visible on the initial radiograph.[4] In addition to the high diagnostic rate of CT scan for pulmonary contusion, it may also be possible to anticipate complications such as acute lung injury (also known as *acute respiratory distress syndrome* or *noncardiogenic pulmonary edema*), depending on the extent of the pulmonary contusion. Patients who have a contusion >20% of lung volume have up to an 80% risk of developing acute lung injury.[24]

Treatment primarily involves maintenance of adequate ventilation and pain control. Epidural analgesia is the preferred method of pain control; however, consider intercostal nerve blocks and paravertebral analgesia when an epidural is contraindicated.[25] The volume of contused lung influences the need for mechanical ventilation. Patients with less than one fourth of total lung volume involvement (about one lobe) usually do not require such support. If ventilatory assistance is required, avoid overinflation of normal alveoli. Placing the noninjured lung dependent by turning the patient to the decubitus position may improve ventilation–perfusion matching. Patients with extensive pulmonary contusion may be candidates for high-frequency oscillatory ventilation, a technique that can improve oxygenation, although it may not improve survival.[26] Guidelines for the management of pulmonary contusion and flail chest are listed in **Table 261-4**.[25]

Patients with severe unilateral lung injury who are not responding to conventional mechanical ventilation may benefit from synchronous independent lung ventilation provided through a double-lumen endobronchial catheter. This technique helps prevent overinflation of the normal lung and underinflation of the damaged, poorly compliant lung.

HEMOTHORAX

Bleeding from direct lung injury is the most common cause of hemothorax. The compressing effect of the blood within the pleural space, high concentration of lung thromboplastin, and low pulmonary arterial pressure help limit bleeding as a result of torn lung parenchyma. Bleeding into the hemithorax may arise from mediastinal, diaphragmatic, pulmonary, pleural, chest wall, or even abdominal injuries. Bleeding of venous origin usually tamponades without intervention. Damage to intercostal or internal mammary arteries or pulmonary vessels causes more severe bleeding and almost always requires invasive management.

Evacuate hemothoraces of >300 to 500 mL expeditiously to avoid complications. Large clots in the pleural space can act as a local anticoagulant by releasing fibrinolysins from their surface. Bleeding from multiple small intrathoracic vessels often stops fairly rapidly after the hemothorax is completely evacuated.

Fluid collections >200 to 300 mL can usually be seen on upright or decubitus chest radiographs. However, if the patient is supine, >1000 mL of blood may be missed due to posterior layering of blood, producing only diffuse haziness on that side (**Figure 261-8**). Point-of-care US may be used in the critically ill patient to detect hemothorax (**Figure 261-9**), showing a fluid density between visceral and parietal pleura normally occupied by lung tissue. **CT has the highest sensitivity and specificity for detecting hemothorax.**

If the hemothorax is judged large enough to drain (>200 to 300 mL), tube thoracostomy remains the standard of care.

INDICATIONS FOR OPERATIVE INTERVENTION

Most patients with intrathoracic bleeding can be treated adequately by IV administration of fluids and evacuation of the hemothorax with a chest tube. Fewer than 5% of patients will require operative management. **Consider surgical exploration in the following circumstances:**

TABLE 261-4 Eastern Association for Surgery of Trauma Practice Management Guideline for Pulmonary Contusion—Flail Chest

Level 1 recommendations (convincingly justifiable based on the available scientific information alone)	None.
Level 2 recommendations (reasonably justifiable by available scientific evidence and strongly supported by expert opinion)	Unnecessary fluid administration should be meticulously avoided; a pulmonary artery catheter may be useful to avoid fluid overload. Obligatory mechanical ventilation should be avoided. The use of optimal analgesia and aggressive chest physiotherapy should be applied to minimize the likelihood of respiratory failure and ensuing ventilatory support. Patients with pulmonary contusion requiring mechanical ventilation should be weaned from the ventilator at the earliest possible time. Positive end-expiratory pressure/continuous positive airway pressures should be included in the ventilatory regimen. Steroids should not be used in the therapy of pulmonary contusion.
Level 3 recommendations (supported by available data but adequate scientific evidence is lacking)	A trial of mask continuous positive airway pressure should be considered in alert, compliant patients with marginal respiratory status. Independent lung ventilation may be considered in severe unilateral pulmonary contusion. Diuretics may be used in the setting of hydrostatic fluid overload as evidenced by elevated pulmonary capillary wedge pressures in hemodynamically stable patients or in the setting of known concurrent congestive heart failure. Surgical repair may be considered in severe unilateral flail chest or in patients requiring mechanical ventilation when thoracotomy is otherwise required.

>1500 mL of blood is evacuated immediately after tube thoracostomy, chest tube drainage of blood occurs at 150 to 200 mL/h for 2 to 4 hours, or persistent blood transfusion is required to maintain hemodynamic stability.

PNEUMOTHORAX

To establish the diagnosis of a pneumothorax with upright plain chest radiography, identify a thin white pleural line usually seen best in the upper lateral aspect of the affected hemithorax in the **upright** patient (**Figure 261-10**). Avoid interpreting skinfolds or a scapular border as a pneumothorax. If the radiograph is obtained with the patient supine, small pneumothoraces may not be apparent as air migrates to the anterior chest, resulting in loss of the interface between the parietal pleura and the air-filled pleural space. Point-of-care US can also diagnose simple pneumothorax. Sonographic imaging of a *normal* lung with the high-frequency linear probe at the anterior superior aspect of the chest will reveal "marching ants" or the "sliding lung sign," a result of the movement of the pleural layers during the ventilatory phase. This movement is absent in the presence of pneumothorax.

Pneumothorax is found in approximately 20% of patients with significant chest trauma.[26] Traumatic pneumothorax can be open, closed, or occult. In an individual without preexisting cardiopulmonary disease, an isolated pneumothorax usually does not cause severe symptoms unless it occupies >40% of the hemithorax. Occult pneumothoraces may complicate the management of patients who are emergently taken to the operating room because intubation and positive-pressure ventilation may convert a small occult pneumothorax into a tension pneumothorax.

A pressure differential across the pulmonary pleura results in airflow down the gradient. Therefore, positive pulmonary pressure or negative intrapleural pressure during inspiration increases the tendency for air or blood to leak into the pleural cavity through any wound in the lung or chest wall. Any collection of air or blood within

Hazy opacity on the left, with associated volume loss in the left lung, is indicative of posteriorly layering hemothorax and atelectatic change. **B.** CT image in the same patient showing large hemothorax layering dependently in the supine patient. [Reproduced with permission from Block J, Jordanov MI, Stack LB, Thurman RJ (eds): *The Atlas of Emergency Radiology*. McGraw-Hill, Inc., 2013. Fig 4.23 & 4.24.]

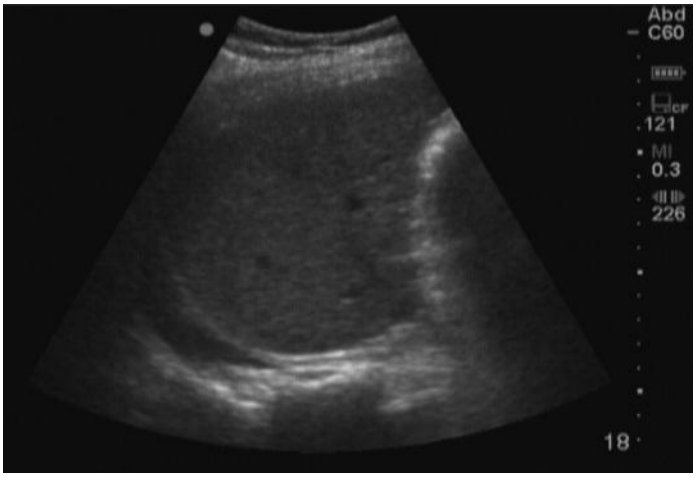

FIGURE 261-9. Hemothorax. US can evaluate for pleural fluid, which usually represents hemothorax. Pleural fluid (hemothorax) can be seen superior to the diaphragm.

the pleural cavity may reduce vital capacity, increase intrathoracic pressure, and decrease minute ventilation and venous return to the heart. Additional air may be forced into the pleural cavity during expiration in patients with outflow obstruction, such as in chronic obstructive lung disease or airway occlusion, thus increasing the likelihood of tension pneumothorax.

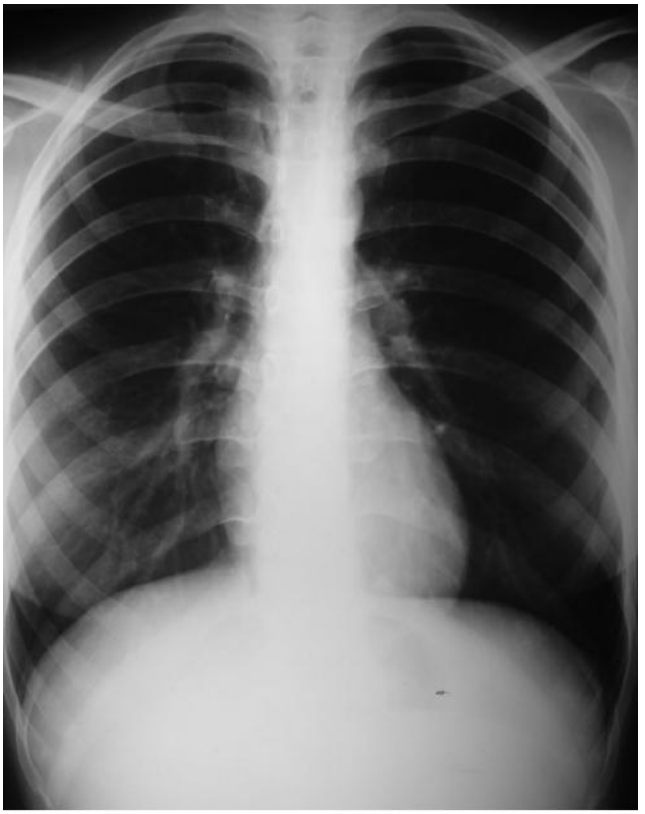
Maintain a high suspicion for occult pneumothoraces in patients with more subtle injuries. **Although chest radiography remains the most common diagnostic tool for detecting pneumothorax in the ED (Figure 261-11), it will miss between 17% and 80% of pneumothoraces for upright and supine chest radiographs, respectively.** US is more sensitive than a supine radiograph and is rapid and accurate for detecting pneumothorax.[10,11,13] Occult pneumothoraces are usually detected by CT (**Figure 261-12**).[26] Importantly, with the exception of patients who may require intubation and positive-pressure ventilation (which may convert a small occult pneumothorax into a tension pneumothorax), the detection of occult pneumothoraces using chest CT has minimal clinical significance and does not improve outcome.[7,8]

If pneumothorax is suspected despite normal initial chest radiography, repeat films or performing US or CT may be helpful. **Pneumothorax after a stab wound may be delayed for up to 6 hours.** Consequently, repeat chest imaging in 4 to 6 hours is indicated in these patients or at any time when symptoms worsen. Patients with initially asymptomatic stab wounds to the chest have a reported 12% incidence of delayed hemothorax or pneumothorax that required tube thoracostomy.[27] A common practice is to observe patients with asymptomatic thoracic stab wounds, repeat the chest radiograph in 4 to 6 hours, and discharge the patient if no delayed pneumothorax is seen in the absence of other concerns.

If the patient cannot be observed closely, requires intubation and mechanical ventilation, or will be transported by air or over a long distance, insert a chest tube or small pleural catheter. Small pneumothoraces (<1.0 cm wide, confined to the upper third of the chest) that are unchanged on two chest radiographs taken 4 to 6 hours apart in an otherwise healthy individual can usually be treated by observation alone.

Occult pneumothoraces (small pneumothoraces not apparent on conventional chest imaging, but seen on a CT scan of the chest or abdomen) usually do not require chest tube drainage unless the patient requires mechanical ventilation. Avoid unnecessary tube thoracostomy because there is a 22% risk of major insertional, positional, and infective complications.[28]

In general, small- or moderate-sized pneumothoraces, once treated, do not cause significant problems unless there is a continuing air leak or preexisting cardiopulmonary disease. Even a small air leak usually will not result in serious complications, provided the lung is completely expanded. However, the incidences of empyema and bronchopleural fistula are greatly increased in pneumothoraces with continued air leak persisting for >24 to 48 hours.



A

B

FIGURE 261-10. Pneumothorax. **A.** The pleural line is seen in the left hemithorax, but lateral to the pleura, there is increased lucency (air density) and an absence of lung markings. These findings should prompt concern for a pneumothorax. **B.** Enlarged area of the same image to further illustrate the increased lucency and absent lung markings lateral to the pleural line.

FIGURE 261-11. Pneumothorax. This right-sided pneumothorax can be diagnosed by the absence of lung markings and increased (air density) lucency lateral to the pleural line.

If the lung does not completely expand or the pneumothorax does not evacuate, then investigate potential causes (**Table 261-5**).

If a pneumothorax persists or there is a large air leak, perform emergency bronchoscopy to examine and clear the bronchi or to identify and repair any damage to the tracheobronchial tree. Continued large air leakage or failure of the lung to adequately expand, despite these measures, is an indication for early thoracotomy.

PNEUMOMEDIASTINUM

Subcutaneous emphysema in the neck or the presence of a crunching sound (Hamman's sign) over the heart during systole suggests the presence of a pneumomediastinum. This diagnosis can usually be made on chest radiography (**Figure 261-13A**) and is readily apparent on CT images of the chest (**Figure 261-13B**). Pneumomediastinum in blunt chest trauma is most commonly the result of alveolar rupture, followed by dissection along the bronchoalveolar sheath and subsequent spread of air to the mediastinum, a process known as the *Macklin effect*. Traumatic pneumomediastinum may be asymptomatic or can cause mild to moderate chest pain, voice change, cough, or stridor. **Pneumomediastinum alone does not require further diagnostic testing or intervention unless the patient is symptomatic,** in which case a search for other serious injuries to the larynx, trachea, major bronchi, pharynx, or esophagus is essential.

FIGURE 261-13. Pneumomediastinum. **A.** Blunt trauma to the chest while playing basketball. Patient had sudden onset of chest pain and shortness of breath. Subcutaneous emphysema was evident in the neck. Chest radiograph reveals mediastinal and subcutaneous air. **B.** In this same patient, a CT scan shows pneumomediastinum.

PULMONARY HEMATOMA

Pulmonary hematomas are parenchymal tears filled with blood. Although these generally resolve spontaneously over a few weeks, they sometimes can become infected and progress to lung abscesses. Infection is more likely in patients on a ventilator, who require prolonged chest tube drainage or who are post-thoracotomy.

PULMONARY LACERATION WITH HEMOPNEUMOTHORAX

Hemorrhage from pulmonary lacerations is most commonly seen in the setting of displaced rib fractures due to direct trauma from the exposed ends of bone. Hemorrhage may also be due to the effect of shear forces on preexisting pleural adhesions during rapid deceleration injuries or from penetrating chest injuries.

TRACHEOBRONCHIAL INJURY

INTRABRONCHIAL BLEEDING

Intrabronchial bleeding can lead to severe hypoxemia and rapid death. Hemorrhage into dependent alveoli hinders gas exchange in a mechanism similar to drowning. It is important to identify the involved lung and to keep the other lung as free of blood as possible. Bronchoscopy is often necessary to identify injury and control bleeding. Intubation with frequent tracheal suction may be effective. If the hemorrhage is severe, a double-lumen endotracheal tube can be used as a temporizing measure to confine the bleeding to one lung. If a double-lumen endotracheal tube is not available, a standard tube may be inserted over a flexible bronchoscope into the unaffected lung, or an endotracheal tube can be purposely passed into the right mainstem bronchus as a diagnostic measure and the patient placed with the affected lung in the dependent position.

ASPIRATION

Aspiration of gastric contents is common after severe trauma, especially if the patient was unconscious at any time. Radiologic changes may be delayed for up to 24 hours and can include consolidation virtually anywhere in the lungs, with the most common sites being the right middle and lower lung fields. This is the result of a chemical pneumonitis as lung parenchyma is exposed to gastric contents. Frequent suctioning is indicated, as well as continual assessment of the need for endotracheal intubation if the patient is at further risk for aspiration. **There is no evidence to support the use of prophylactic antibiotics to prevent pulmonary infection after gastric aspiration.**

Aspirated opaque foreign bodies in the tracheobronchial tree may be diagnosed on plain radiographs, but even teeth can be easily missed due to size, relative lucency, and the presence of overlying bone and soft tissue densities. Once recognized, prepare for urgent bronchoscopy to remove tracheal or bronchial foreign bodies.

Expiratory chest radiographs may help diagnose foreign bodies that act as a one-way valve, causing air trapping and hyperinflation on the affected side. Undiagnosed bronchial foreign bodies lead to recurrent or difficult-to-treat pulmonary infections, sometimes taking months to discover. Persistent or recurrent cough, atelectasis, and pneumonia after trauma are indications for bronchoscopy.

LOWER (INTRATHORACIC) TRACHEA AND MAJOR BRONCHI

Injuries to the major bronchi occur primarily due to rapid deceleration injuries, which cause shear forces to mobile distal bronchi relative to more fixed proximal structures. Forced expiration against a closed glottis and compressive forces on the pulmonary tree against the vertebral column may also cause injury to these structures. **Most tracheobronchial injuries occur within 2 cm of the carina or at the origin of lobar bronchi.**

The most common presenting signs and symptoms are dyspnea, hemoptysis, subcutaneous emphysema, Hamman's sign, and sternal tenderness. A large pneumothorax, pneumomediastinum, or deep cervical emphysema may also suggest tracheobronchial injury. On careful inspection, the endotracheal tube balloon may have a spherical rather than oval appearance on chest radiographs. Approximately 10% of patients present with very mild symptoms or are completely asymptomatic.

The air leak due to bronchopleural fistula following tube thoracostomy is continuous and massive. High-frequency oscillation is the ventilator modality of choice to maintain gas exchange and expand the alveoli in the face of the massive gas leak.

All lacerations of the bronchi involving more than one third of the circumference should be surgically repaired. Untreated tracheal tears may result in severe mediastinitis or can lead to severe bronchial stenosis with atelectasis and repeated pulmonary infections.

Intrathoracic tracheal transection is usually associated with two or more major injuries and is almost invariably fatal. Patients who survive a tracheal transection generally sustain an injury in the cervical trachea and have no other associated injuries. Concurrent esophageal injuries occur in almost 25% of penetrating tracheobronchial injuries and can be missed unless esophagoscopy or contrast studies are also performed.

CERVICAL TRACHEAL INJURIES

Blunt injuries to the upper (cervical) trachea are usually found at the junction of the trachea and cricoid cartilage. This most frequently occurs when the anterior neck strikes the steering wheel or dashboard in an automobile accident. **Evidence of direct trauma to the neck, including subcutaneous emphysema and inspiratory stridor, should raise suspicion for this injury as well as accompanying vascular and spinal injuries.** Cricotracheal separation may not be suspected until attempts to pass the endotracheal tube past the cricoid cartilage are unsuccessful. Treatment and diagnosis are discussed in chapter 260, "Trauma to the Neck."

DIAPHRAGMATIC INJURY

Diaphragmatic injuries are caused most frequently by penetrating trauma, particularly gunshot wounds of the lower chest or upper abdomen. Diaphragmatic rupture due to blunt trauma is much less common and occurs in <5% of patients hospitalized with chest trauma. If there is a fracture of the pelvis, the incidence of diaphragmatic hernia increases.

More diaphragmatic injuries following blunt trauma are diagnosed on the left hemidiaphragm compared to the right.[29] This left-sided predominance is likely the result of the protective effect of the liver on the right hemidiaphragm and the possible increased weakness of the left posterolateral diaphragm.

The initial signs and symptoms of diaphragmatic hernia are often masked by other injuries and have a delayed presentation unless the defect is large. Over time, the abdominal viscera can gradually migrate into the chest through even small diaphragmatic tears; patients may present years after the initial injury with a traumatic diaphragmatic hernia. The intrathoracic bowel may become obstructed or ischemic due to torsion or strangulation or cause severe compression of the adjacent lung, a phenomenon referred to as *tension enterothorax*.

If a penetrating wound of the abdomen is associated with intrathoracic injury or foreign body, it should be assumed that the injury traversed the diaphragm. Chest radiographs may display injury to the diaphragm in only approximately 25% of such patients.[30] With blunt trauma, any abnormality of the diaphragm or lower lung fields on chest images should arouse suspicion of a diaphragmatic tear (**Figure 261-14**).

Techniques for diagnosing diaphragmatic injuries include (1) orogastric tube placement with evaluation to see if the tube curves up from the abdomen into the chest; (2) upper GI series looking for displacement of viscera into the chest; and (3) CT of the chest and abdomen with contrast. **CT is the imaging standard for diaphragmatic injuries (Figure 261-15).**[31] Still, many diaphragmatic injuries are diagnosed only during a thoracotomy or laparotomy.

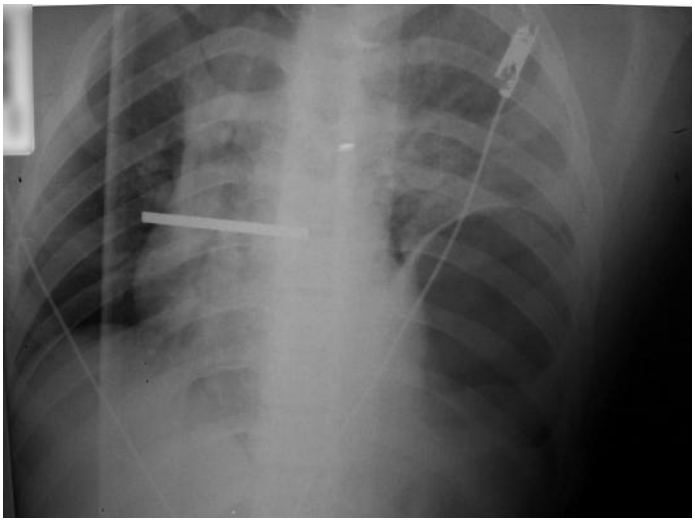

FIGURE 261-14. Diaphragmatic injury. Patient with diminished breath sounds of the left hemithorax after blunt thoracoabdominal injury. Chest radiograph shows left diaphragmatic injury.

Laparotomy is necessary to repair the diaphragm, and thoracotomy may be necessary for associated chest injury, resuscitation, delayed repair of the diaphragm, or management of thoracic complications.

ESOPHAGEAL AND THORACIC DUCT INJURIES

ESOPHAGEAL INJURIES

Injuries to the thoracic esophagus may occur through direct penetrating trauma and, less often, via blunt trauma. Mortality is high as a result of associated injuries to other organs in the chest. Lacerations of the esophagus also occur iatrogenically as a result of endoscopic biopsy or dilatation of a narrowed or obstructed esophagus. Swallowed foreign bodies can also traumatize the esophagus.

If esophageal injury is suspected, obtain an esophagogram using water-soluble contrast**.** It is recommended that a negative study with water-soluble contrast be repeated with barium due to the relatively high false-negative rate.

Flexible esophagoscopy is being increasingly performed for diagnosis but may miss occasional injuries, even if combined with an esophagogram. Some trauma surgeons prefer rigid esophagoscopy in combination with bronchoscopy to rule out associated tracheobronchial injuries. Neither barium nor water-soluble contrast will interfere with a subsequent esophagoscopy.

Despite the diagnostic and therapeutic advances, esophageal injuries are associated with significant morbidity and mortality, particularly if there is a delay in recognition and definitive management.

FIGURE 261-15. Diaphragmatic injury. Right diaphragmatic injury on CT.

THORACIC DUCT INJURIES

Suspect thoracic duct injuries in patients with penetrating trauma near the left proximal subclavian vein. Although the diagnosis is rarely made in the ED, the development of a chylothorax, accumulation of lymphatic fluid in the pleural space, is associated with a mortality rate of ~50% and should be considered in chest trauma patients.

INJURIES TO THE CHEST WALL

BLEEDING AND TISSUE LOSS

Probing of a penetrating chest wound to determine its depth or direction is not recommended and may not give an accurate picture of the depth of penetration. Such wounds, especially if there is continued bleeding, are better managed by local exploration in the operating room.

Injuries caused by high-powered rifles or close-range shotgun blasts may cause large tissue defects of the chest wall. In such patients, intubation and mechanical ventilation are required until the defect is definitively closed.

SUBCUTANEOUS EMPHYSEMA

Subcutaneous emphysema usually develops because air from lung parenchyma or the tracheobronchial tree gains access to the chest wall through an opening in the parietal pleura. The air may also reach the chest wall from an interstitial lung injury by dissecting back along the bronchi into the hilum and mediastinum and then into the extrapleural spaces. Extensive subcutaneous emphysema may also suggest an injury to the pharynx, larynx, or esophagus.

Presume patients with subcutaneous emphysema have an underlying pneumothorax, even if it is not visible on the chest radiograph. If the patient requires intubation and subsequent positive-pressure ventilation, insert a chest tube on the involved side. If subcutaneous emphysema is severe, suspect a major bronchial injury and investigate further by bronchoscopy.

RIB FRACTURES

Rib fractures are the most common bony injuries in chest trauma and are diagnosed in approximately 50% of patients admitted to the hospital following chest trauma.[26] Rib fractures are painful injuries, heal slowly, and are closely associated with mortality and morbidity.[32] Rib fractures can be markers of potential internal injury; the principal diagnostic goal with clinically suspected rib fractures is the detection of significant associated complications, such as hemopneumothorax, pulmonary contusion, intra-abdominal injury, or major vascular injury. In the patient with severe chest trauma or significantly displaced rib fractures or in the presence of other injuries, perform serial chest imaging to evaluate for developing pneumothoraces or other injuries.

Assume the presence of rib fractures in any patient with localized pain and tenderness over one or more ribs after chest trauma. Up to 50% of rib fractures (especially those involving the anterior and lateral portions of the first five ribs) are not be apparent on conventional radiography, particularly in the first few days after injury.[33] Furthermore, injuries to the cartilaginous portions of the ribs may never be appreciated on plain radiographs. US is a promising diagnostic tool for evaluating rib fractures and even for cartilaginous injury.[34]

The pain of rib fractures can greatly interfere with ventilation and cause splinting and atelectasis. Rib fractures can also prolong the time

for weaning from ventilator support. Do not immobilize the chest wall with tape or binders. A combination of opioids, benzodiazepines, topical lidocaine patch, and nonsteroidal anti-inflammatory drugs provides the most effective analgesia for mild to moderate chest wall pain.

For patients admitted to the hospital, an intercostal nerve block with a long-acting agent such as bupivacaine will relieve pain associated with muscle spasm and ventilation for up to 12 hours. Epidural analgesia or intrapleural catheters for administration of local anesthetics also relieve chest wall pain.[35] Epidural analgesia for blunt chest trauma may be a better choice than IV opioid analgesia.[36]

With the exception of direct local trauma, **it takes great force to fracture the first and second ribs,** given their short length, relative immobility, and protection by other structures in the upper chest. Such fractures can be associated with significant injuries to underlying organs such as blunt myocardial injury, bronchial tears, or a major vascular injury, with 15% to 30% associated with poor outcome, usually from head injury or rupture of a major vessel.

In patients with multiple fractured ribs (especially ribs 9, 10, and 11), unexplained hypotension may be the result of intra-abdominal bleeding from the liver or spleen. Consider imaging of the abdomen by CT or US in any patient with lower rib fractures. Patients with multiple fractured ribs will often have difficulty coughing or adequately clearing secretions and should be considered for 24- to 48-hour observation unit admission, especially the elderly or those with preexisting pulmonary disease.

FLAIL CHEST

Segmental fractures of three or more adjacent ribs anteriorly or laterally often result in an unstable chest wall physiology known as *flail chest*. This injury is characterized by a paradoxical inward movement of the involved chest wall segment during spontaneous inspiration and outward movement during expiration. Although paradoxical motion can greatly increase the work of breathing, the primary cause of the hypoxemia is contusion to the underlying lung. These patients may fatigue rapidly as a vicious cycle of decreasing ventilation, increased work of breathing, and hypoxemia may develop, resulting ultimately in sudden respiratory arrest.

Patients with mild to moderate flail chest and, importantly, little or no underlying pulmonary contusion or associated injury can often be managed without a ventilator. Adequate pain relief by analgesics or intercostal nerve block and maintaining good ventilation and pulmonary toilet are important adjuncts when managing these patients. **Indications for early ventilatory support include shock, severe head injury, comorbid pulmonary disease, fracture of eight or more ribs, other associated injuries, age >65 years, or arterial partial pressure of oxygen (Po2) <80 mm Hg despite supplemental oxygen.** Early intubation and ventilatory assistance in patients with flail chest reduce mortality compared with delaying intubation until the onset of respiratory failure.

The role of surgical fixation in the management of rib or sternal fractures remains controversial. The aim of fixation is to reduce the need for ventilatory assistance; however, improved pain relief and ventilatory support may achieve a similar goal.[37,38] The Eastern Association for the Surgery of Trauma recommends consideration of surgical fixation in flail chest patients requiring mechanical ventilation when thoracotomy is undertaken to manage other injuries (Table 261-3).[25]

STERNUM FRACTURE

Tenderness over the sternum may indicate sternal fracture. Sternal fractures usually occur at the body.[39] Lateral chest radiography can detect a fracture (**Figure 261-16**), but diagnosis is usually made by CT (**Figure 261-17**).[24] US is more sensitive and specific than chest radiographs for sternal fractures.[40,41]

Fracture of the sternum has been historically considered a marker of serious life-threatening injury, particularly cardiovascular injury. However, in clinical practice, it is the type of associated injury that determines morbidity and mortality. Patients with isolated sternal fractures and otherwise negative workup (including chest CT, echocardiogram, cardiac US, and cardiac enzymes at the time of presentation and 6 hours afterward) can safely be discharged home.[42] Current experience with sternal fractures as a result of motor vehicle crashes notes a 1.5% incidence of cardiac dysrhythmias requiring treatment and a mortality rate of <1%.[43] Such data suggest that sternal fractures are not an indicator of significant blunt myocardial injury. Patients with sternal fractures presenting with normal vital signs and an initial normal ECG should have a repeat ECG in 6 hours and, if unchanged, require no further workup for cardiac injury.[44,45]

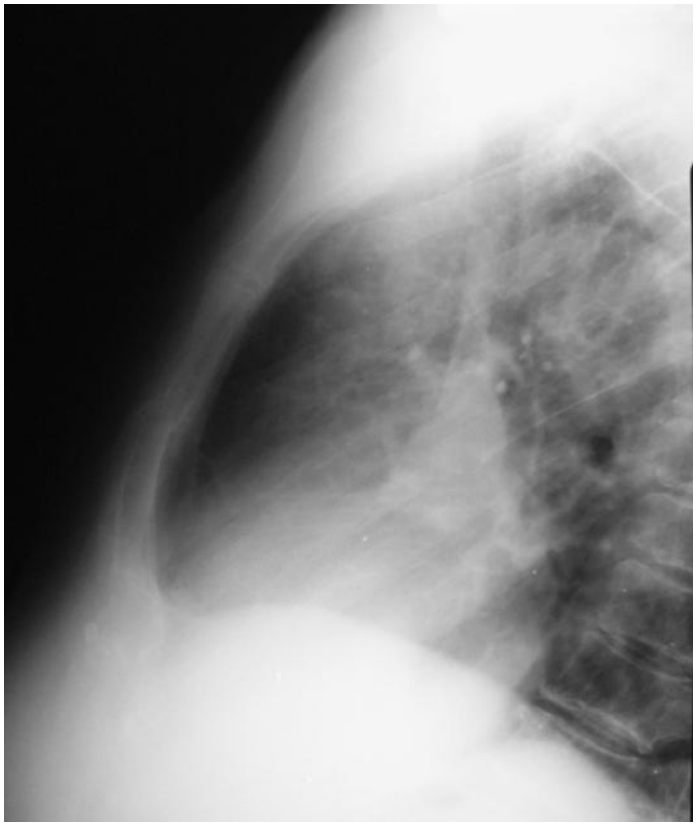

FIGURE 261-16. Sternal fracture. Lateral chest radiograph reveals a sternal body fracture after blunt chest injury.

FIGURE 261-17. Sternal fracture. Patient presents with seat belt sign on the chest wall and tenderness over the sternum. CT shows vertical fracture of sternum and mediastinal hematoma under the fracture.

TRAUMATIC ASPHYXIA

Sudden, severe crush injury to the chest may be associated with subconjunctival hemorrhage, petechiae, vascular engorgement, facial edema, and cyanosis of the head, neck, and upper extremities. This clinical picture is likely due to an abrupt sustained rise in superior vena caval pressure and concurrent closure of the airway after deep inspiration. Although these patients often look moribund initially, neurologic impairment, if any, is usually temporary, and any long-term morbidity is due primarily to associated injuries.

CHAPTER 262

Cardiac Trauma

Christopher Ross
Theresa Schwab

INTRODUCTION AND EPIDEMIOLOGY

Detection of cardiac injuries is critical for patient survival. Penetrating cardiothoracic injury causes 25% of deaths immediately following trauma, and the majority of these fatalities involve either cardiac or great vessel injury.[1] Cardiac injury may account for up to approximately 10% of deaths from gunshot wounds.[2] The incidence of blunt cardiac injury has been reported to range anywhere from 8% to 71%.[3] Suspect the diagnosis of cardiac and great vessel injury in a patient with chest, lower neck, epigastric, or precordial injury. Closely observe for evidence of hemodynamic instability, loss of circulating blood volume, electrocardiographic changes, cardiac tamponade, and hemothorax.

Penetrating cardiac injury results when a foreign object enters the body and pierces the pericardium or heart. Blunt cardiac injury results from physical forces acting externally on the body. Iatrogenic injuries to the heart are due to the invasive nature of procedures. All invasive cardiac procedures and therapies have the potential to cause trauma to both the pericardium and myocardium. Even noncardiac procedures like central lines placed into the internal jugular vein can lead to penetration of the pericardium, heart, and great vessels.[4]

PENETRATING CARDIAC TRAUMA

Most injuries occur from guns and knives.[5] The injury usually involves only the free cardiac wall, but other structures can be injured, such as cardiac valves, chordae tendineae, papillary muscles, atrial or ventricular septum, coronary arteries, and conduction system (**Table 262-1**).[6]

ANATOMY AND PATHOPHYSIOLOGY

Pericardial injury can result in acute tamponade. Rates of involvement of cardiac structures due to penetrating injuries to the right ventricle, left ventricle, right atrium, and left atrium are approximately 40%, 35%, 20%, and 5%, respectively.[7,8] The right ventricle is at greatest risk due to its large anterior exposure on the chest wall. The right and left atria are less frequently involved due to their smaller surface area. Knives tend to involve a single chamber, producing a single slit-like defect that is often more amenable to medical and surgical therapy than gunshot wounds. Gunshot wounds can leave a spectrum of injury from multiple-chamber perforation to gaping defects depending on the caliber and velocity of the missile. Patients with stab wounds to the heart are 17 times more likely to survive than those with gunshot wounds.[9] Atrial injuries are less common and generally less severe, whereas multichamber injuries are associated with higher mortality.

Thrombus (septic or sterile)
Infective endocarditis
Rhythm or conduction disturbance

The anatomic "cardiac box" (Figure 262-1) is the area of the chest bounded by the sternal notch superiorly, the xiphoid process inferiorly, and the nipples laterally. Most stab wounds injuring the heart enter through this area. Gunshot wounds, however, may enter at regions well outside this area, so any penetrating injuries involving the thoracoabdominal region, back region, or any potential of transmediastinal trajectory place the heart at risk for injury.

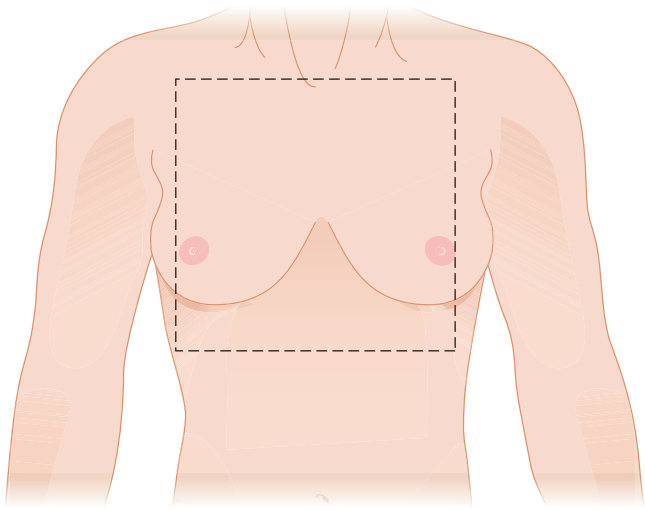

FIGURE 262-1. The cardiac box: chest area with potential for cardiac injury.

The two conditions that can occur after penetrating cardiac injury are exsanguinating hemorrhage and cardiac tamponade. Pericardial defects that are large or remain open may present with hemothorax and clinical signs of blood loss that may progress to rapid exsanguination and death. If the pericardial wound seals itself, which is common with the linear defect in a stab wound, the result is intrapericardial hemorrhage that may progress to cardiac tamponade. The location of the wound will also determine the rate of accumulation. Right ventricular wounds tend to seal themselves more readily than right atrial wounds due to the thicker, more muscular walls of the ventricle. Atrial injuries may have subtle or no clinical findings initially; however, rapid clinical deterioration can occur. Injury to the coronary arteries is manifested by tamponade or myocardial ischemia.

CARDIAC TAMPONADE

Cardiac tamponade, characterized by the accumulation of pericardial fluid under pressure, can be found in up to 2% of penetrating trauma to the thoracoabdominal region and very rarely in blunt trauma. Up to 80% of myocardial stab wounds may develop cardiac tamponade. Gunshot wounds leave defects in the pericardium that are larger and more irregular than stab wounds. Gunshot wounds are therefore less likely to develop tamponade because it is more difficult for the pericardium to seal the defect.[10]

Blood in the pericardial cavity may be defibrinated by the lytic activity normally present in the pericardium, resulting in a hematoma that may inhibit normal myocardial function. Intrapericardial blood accumulation eventually causes elevated intrapericardial pressure, which leads to decreasing right and left ventricular filling. Catecholamines are released in this state as a compensatory mechanism that results in tachycardia and further elevated right-sided filling pressures. Once the distensibility limits from intrapericardial fluid are reached by the pericardium, the myocardial septum shifts toward the left side, which further reduces left ventricular filling and subsequent cardiac output. This downward spiral eventually produces irreversible shock and death. Even small amounts of blood (65 to 100 mL) can lead to an acute rise in intrapericardial pressure. Hypovolemic shock from other injuries may partially or completely compensate for the elevated right-sided pressures, resulting in normal or even low central venous pressures.

Cardiac tamponade is identified by the FAST exam. Without bedside US, cardiac tamponade can be deceptively difficult to diagnose as the body compensates for the hemodynamic effects by various mechanisms. The reduced cardiac output is offset by the increase in heart rate and increase in systemic vascular resistance. Often, the only clinical finding of pericardial tamponade is sinus tachycardia. Hypotension may be a sign of ominous decompensation and emergent need for surgical intervention if due to pericardial tamponade or systemic hypovolemia from other injuries. The classic finding of Beck's triad of muffled heart sounds, hypotension, and distended neck veins is present in less than 10% of cases.[2] Pulsus paradoxus, a substantial fall in systolic blood pressure during inspiration, and Kussmaul's sign, an increase in jugular venous distention on inspiration, are not reliable signs and may only be found with moderate to severe tamponade.[11] A more reproducible sign of cardiac tamponade is a narrowing of the pulse pressure, which along with elevation of the central venous pressure, is cardiac tamponade until proven otherwise. The narrowed pulse pressure is not sensitive, and its absence should never be used to exclude tamponade. Usually the jugular venous pressure is elevated and may be associated with venous distention of the neck veins, forehead, and even scalp.

INTRACARDIAC MISSILES

The heart may have a retained missile from a direct injury or as a result of venous migration from another injury. These missiles, or the thrombus that may form as a result, may embolize into systemic or pulmonary arteries.[12] Many patients with a retained cardiac missile are hemodynamically stable. The patients may do well with prolonged observation and no operative intervention.[13] The treatment for missiles is highly variable, depending on missile size, shape, and location. Missiles that cause any hemodynamic instability or symptoms should be removed. A left ventricular missile that is free or partially exposed should be removed to prevent systemic embolization.[13] Right-sided missiles may be removed or left alone because embolization to the pulmonary vascular bed usually has minimal consequences.[14] Most intramyocardial and intrapericardial bullets and pellets are generally well tolerated and left in place. Embolized missiles need immediate removal because of the downstream ischemic effects of arterial occlusion. If a missile is embedded or adjacent to a coronary artery, it should be removed because of the potential for erosion and bleeding, which may lead to myocardial infarction and pericardial tamponade. Long-term effects of a retained missile may include bacterial endocarditis, thrombosis, embolization, and cardiac neurosis (many patients feel that they need any missile removed at all cost).[13]

IATROGENIC CARDIAC INJURY

Diagnostic and therapeutic percutaneous procedures may lead to many cardiovascular complications. Vascular (including extra- and intracardiac), valvular, and myocardial injuries are well-recognized complications of procedures such as central line placement, thoracentesis, chest tube placement, pericardiocentesis, percutaneous coronary catheterization, valvuloplasty, and electrophysiologic lab procedures.[15]

TREATMENT OF PENETRATING CARDIAC TRAUMA

Perform pericardiocentesis if cardiac tamponade is identified on the FAST exam. This may be an effective temporizing measure. Perform ED thoracotomy in unstable patients with cardiac tamponade who may not survive transfer to an operating room.

PERICARDIOCENTESIS

Pericardiocentesis is a prelude to formal thoracotomy if there are inevitable delays to definitive surgery (i.e., transport to trauma center). Use of US guidance of the needle increases accuracy and is a class I American College of Cardiology/American Heart Association recommendation for critically injured patients. Detailed discussion is provided in chapter 34, "Pericardiocentesis."

ED THORACOTOMY

Patients in extremis but with electrical cardiac activity should be rapidly transported to the ED. Resuscitative ED thoracotomy can be lifesaving in carefully selected patients. The decision to perform an ED thoracotomy or alternately determine that resuscitation is futile must be made in short order under highly stressful circumstances.

Candidates for ED thoracotomy include penetrating chest trauma patients who are hemodynamically unstable and those who demonstrated signs of life (palpable pulse, a blood pressure, pupil reactivity, any purposeful movement, organized cardiac rhythm, or any respiratory effort) either in the field or ED but subsequently lost these signs of life. Resuscitative ED thoracotomy is likely to be futile in patients under the following clinical scenarios: (1) no pulse or blood pressure in the field; (2) asystole is the presenting rhythm and there is no pericardial tamponade; (3) prolonged pulselessness (>15 minutes) at any time; (4) other massive, nonsurvivable injuries; or (5) blunt traumatic cardiac arrest.

Exposure to the heart is accomplished by a left anterolateral thoracotomy. No matter where the penetrating injury occurs, use the left-sided approach initially. This approach allows for quick access to the pericardium and heart and exposure for aortic cross-clamping if necessary. Identify the left fourth or fifth intercostal space, which corresponds to an intercostal space below the male nipple or at the inframamillary fold in a woman. Make the incision in a single stroke through all layers down through the intercostal musculature from sternum to posterior axillary line. Use Mayo scissors to cut the remaining intercostal muscles. Insert a Finochietto retractor with the crank positioned near the bed. Open the retractor to allow exposure of the left thorax. Remove blood and inspect for brisk bleeding. Control intrathoracic hemorrhage with direct pressure, the application of appropriate pulmonary or vascular clamps, and direct suture ligation. Gently push the lung out of the field

to expose the pericardium. To minimize the left lung obscuring the field, a right mainstem bronchus intubation may be performed.

A distended, discolored, and often tense pericardial sac confirms cardiac injury. Perform a pericardiotomy by making a long incision from the apex of the heart to the root of the aorta just anterior to the phrenic nerve. Remove any blood and clot from the pericardial sac. Patients who do not have blood in the pericardium and do not exhibit cardiac activity may be declared dead at this point. If there is evidence of blood in the pericardium or cardiac activity, then expose the heart for inspection. After extruding the heart through the incision in the pericardium, identify the cardiac wound. One of several techniques may be used to control hemorrhage (**Figure 262-2**). Simple digital occlusion on top of the wound is the first maneuver to attempt initial hemostasis. Never insert a finger into the wound because this may extend the defect. The defect can then be stapled with regular skin staplers, which is a quick and easy method of temporary cardiac repair. Suturing of wounds is often technically difficult due to the dynamic nature of the myocardium, the slippery edges, the ease with which the sutures pull through the myocardium, inadequate lighting, and bloody field. Putting a Foley catheter into the defect and blowing up the balloon can fill a large circular defect. Gentle traction on the catheter will allow the balloon to seal the defect. A purse string suture can then be placed around the Foley catheter so that when the catheter is removed, tightening of the suture will seal the defect. Myocardial defects can be sutured with horizontal mattress sutures, but use pledgets to reinforce the repair and prevent cutting through the heart tissue.

Perform internal cardiac massage in the absence of coordinated cardiac function. Whatever type of repair is attempted, be careful and do not ligate major coronary vessels. If there is no evidence of injury to the left side or there is a high index of suspicion of right-sided injury, the ED thoracotomy incision can be extended to the right side. This is done by extending the incision across the sternum ("clam shelling") in the same manner as the primary left-sided incision to gain access to the right side of the chest and allow for better exposure of the right ventricle and atrium. Patients with suspected intra-abdominal hemorrhage should have the descending aorta cross-clamped.

After resuscitative ED thoracotomy, if vital signs are regained, transfer the patient to the operating room for definitive repair. The survival rate for patients who make it to the operating room is 70% to 80% for stab wounds and 30% to 40% for gunshot wounds.

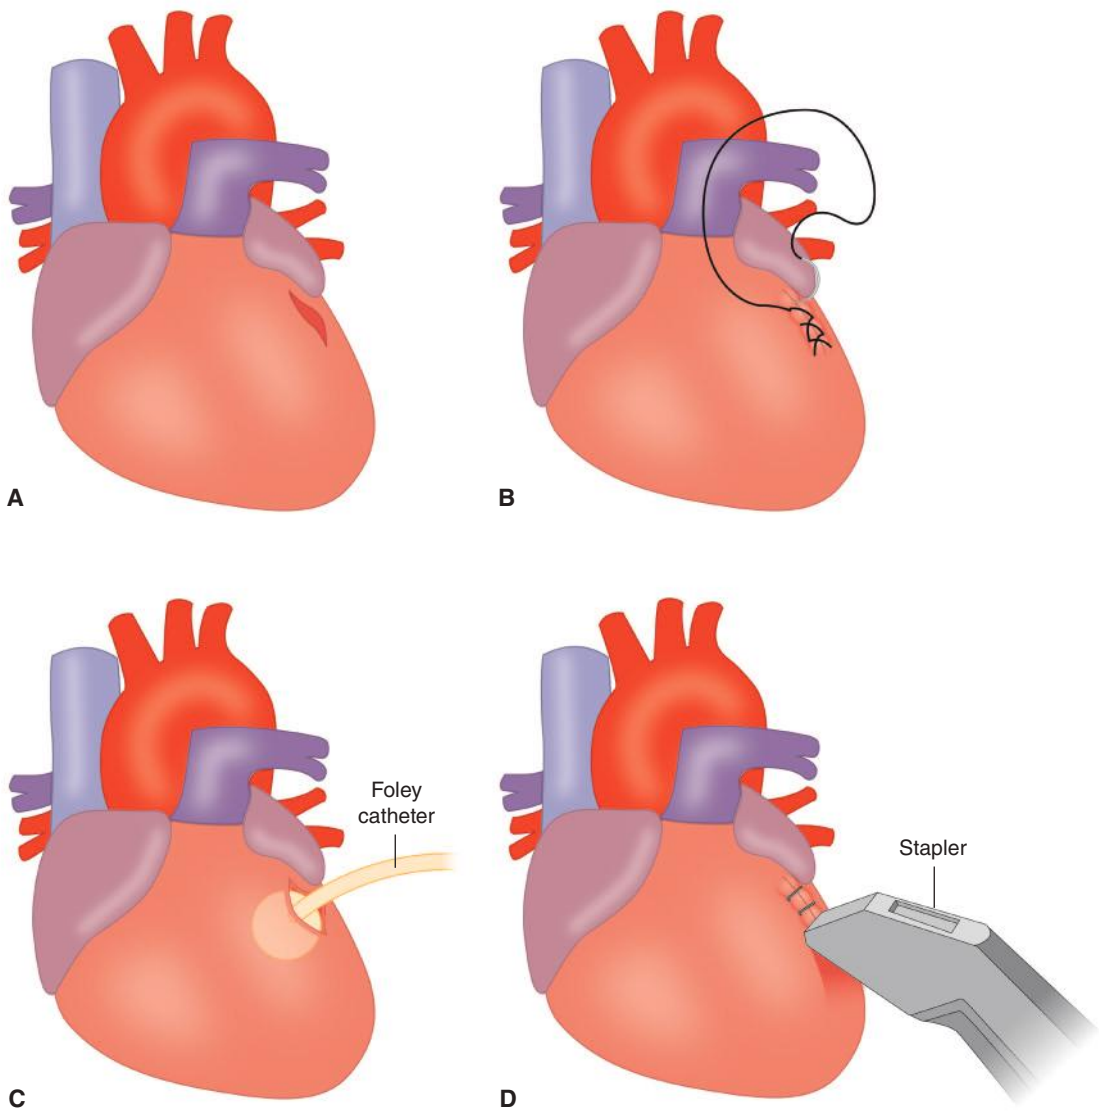

FIGURE 262-2. Temporary techniques to control bleeding of myocardial laceration. Emergency center management of injury to the epicardium. **A.** Stab wound to the left ventricle. **B.** Initially managed with either a continuous 4-0 polypropylene suture or interrupted sutures tied beneath the surgeon's finger. **C.** Injuries that are more complex and cannot be managed in the ED can be temporized using a Foley catheter for ventricular injuries and either a Foley catheter and/or partial occluding clamp for atrial injuries. **D.** Because of concerns about surgeon needle stick during cardiorrhaphy on the beating heart, hemostasis can initially be achieved with the skin stapler. Care must be observed in avoiding ligation of coronary arteries.

BLUNT CARDIAC TRAUMA

Up to 20% of all motor vehicle collision deaths are due to blunt cardiac injury, which can be sustained from any of the mechanisms listed in **Table 262-2**.[16] Rapid deceleration is the most common mechanism responsible for most blunt cardiac injury followed by a direct blow to the precordium. Blunt cardiac injury results in a range of conditions from clinically silent transient dysrhythmias to cardiac wall rupture

The most common reported injury is "myocardial or cardiac contusion." These terms are nonspecific and have been used to report a wide range of injuries. Further, there is not a clear definition or a gold standard for testing, which makes the diagnosis and treatment difficult. The term *blunt cardiac injury* has replaced the terms *cardiac contusion* and *myocardial contusion*. Blunt cardiac injury can encompass cardiac dysfunction (diminished contractility in the absence of dysrhythmia or hemorrhage), dysrhythmias, specific injuries (septal rupture, valvular injuries, myocardial infarction), and cardiac rupture, the most devastating blunt cardiac injury.[3,17,18]

PATHOPHYSIOLOGY

Blunt cardiac injury most often involves the right heart due to the anterior location of the right atrium and ventricle within the mediastinum. Injury often involves more than one chamber in over half of the reported cases.[19]

The pathologic changes seen in blunt cardiac injury typically include subendocardial hemorrhage and a much larger area of focal myocardial edema, interstitial hemorrhage, and myocytolysis with infiltrates of polymorphonuclear leukocytes. Additional myocardial injury may occur if there are concomitant intimal tears or compression from adjacent hemorrhage or edema. Myocardial injury may also be due to redistribution of coronary blood flow. Minor myocardial marker elevation or ECG abnormalities and dyskinesia or dysrhythmias resolve over time, usually within the first 24 hours.[16] Blunt cardiac injury can lead to death from complex dysrhythmias, acute heart failure, cardiac-free wall rupture, or laceration of a coronary artery that causes extracardiac hemorrhage. Most of these lethal mechanisms result in death at the scene of the injury.[20-22] Less severe injuries to the ventricular wall may lead to delayed necrosis and clinically manifest as delayed rupture days after admission. If a low-pressure chamber or coronary vein is injured, patients may survive until presentation to the hospital.[23]

Blunt cardiac injury can also result in rupture of an atrial or ventricular septum, resulting in shunting of blood and presentation similar to heart failure.[24] Similarly, blunt cardiac injury can result in regurgitation of blood from a high-pressure chamber or artery into a lower-pressure chamber, such as with an acute valve dysfunction or papillary muscle injury.[25,26] Valvular injury, as opposed to blunt myocardial injury, tends to worsen over time. The degeneration of the valve's function appears to depend on its location. High-pressure valves like the aorta and mitral valves tend to manifest symptoms immediately or within the first few weeks, whereas lower-pressure valves like the pulmonic and tricuspid can be asymptomatic for years.[16] Coronary arteries can have occlusion, dissection, or spasm that can manifest as immediate or delayed injury patterns. Coronary artery injury presents most often in a myocardial infarction pattern.[27]

Nonspecific signs and concomitant injuries will affect clinical presentation. These other findings in the trauma patient may make it difficult to determine whether symptoms stem from cardiac or other injuries. Specific signs of cardiac injury (e.g., distended neck veins or specific murmurs) may not be present if the patient is hypotensive from other injuries. Symptoms of cardiac injury may occur in a delayed fashion coincident with fluid resuscitation.

TABLE 262-2 Mechanisms for Blunt Cardiac Injury

Direct precordial impact
Crush injury from compression between the sternum and spine
Abrupt pressure fluctuations in the chest and abdomen
Shearing from rapid deceleration or torsion causing a tear in the heart at a point of fixation (right atrium and vena cava)
Injury from rib fracture fragments
Hydraulic effect resulting in cardiac rupture
Blast injury

COMMOTIO CORDIS

Commotio cordis, meaning "disturbance of the heart" in Latin, is sudden death as a result of blunt trauma to the chest wall. It often results from an innocent-appearing chest wall blow. It is the second most common cause of death in youth athletics following hypertrophic obstructive cardiomyopathy. Usually victims are young athletes who are struck in the chest by hard projectiles that are used in the particular sport. Sports using small dense projectiles like baseball, hockey, and lacrosse have the highest incidence of commotio cordis. The hardness of the impact object, location of impact, and velocity of the object impacts the risk of development of ventricular fibrillation. Commotio cordis blows are generally low impact, most of which are insufficient to cause any significant structural damage to the ribs, sternum, or heart. Commotio cordis is a primary electrical event resulting in the induction of ventricular fibrillation; it is a result of a blow that occurs 10 to 30 ms before the peak of the T wave, a time of vulnerability to ventricular fibrillation. Autopsy findings show normal cardiac anatomy with no evidence of injury. The overall survival rate is less than 15%, but due to increasing prevalence of automated external defibrillators being placed in sporting venues, survival rates may improve.[28]

CARDIAC DYSFUNCTION

The exact incidence of cardiac dysfunction (decreased contractility) in blunt cardiac injury is unknown. Further, the cause of dysfunction may be difficult to determine in the hypotensive, multiply injured trauma patient. Patients almost universally present with chest pain. The pain usually results from associated thoracic trauma (**Table 262-3**). Associated blunt injury to the lung can lead to a rise in pulmonary vascular resistance, which can result in a reduction in preload of the left ventricle. This, coupled with the reduced cardiac output of the involved right ventricle, can lead to hypotension.[18,29] The damaged myocardial tissue may be a focus for both atrial and ventricular dysrhythmias, which may further produce decreased contractility and hemodynamic deterioration.

Monitor for dysrhythmias. Persistent tachycardia, new bundle branch block, supraventricular tachycardia, atrial and ventricular fibrillation, and minor dysrhythmias (occasional premature ventricular contraction) can occur after blunt injury.

TABLE 262-3 Associated Injuries with Blunt Cardiac Trauma[3]

Associated Injuries	Incidence of Finding in Patients with Blunt Cardiac Injury
Thoracic injury	
Chest pain	18%–92%
Rib fracture	18%–69%
Aortic or great vessel injury	20%–40%
Hemothorax	7%–64%
Pulmonary contusion	6%–58%
Pneumothorax	7%–40%
Flail chest	4%–38%
Sternal fracture	0%–60%
Head injury	20%–73%
Extremity injury	20%–66%
Abdominal solid organ injury	5%–43%
Spinal injury	10%–20%

INJURY TO THE PERICARDIUM

Direct impact or increased intra-abdominal pressure can cause pericardial tears. The tears usually occur on the left side of the pericardium parallel to the phrenic nerve. Herniation can occur through the defect leading to cardiac dysfunction and dysrhythmias. These tears in the pericardium often are missed and may have little clinical impact. Physical examination (pericardial rub), point-of-care US, or CT findings (pneumopericardium, displacement of the heart, abnormal bowel gas in chest or around heart, or evidence of intra-abdominal contents inside pericardium) may lead to the diagnosis. Patients with detectable pericardial rents are usually taken to the operating room for repair unless the tear is too large so that closure would lead to tension on the pericardium and potentially produce myocardial dysfunction.

INJURY TO CARDIAC VALVES, PAPILLARY MUSCLES, CHORDAE TENDINEAE, AND SEPTUM

Injury to cardiac valves occurs in approximately 10% of blunt cardiac injury. Isolated valvular injuries appear to be rare. The aortic valve is most often involved, followed by the mitral and tricuspid valves. Injury to the aortic valve can cause severe regurgitation with development of pulmonary edema. Presentation may vary from new murmur to acute valvular insufficiency with right- or left-sided cardiac failure. A widened pulse pressure can be seen with acute aortic valvular injuries. Septal injuries are also rare with variable presentations, ranging from insignificant tears to frank rupture. They may occur in isolation or with valvular injury. The muscular portion of the septum can rupture several days after blunt trauma. Suspect patients with new-onset murmurs of having valvular, septal, or papillary muscle pathology. Any patients with clinical or echocardiographic evidence of injury require emergent surgical consultation. Treatment for septal and valvular injury is generally surgical, and timing depends on the presenting signs and acuity. Acute heart failure resulting from elevated pulmonary pressure due to structural injury warrants rapid surgical intervention, whereas small septal injuries with minimal clinical effects can be treated conservatively because many eventually close spontaneously.[30]

INJURY TO CORONARY VESSELS/MYOCARDIAL INFARCTION

Although blunt cardiac injury rarely leads to injury of the coronary vessels, arteriovenous fistula, coronary artery dissection, and coronary thromboses have been reported.[31,32] The most common artery involved is the left anterior descending artery. Coronary artery injury presents in the same fashion as atherosclerotic heart disease, has similar treatment by percutaneous coronary intervention with stenting, and has a more favorable prognosis. Because of the possibility of other injuries, extreme caution must be taken in using anticoagulation therapy due to bleeding complications.[31,32] Fibrinolytic therapy is contraindicated.

CARDIAC RUPTURE

The most severe form of blunt cardiac injury is cardiac rupture. Most patients with cardiac rupture die at the scene of the trauma. The right-sided portion of the heart is much more prone to rupture due to its more anterior location, as are the thin-walled atria compared with the thicker-walled, stronger ventricles. In patients who survive to ED arrival, the physical examination may reveal a "splashing mill wheel" sounding murmur ("bruit de Moulin"), but this finding is rare. ECG may show conduction defects or, if herniation has occurred, axis deviation. A skilled sonographer can rapidly reveal the diagnosis, and immediate thoracotomy is required for survival.[22]

CLINICAL FEATURES OF BLUNT CARDIAC TRAUMA

HISTORY

The most common symptom of cardiac trauma is chest pain. All different qualities of chest pain occur, ranging from pleuritic to pressure-like. Even the classic crushing retrosternal pain of myocardial ischemia can occur if coronary arteries are involved. Patients with injuries on the chest wall such as rib fractures, sternal fractures, or clavicular fractures may have underlying cardiac injury. Be cautious about attributing symptoms only to superficial chest wall because pericardial and myocardial structures may be damaged as well. Patients may have shortness of breath due to overlying chest and pulmonary injury or due to myocardial dysfunction from cardiac tamponade or heart failure. Other nonspecific symptoms such as lightheadedness and palpitations are also common.[18] Clinical findings vary widely depending on the structures injured, the extent of the injuries, concomitant injuries, and the patient's body habitus and mental status.

PHYSICAL EXAMINATION

Close observation of heart rate and blood pressure and their associated trends is important. Listening to breath sounds and heart sounds may assist in diagnosing cardiac injury. Clear lungs with muffled heart sounds may be indicative of cardiac tamponade, but this finding is quite rare and difficult to detect in a noisy ED. Course crackles in the lungs, extra heart sounds, and elevated jugular venous pressure may be present if myocardial dysfunction leads to heart failure. Often, the presence of unexplained tachycardia may be the only finding of cardiac injury.

DIAGNOSIS

ELECTROCARDIOGRAM

Place the patient on a cardiac monitor, and obtain an ECG. The negative predictive value for cardiac injury in a patient with a normal ECG is about 80% to 90%, but using the ECG alone does not exclude cardiac injury.[18,33] A clinically significant cardiac event can occur over the first 24 hours following injury.[34] The ECG is more sensitive for left ventricular injury than right-sided injury and is poorly sensitive for the more common right-sided injuries. Nondiagnostic findings on ECG, such as sinus tachycardia and nonspecific ST-T wave changes, do not help diagnose blunt cardiac injury. A small subset of blunt cardiac injury patients may have symptoms and ECG findings consistent with myocardial infarction. In such patients, consider coronary artery disease or acute coronary artery dissection, which may manifest with thrombosis of a cardiac artery and typically develops 5 to 7 days after injury[17,35] (**Table 262-4**).

In patients in whom concern for blunt cardiac injury exists but in whom the ECG is normal, monitor for 4 to 6 hours with repeat examinations,

TABLE 262-4 Electrocardiographic Findings in Cardiac Injury[36]

Nonspecific abnormalities
Pericarditis-like ST-segment elevation
Prolonged QT syndrome
Myocardial injury
New Q wave
ST-T segment elevation or depression
Conduction disorders
Right bundle branch block
Fascicular block
Atrioventricular nodal conduction disorders (first-, second-, and third-degree atrioventricular block)
Dysrhythmias
Sinus tachycardia (most common)
Atrial and ventricular extrasystoles
Atrial fibrillation
Ventricular tachycardia
Ventricular fibrillation
Sinus bradycardia
Atrial tachycardia

ECGs, and cardiac monitoring. If there are no new signs or symptoms and no abnormalities occur during this time period, patients can be safely discharged in absence of any other injuries.[37] If the ECG is abnormal but there is no hemodynamic instability, admit the patient to a monitored setting, with serial ECGs to monitor for disease progression.

CARDIAC BIOMARKERS

Although cardiac markers can be used to assist in the diagnosis of myocardial trauma, the utility of cardiac biomarkers in the setting of blunt cardiac injury remains unclear.[38] Creatine kinase has limited reliability in the trauma patient because it is elevated in cases of severe skeletal muscle, liver, diaphragm, or intestinal injury; the creatine kinase-MB fraction will therefore be elevated as well. Creatine kinase-MB fraction elevation has been shown to occur in this situation in the absence of clinical evidence of cardiac injury. The isolated elevation of creatine kinase-MB, with no other associated injury, is not predictive of complications and mortality.[39] Thus, obtaining creatine kinase-MB measurements is of no value.

Cardiac troponins, specifically troponin I and troponin T, are very specific to myocardial injury and can detect very small amounts of myocardial necrosis. Neither cardiac troponin I nor cardiac troponin T is released with skeletal muscle injury. Elevation of troponins occurs in all myocardial trauma, including both blunt and penetrating trauma, surgery, ablation, pacing, defibrillator shocks, cardioversion, and interventional cardiac procedures. The sensitivity and specificity of troponins for blunt cardiac injury vary from 12% to 23% and 97% to 100%, respectively.[33,40] Also, injuries remote from the chest from multisystem trauma and the presence of preexisting disease may result in dysrhythmia and elevated biomarkers, making their presence even less specific.[41]

Troponins in conjunction with a presenting ECG may increase the effectiveness of risk stratification. Patients with a normal ECG and normal serial measurements of serial cardiac troponin I had no significant blunt cardiac injury–related complications in one study.[42] The sensitivity of an abnormal ECG and elevated cardiac troponin I for clinically significant blunt cardiac injury (cardiogenic shock, dysrhythmias requiring intervention, or structural cardiac abnormalities related to trauma) was 100%, with a positive predictive value of 62%.[40] Clinically significant blunt cardiac injury can occur without elevation of troponins, but there is usually an abnormality of the ECG. Monitor any serum troponin elevation and follow serially. Increased troponin levels at admission or within 6 hours of arrival have correlated with increasing risk of dysrhythmia and decreased ejection fraction.[43] Troponin elevations have been associated with ventricular dysrhythmias and left ventricular dysfunction.[44]

Ultimately, the use of cardiac biomarkers may not affect the management of blunt trauma patients with hemodynamic instability, signs of severe injury, or an abnormal ECG. Such patients generally undergo echocardiography and are admitted regardless of biomarker elevation.

In rare blunt trauma patients with ECG findings of myocardial infarction, obtain cardiac biomarkers and immediately consult with cardiology and cardiac surgery.

ECHOCARDIOGRAPHY

The FAST examination includes a cardiac window using either the subxiphoid (**Figure 262-3**) or parasternal long-axis approach. This allows detection of free pericardial fluid and can give an estimation of general cardiac function. Point-of-care US has been shown to have a sensitivity of 100% and a specificity of 99% for detecting pericardial effusion.[45]

Point-of-care US is an invaluable tool for blunt trauma patients with unexplained, persistent shock out of proportion to apparent injuries and in any patients with signs consistent with blunt cardiac injury. Echocardiography provides information about global cardiac function, individual chamber function and wall motion, valvular function, and ejection fraction. It can also assist in alternative diagnoses for conditions such as aortic disruption/dissection, pericardial effusion, pleural effusion, and intracardiac thrombus.[46] Transesophageal echocardiography has been shown to be up to three times more sensitive in diagnosing blunt cardiac injury than transthoracic echocardiography.[47] Transthoracic echocardiography and transesophageal echocardiography, however, are not helpful in identifying patients at risk for developing blunt cardiac injury–related complications.[16] Order echocardiography for patients demonstrating elevated cardiac markers, dysrhythmias, or myocardial dysfunction.[48]

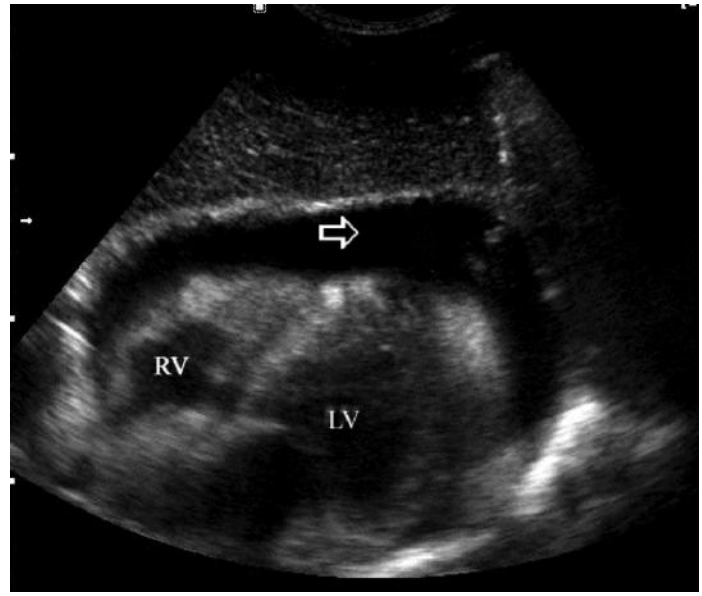

FIGURE 262-3. Traumatic pericardial effusion. Large pericardial effusion (*arrow*) after stab wound to chest visualized by subxiphoid approach of a FAST scan. The effusion can be seen outside the right ventricular (RV) and left ventricular (LV) walls.

TREATMENT OF BLUNT CARDIAC INJURY

Treat hypotension with boluses of crystalloid to optimize intravascular blood volume, which will also optimize preload. Trauma patients often have multiple injuries, especially in blunt injury, so the most common reason for hypotension is due to hypovolemia, not myocardial dysfunction.

Otherwise, the management of blunt cardiac injury (myocardial or cardiac contusion) is not standardized. The only universally accepted practice pattern is to observe patients with hemodynamic and continuous cardiac monitoring.[18] It is generally agreed that low-risk patients (minor injuries, no dysrhythmias, and normal ECG) usually will not develop complications so that further workup is not warranted. Moderate- to high-risk patients (evidence of associated injuries, dysrhythmias, abnormal ECG) should have an evaluation that includes myocardial markers and echocardiogram. Admission to ward telemetry is appropriate for the patient with minor ECG abnormalities (premature ventricular or atrial contractions), no significant concomitant injuries, and normal hemodynamics.[49,50] Telemetry monitoring criteria do not exist, but 24 to 48 hours of monitoring are reasonable for minor abnormalities.

Subsequent management depends on complications. After ruling out hypovolemia as the source of hypotension, inotropic support may be required to maintain cardiac output and blood pressure. Dysrhythmias that result in hemodynamic instability or are ventricular in origin are treated according to advanced cardiac life support algorithms. Evaluate patients who present in cardiogenic shock for a structural injury. Patients with cardiac rupture, valvular injury, papillary muscle or chordae tendineae rupture, or coronary thromboses or dissection require emergent surgery or percutaneous coronary intervention.

SPECIAL CONSIDERATIONS

PERICARDIAL INFLAMMATION SYNDROME

The cause of pericardial inflammation may be a delayed hypersensitivity reaction to the presence of damaged myocardium in the pericardial cavity. Consider this syndrome in individuals who develop chest pain,

fever, and pleural or pericardial effusions 2 to 4 weeks after cardiac trauma (or surgery). Patients may also have friction rubs, arthralgia, and pulmonary infiltrates. The ECG will often show ST-T wave changes consistent with pericarditis. Treatment is primarily symptomatic. Nonsteroidal anti-inflammatory drugs and rest can often reduce symptoms dramatically within 12 to 24 hours, and glucocorticoids are occasionally required. Rarely, drainage of pleural or pericardial fluid may be required to relieve symptoms or to exclude other problems.

INJURY TO THORACIC GREAT VESSELS

The thoracic great vessels consist of the aorta and its brachiocephalic trunk and its branches; the left subclavian, left common carotid, and pulmonary arteries and veins; the superior and intrathoracic venae cavae; and the innominate and azygos veins. Injuries to these vessels occur in both penetrating and blunt trauma. The large blood volume flowing through these vessels leads to exsanguinating hemorrhage as the primary acute manifestation of trauma. Even if not immediately ruptured, injury to these vessels can produce aneurysm and pseudoaneurysm through fistula formation, which in turn can lead to massive hemorrhage. Most patients who present with thoracic great vessel injury have sustained penetrating trauma and have a dire prognosis; most die before they reach medical care.[51] Aortic injuries from blunt trauma are usually due to motor vehicle crashes. Over 90% of patients who sustain this injury die at the scene; of the remaining 10% who survive, 50% die within 24 hours and 90% die within 4 months.[52] The mortality for untreated patients is 1% per hour for the initial 48 hours.[53]

PATHOPHYSIOLOGY

BLUNT INJURY

Blunt trauma injury to the great vessels involves high-speed deceleration. Usually the chest strikes the steering wheel, which subsequently transmits the force across the mediastinum. There may also be vascular compression of the vessels between the sternum and vertebral bodies and subsequent marked increases in intraluminal pressure.[53] Consider blunt aortic injury when the mechanism involves sudden deceleration such as a fall over 10 ft (3 m) or a motor vehicle collision at speeds greater than 30 mph (50 km/h).

The proximal descending aorta is most commonly injured in blunt trauma because of the fixation of the vessels between the left subclavian artery and the ligamentum arteriosum. The aorta is mobile and continues to move forward as the tethered portions decelerate with the remainder of the chest, leading to shearing forces that produce aortic injury. The diagnosis of ascending aortic injury is rarely made since very few patients survive long enough to diagnosis and repair. Ascending aortic injuries are frequently associated with cardiac rupture or severe myocardial contusion, and the aortic tears are often multiple. Usually large amounts of energy are required to injure the ascending aorta. The distal descending aorta is also a less frequently injured structure. Patients may present with paraplegia, mesenteric ischemia, anuria, or lower extremity ischemia. The more distal the injury, the better is the anticipated outcome, provided the patient does not exsanguinate prior to repair.

Although the subclavian artery is occasionally avulsed at its origin because of sudden deceleration, direct trauma to the distal artery with intimal damage and occlusion associated with fractures of the first rib or clavicle is more likely. Shoulder restraints that are loose may be a major factor in causing this injury. Injuries to the innominate artery are second in frequency only to rupture of the aorta at the isthmus. This injury is difficult to diagnose because less than half of patients have any physical findings at all and those who do have some diminution of the right radial or brachial pulse, a systolic murmur, or distal ischemia (rarely).

The pulmonic veins and the venae cavae attach to the atria and can serve as a nidus for injury with shearing forces. Venous thoracic great vessel injury is extremely rare, and most are fatal. Suspicion of inferior vena caval injury should occur with major hepatic injury, and both the superior and inferior venae cavae should be considered a source if there is cardiac tamponade or arterial bleeding that cannot be identified.

The aorta is primarily involved in about 85% of cases, but branch vessels are involved in 15% of documented vascular injuries.[54] The branch injuries are potentially fatal so their identification is of the utmost importance as well. Concurrent vascular injuries should be identified because the definitive surgical approach may change depending on where the injuries occur.[55]

PENETRATING INJURY

The pathophysiology of penetrating trauma to the great vessels is straightforward: either there is direct vessel injury or the kinetic energy damages the vessels by propagation through the tissues. Patients with penetrating injuries rarely survive to reach the hospital. Iatrogenic injuries from central line placement and other invasive thoracic procedures can lead to great vessel injury.

Bullets entering large systemic veins or the right heart can embolize to the lungs, whereas bullets entering the pulmonary veins or left heart can embolize to major systemic arteries. Some of these embolized foreign bodies do not cause symptoms or signs and can be located only after taking multiple radiographs. Suspect embolization if the missile appears distant from the anticipated trajectory. The other explanation for missiles off trajectory is gravity: low-velocity bullets that violate the pleural space but are not trapped in lung parenchyma often fall to the lowest place in the hemithorax, namely the posterior costophrenic recess.

CLINICAL FEATURES

Blunt trauma involving motor vehicle crashes can injure the aorta with side-impact collisions just as often as head-on collisions. Any blunt trauma from significant force (falls from a significant height, blast injuries, high-speed motor vehicle crash, crush injuries, pedestrian versus automobile injuries) can lead to blunt aortic injury.

Half the patients with blunt thoracic vascular injury present without external physical signs of injury. Although the physical examination findings of great vessel injury can be minimal to nonexistent, several important clues should be investigated. Hypotension, hypertension in the upper extremity and hypotension in the lower extremity, unequal blood pressures in the extremities, external evidence of major chest trauma (seatbelt or steering wheel contusion on the chest), thoracic outlet expanding hematoma, intrascapular murmurs or bruits, palpable fractures of the sternum and ribs, or flail chest should increase suspicion of great vessel injury.

Proximity of a missile trajectory to the brachiocephalic vessels, even without any physical findings of vascular injury, is an indication for pursuing a diagnosis of vascular injury. Close inspection of a penetrating wound should look for evidence, by inspection only, of retained implement or foreign body. Under no circumstances should the wound be deeply probed to determine depth or trajectory. Perform a complete neurologic examination due to involvement of the spinal arteries from the initial trauma.

DIAGNOSIS

CHEST X-RAY

Many findings on the initial chest radiograph may be indicative of great vessel injury (**Tables 262-5 and 262-6**), but many of these findings are insensitive and nonspecific.

Widening of the mediastinum on chest radiograph (**Figure 262-4**) has classically been considered as being a very sensitive test for detection of major vascular injury. Definitions of a widened mediastinum have included a measured width greater than 8 cm or a clinician gestalt of mediastinal widening and chest width ratio of >0.38. Trauma patients have <20% probability of having major thoracic vascular injury with this finding on chest radiograph.[56] However, a normal mediastinum on chest

radiograph does not rule out aortic injury. Therefore, the investigation of great vessel injury should occur if mechanism of injury, physical examination findings, or radiographic indicators are consistent with injury. One sensitive radiographic sign for traumatic aortic injury is deviation of the esophagus more than 1 cm to the right of the spinous process at T4.[57]

CT ANGIOGRAPHY

CT angiography is the diagnostic modality of choice for both penetrating and blunt trauma of the thorax. Because CT is widely used in the evaluation of multisystem trauma, incorporating CT imaging for vascular injury can be easily done. Newer-generation multidetector scanners are very sensitive and specific for injury to the great vessels. Three-dimensional reconstructions of high-resolution data sets produce extremely accurate representations of the vascular anatomy and may be the only diagnostic imaging studies required by vascular surgeons. Although CT does require the patient to leave an intensive monitoring area, the information it provides can lead to treatment avenues vital for patient survival. Full-body scans are relatively rapid, with image acquisition occurring in less than 5 minutes. In comparison to classical angiography, CT angiography is faster, less expensive, and eliminates complications related to vessel catheterization. Most institutions use multidetector CT scanners with CT angiography as the screening study of choice for aortic injury. Thin-slice multidetector CT with rapid scanning and contrast-bolus timing has shown great promise in detecting and localizing a variety of nonaortic vascular injuries, including active bleeding that can lead to early surgical or angiographic intervention to control blood loss.[55] Major CT angiography findings for blunt trauma can be seen in **Table 262-7**.

The major role of CT in penetrating trauma is determination of the presence or absence of mediastinal involvement along or near the course of the penetrating object (**Figure 262-5**). This can lead to direct finding

TABLE 262-6 Reliability of Selected Clinical and Radiographic Criteria in the Detection of Traumatic Rupture of the Aorta*†

Chest X-Ray Finding	Correlation with TAI (*P* value)	Sensitivity	Specificity	Accuracy
Widened mediastinum (<65 years old)	.001	0.95	0.82	0.84
Widened mediastinum (all ages)	.001	0.80	0.82	0.82
Murmur	.002	0.32	0.93	0.84

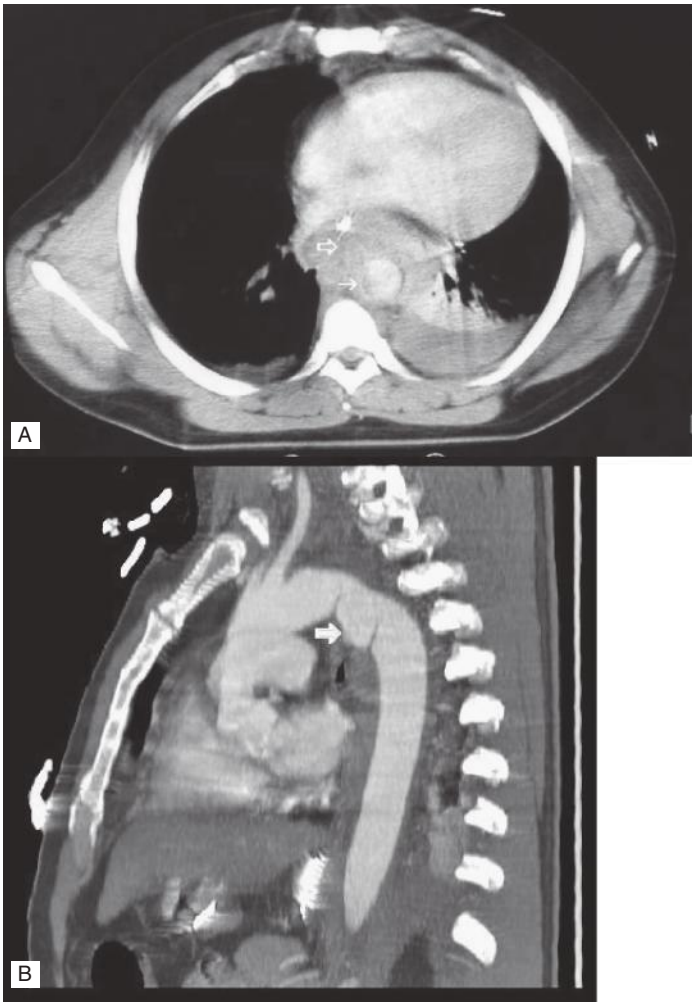

FIGURE 262-5. CT scan of traumatic aortic injury. **A.** Axial CT scan showing mediastinal hematoma (*open arrow*) and irregularity and thrombus in the aorta (*closed arrow*). **B.** Sagittal CT scan of same patient with pseudoaneurysm (*arrow*) from tear in aorta distal to left subclavian artery.

of injury to major mediastinal structures. Aortic or major arterial injuries can be detected and appear as irregular vascular contours, luminal narrowing or irregularity, pseudoaneurysms, dissections, and acute bleeding. CT angiography is also helpful in penetrating injury to the thoracic great vessels.[55] In some cases, the vessel lumen may appear completely normal on CT due to the external forces to the vessel. Damage surrounding the vessel, usually in the form of perivascular hemorrhage, is present. Following the tract of the missile on CT should also help in determining the likelihood of direct vascular involvement.[55]

OTHER IMAGING MODALITIES

MRI and magnetic resonance angiography provide similar detailed information. However, MRI and magnetic resonance angiography require lengthy study times, have limited emergent availability at most institutions, and require the transport of a potentially unstable patient away from a monitored environment. These limitations make MRI and magnetic resonance angiography impractical for most trauma patients presenting to the ED.

Transesophageal echocardiography remains a very attractive diagnostic option because of its advantages of speed, portability, immediate availability of results, and low cost. With recent advances in echocardiographic instrumentation and technology, it has evolved as a promising imaging technique that can provide comprehensive information of the location and extent of aortic injury. Transesophageal echocardiography

FIGURE 262-6. Angiogram of the same patient in Figure 262-5 showing pseudoaneurysm (*open arrow*) and irregular lumen (*closed arrow*) of injured aorta.

allows diagnosis of limited intimal lesions frequently missed by other conventional methods and permits rapid diagnosis of complete rupture at the bedside hemodynamically unstable patients. One study demonstrated that despite significant blurring of the aortic outline in 20% of cases and intraluminal artifacts being observed in 36% of cases, the accurate diagnosis of traumatic aortic injury was made.[58] Transesophageal echocardiography is contraindicated in patients with potential airway problems or suspected cervical spinal injuries.

Aortography remains a viable imaging option for determining the location of aortic injury, which is paramount in operative management (**Figure 262-6**). Angiography is more time consuming to perform, invasive, and not as readily available as CT on an acute basis. It more expensive than CT as a screening study. Angiography is useful when CT results are indeterminate and may be required by surgeons for planning and guiding operative repair. Angiography may be used to pursue injury in the aorta or branch vessels in penetrating injuries that have only proximity to these vessels. Caution should be exercised with "negative" results because a clot or an intimal flap may close the luminal defect. The overall complication rate of angiography has remained at about 25%, but rates for serious complications, such as amputation and death, remain low at 0.1% and 0.3%, respectively.[59]

TREATMENT

Consult a trauma or vascular surgeon at the time of initial suspicion of great vessel injury or immediately upon diagnosis. Transport patients with great vessel injury who exhibit hemodynamic instability, profound hemorrhage from chest tubes, and radiographic evidence of a rapidly expanding mediastinal hematoma immediately to the operating room.

Immediate surgical repair may not be possible in all patients. Patients with instability from other injuries, such as from intra-abdominal injuries or severe closed head injuries, may have a delayed repair due to the severity of these other life-threatening issues. Some elderly patients may have comorbidities that require medical management prior to surgery. Pharmacologic control of blood pressure and heart rate is extremely important when delayed or nonoperative management is contemplated.[60] Avoid large swings in blood pressure that may increase vessel-shearing

forces in patients who are hemodynamically stable. Administer sedatives, analgesics, vasodilators, and β-adrenergic blocking agents to keep the patient's systolic blood pressure at safe levels. Use autotransfusion devices in cases of large bleeding vessels.

Traumatic aortic injuries can be partial thickness (as in the classic intimal flap of aortic dissection) or full thickness with containment by surrounding structures. These histopathologic entities mandate a similar therapeutic approach as aortic dissection. Decreasing the slope of the dP/dT (change in pressure over the change in time) will decrease wall tension and shearing forces. This may lead to permissive hypotension and bradycardia as a treatment and temporizing measure in aortic disruption. **Maintain systolic blood pressure in the 100 to 120 mm Hg range with a heart rate around 60 beats/min.** This will decrease the shearing forces on the internal lumen. Patients should not perform any maneuver, like a Valsalva, that will increase intrathoracic pressure. Titrating a short-acting β-blocker, such as esmolol, can decrease the heart rate. Once the heart rate is controlled, an arterial vasodilator, such as sodium nitroprusside, can be added to help control the blood pressure. Do not use sodium nitroprusside alone due to the reactive tachycardia associated with its administration.

CHAPTER 263

Abdominal Trauma

L. Keith French
Stephanie Gordy
O. John Ma

INTRODUCTION

Abdominal trauma accounts for 15% to 20% of all trauma deaths.[1] Although the liver is the most frequently injured abdominal organ, the spleen is the most frequently injured intra-abdominal organ from sports accidents.[2] Death may occur as a consequence of massive hemorrhage and generally results in early demise soon after the injury. Patients who survive the initial traumatic insult are at risk for infection and suffer mortality or morbidity secondary to sepsis.

PATHOPHYSIOLOGY

BLUNT ABDOMINAL TRAUMA

The most common mechanism for blunt abdominal trauma is a motor vehicle collision.[1] All abdominal structures are at risk, and ultimately the biomechanics of the traumatic force determine which organs are affected. Compressive, shearing or stretching, and acceleration/deceleration forces impact the abdominal cavity differently. This potentially leads to abdominal wall, solid organ, or hollow viscous injuries. Abdominal organs may be relatively mobile or fixed. Injury is common in transition areas between these structures. The ligament of Treitz and the distal small bowel represent transition areas where mesenteric or small bowel injuries may occur.

Falls from significant heights produce injury as a function of the fall distance, the surface the victim lands on, and the manner of surface impact. Hollow viscous rupture is the typical intra-abdominal injury.[3] Retroperitoneal injury and hemorrhage may occur as force is transmitted along the axial skeleton.

Pedestrians struck by vehicles or motorcyclists and bicyclists who crash generally have no protection to their abdomen and are at high risk for intra-abdominal injuries.

PENETRATING ABDOMINAL TRAUMA

Stab and gunshot wounds produce injury as the foreign object passes through tissue. With gunshot wounds, there may be additional injury from the transmitted energy of the blast. Furthermore, gunshot wounds create secondary missiles such as fragmented bone that may increase the traumatic burden.

The length, trajectory, and fragmentation of the penetrating object will not necessarily be known during the evaluation. **Therefore, assume any penetrating injury to the lower chest, pelvis, flank, or back to have penetrated the abdominal cavity until proven otherwise.**

CLINICAL FEATURES

Clinical signs may be obvious (such as evisceration) or occult. Factors making the diagnosis of an abdominal injury challenging include concomitant injuries (particularly significant head injuries), referred pain, intoxication with alcohol or other toxicological substances, or language barriers. Young, healthy patients may be able to compensate for intra-abdominal hemorrhage before clinical signs become overt.

PHYSICAL EXAMINATION

Inspect the abdomen for external signs of trauma (e.g., abrasions, lacerations, contusions, seatbelt marks). A normal-appearing abdomen does not exclude serious intra-abdominal injury. **Cullen's sign** and **Grey Turner's sign** (periumbilical and flank ecchymosis) generally represent delayed findings of intraperitoneal bleeding. Following inspection, palpate the abdomen in all quadrants, making note of tenderness, tympany, or rigidity. For patients who are observed in the ED, serial assessments by the same provider are ideal.

Abdominal tenderness, rigidity, distention, or tympany may not be present during the initial examination and may take hours or days to develop. Reliance on physical exam alone, particularly with a worrisome mechanism of injury, may result in an unacceptably high misdiagnosis rate. As many as 45% of blunt trauma patients thought to have a benign abdomen on initial physical exam are later found to have a significant intra-abdominal injury.[4]

ABDOMINAL WALL INJURIES

Contusions of the abdominal wall musculature may result either from a direct blow or indirectly via a sudden muscular contraction. Symptoms include pain with flexion and rotation of the trunk as well as focal tenderness to percussion. Rectus abdominis hematomas may mimic intra-abdominal injury. Rectus hematomas occur from epigastric trauma or injury to the vessels of the abdominal wall. As a hematoma develops between the rectus sheath, the patient develops pain and often a palpable mass inferior to the umbilicus.[2]

SOLID ORGAN INJURIES

Signs and symptoms of a solid organ injury are generally due to blood loss. An increase in pulse pressure may be the only clue to loss of ≤15% of total blood volume. As blood loss continues, heart and respiratory rate increase. Hypotension may not occur until a 30% decrease in circulating volume occurs. At this point, urinary output drops and patients may become anxious and confused. With some injuries, pain and bleeding may be minimal and overlooked or dismissed. Delayed rupture can occur in splenic and hepatic injuries.

Splenic injuries may cause referred pain into the left shoulder or arm. Patients with liver injuries may complain of right shoulder pain. **Pregnancy and mononucleosis are conditions that may predispose a patient to splenic injuries.**

HOLLOW VISCOUS AND MESENTERIC INJURIES

In blunt abdominal trauma, the incidence of blunt bowel and mesenteric injuries varies (1% to 12%) but occurs in about 5% of patients.[5,6] Hollow viscus injuries produce symptoms from the combination of blood loss and

peritoneal contamination by GI contents. Hemorrhage from a mesenteric injury may be minimal and not be obvious on physical exam. Chemical irritation of the peritoneum from gastric acid contents may produce immediate pain, although bacterial contamination of the abdominal cavity may result in delayed signs and symptoms. Delays in diagnosis and operative management are associated with an increase in mortality.[6]

RETROPERITONEAL INJURIES

The retroperitoneal structures discussed in this chapter include the pancreas (excluding the tail) and duodenum. See "Genitourinary Injuries" for a discussion of kidney, ureter, and bladder injuries.

Pancreatic injuries are present in approximately 4% of patients with abdominal trauma and are associated with significant morbidity and mortality.[7] There are no specific signs and symptoms of pancreatic injury, but mechanism of injury provides some clues to diagnosis. Pancreatic trauma often occurs from rapid deceleration. Unrestrained drivers who hit the steering column or bicyclists who fall against a handlebar are at risk for pancreatic injuries. Initial symptoms may be delayed if the injury is minor.

Duodenal injuries may be relatively asymptomatic on presentation, and a small hematoma of the duodenum may go undiagnosed. As a duodenal hematoma expands, however, signs and symptoms of gastric outlet obstruction develop (abdominal pain, distention, and vomiting). Duodenal rupture generally occurs following high-velocity deceleration events where the intraluminal pressure of the pylorus and proximal small bowel rapidly increases. The ruptured contents are generally contained within the retroperitoneum and may be missed with studies that investigate the peritoneum exclusively. For patients with a delayed presentation, fever and leukocytosis herald the development of an abscess or sepsis.

DIAPHRAGMATIC INJURIES

The diaphragm may spasm secondary to a direct blow to the epigastrium. The patient will experience difficulty breathing as the diaphragm loses its ability to relax and allow the lungs to expand. This process is sometimes referred to as "getting the wind knocked out." As the diaphragm relaxes, symptoms abate.

Diaphragmatic rupture may result from a penetrating injury or blunt force mechanism. The condition is uncommon (0.8% to 5% of patients with thoracoabdominal injury) and is almost exclusively a **left-sided** phenomenon.[8] Signs and symptoms are nonspecific and may be attributed to associated injuries. Failure to diagnose and treat diaphragmatic rupture may lead to delayed herniation or strangulation of abdominal contents through the diaphragmatic defect.

DIAGNOSIS

Although multiple diagnostic modalities exist to detect intra-abdominal injuries, no study is fail proof. Therefore, a combination of careful physical exam, attention to the mechanisms and circumstances of injury, and judicious selection of diagnostic studies is used for diagnosis. Hemodynamic instability may limit the utilization of some diagnostic testing before definitive treatment is initiated (such as laparotomy or transfer to a trauma center).

Not every patient with multisystem or isolated abdominal trauma will need a diagnostic evaluation beyond a physical exam. However, because the consequences of a missed intra-abdominal injury may be significant, augment an initial exam with laboratory analysis, imaging study, or repeat examination in several conditions (**Table 263-1**).

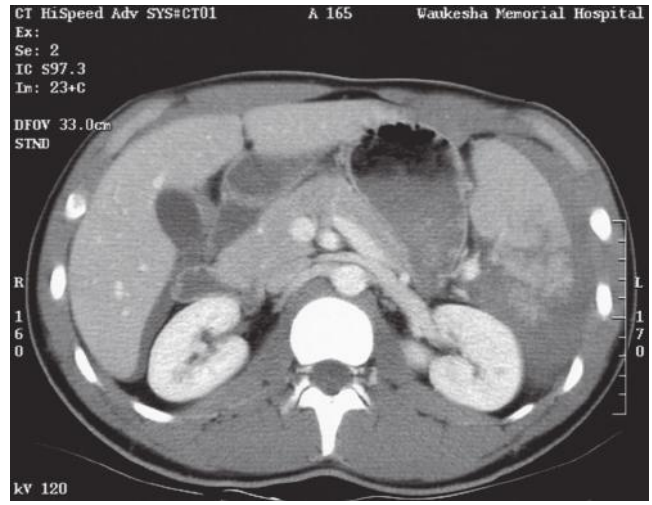
ULTRASONOGRAPHY

The focused assessment with sonography for trauma (**FAST**) examination is a widely accepted primary diagnostic study. The underlying premise of the FAST exam is that many clinically significant injuries will be associated with free intraperitoneal fluid (**Figure 263-1**). **The greatest benefit of FAST is the rapid identification of free intraperitoneal fluid in the hypotensive patient with blunt abdominal trauma.**

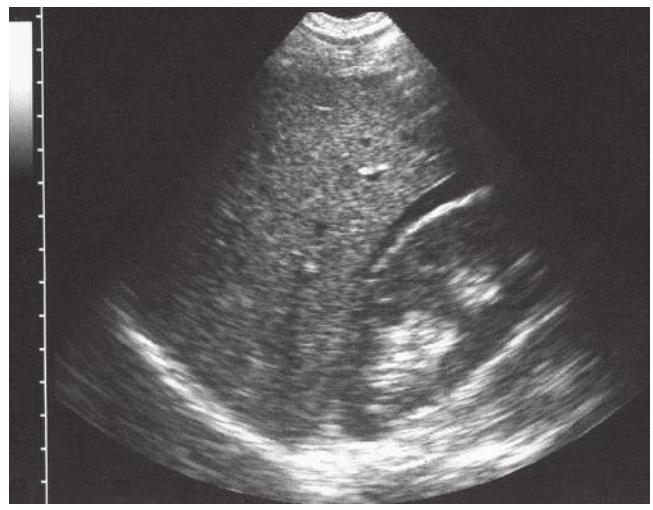
TABLE 263-1 Abdominal Injuries That Need Expanded Evaluation

Presence of abdominal pain, tenderness, distention, or external signs of trauma
Mechanism of injury with a high likelihood of causing an abdominal injury
Suspicious lower chest, back, or pelvic injury
Inability to tolerate a delayed diagnosis (e.g., patients who are elderly, on anticoagulants, or have liver cirrhosis/portal hypertension)
Presence of distracting injuries
Altered consciousness/sensorium (e.g., CNS injury, intoxicating substances)

Advantages of the FAST examination are that it is accurate, rapid, noninvasive, repeatable, and portable, and involves no nephrotoxic contrast material or ionizing radiation exposure to the patient. There is limited risk for patients who are pregnant, coagulopathic, or have had previous abdominal surgery. The average time to perform a complete FAST examination of the thoracic and abdominal cavities is 4 minutes or less.[9] Massive hemoperitoneum is quickly detected with a single view of Morrison's pouch in 82% to 90% of hypotensive patients,[10,11] and this maneuver required an average of only 19 seconds in one study.[10] One



A



B

FIGURE 263-1. Hemoperitoneum. The abdominal IV contrast CT. **A.** A fractured spleen with surrounding hematoma is demonstrated, but a small stripe of fluid is also present above the right kidney in Morrison's pouch. **B.** A right intercostal oblique US view from the same patient reveals a thin stripe of fluid in Morrison's pouch. [Reproduced with permission from Ma OJ, Mateer JR, eds: *Ma and Mateer's Emergency Ultrasound,* 3rd ed. © 2014, McGraw-Hill, Inc. New York.]

major advantage of the FAST examination compared to diagnostic peritoneal lavage (DPL) is the ability of FAST to also evaluate for free pericardial or pleural fluid and for pneumothorax.

The main disadvantage of US compared to CT is the inability to identify the exact source of free intraperitoneal fluid. This limitation may change with the adoption of contrast-enhanced US for the identification and treatment of solid organ injuries.[12,13] Other potential disadvantages of the FAST examination are the operator-dependent nature of the examination, the difficulty in interpreting the images in patients who are obese or have subcutaneous air or excessive bowel gas, and the difficulty in distinguishing intraperitoneal hemorrhage from ascites. The FAST examination also cannot evaluate the retroperitoneum as well as CT. Therefore, US and CT are complementary rather than competing technologies when time permits and the potential benefits of CT outweigh the risks.

US has other useful applications in the trauma bay. For example, US may guide the placement of a suprapubic catheter when indicated. The inferior vena cava diameter of trauma patients, as measured on initial CT imaging, is a marker of intravascular volume and a predictor of mortality.[14,15] Although the best modality to measure inferior vena cava diameter is debated,[16] US can be a clinically helpful tool for trauma resuscitation.

Because the FAST examination can reliably detect small amounts of free intraperitoneal fluid and can estimate the rate of hemorrhage through serial examinations, US has essentially replaced DPL for blunt abdominal trauma in the majority of North American trauma centers. A positive DPL in isolation is no longer an absolute indication for exploratory laparotomy; the amount of hemorrhage and the hemodynamic status of the patient are important factors for determining further management steps.

COMPUTED TOMOGRAPHY

Abdominopelvic CT with IV contrast is the noninvasive gold standard study for the diagnosis of abdominal injury (unless the patient has allergy to iodinated contrast). The addition of PO contrast can result in aspiration and is too time-consuming to be practical in trauma management. Although most institutions use IV contrast CT for trauma assessment, there are still some institutions that use noncontrast CT or add PO contrast in the evaluation of trauma.[17] The major advantage of IV contrast CT over other diagnostic modalities is that the precise location(s) and grade of injury can be identified (Figure 263-1). CT can quantify and differentiate the amount and type of free fluid in the abdomen. Because CT can evaluate for retroperitoneal injuries, it is the ideal study for assessment of the duodenum and pancreas. The use of multiphasic CT (arterial, portal, and equilibrium phases) accurately identifies life-threatening mesenteric hemorrhage and transmural bowel injuries.[5] CT evidence of a flat inferior vena cava suggests hypovolemia.

Some patients with free intraperitoneal fluid seen on CT with IV contrast but without an obvious solid visceral injury may have a very small liver or splenic injury that is missed by CT, although mesenteric or small bowel injuries must also be considered. Often the safest course is surgical exploration to avoid late diagnosis of GI perforation or ischemia. Careful observation and repeat CT with the addition of oral contrast is also an option.

Two distinct disadvantages of CT are the ionizing radiation burden and the need to leave the trauma bay to obtain imaging. Radiation is of great concern in children and young adults. Although CT is the most sensitive modality, use it judiciously based on the clinical circumstances. Furthermore, limit the practice of repeat CT imaging following transfer to another facility whenever possible. Outcomes and time to definitive care are not significantly improved when imaging is repeated at the accepting trauma center.[18]

DIAGNOSTIC PERITONEAL LAVAGE

Despite the reproducibility and prospectively validated sensitivity of DPL to diagnose intraperitoneal injury, the advent and acceptance of other diagnostic modalities have reduced the frequency of DPL.[19] DPL can be performed using a closed (**Figure 263-2**) or open technique. However, the open DPL technique requires advanced training and expertise. Some advocate the use of DPL in the hemodynamically unstable patient with concern for intra-abdominal injury when the FAST exam is negative.[19] **Table 263-2** lists criteria for laparotomy based on DPL results.[20]

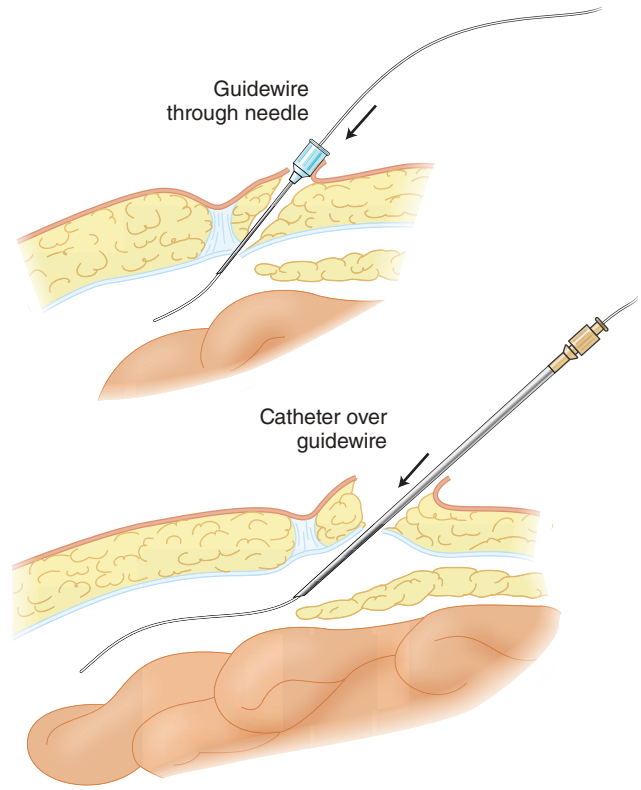


FIGURE 263-2. Closed diagnostic peritoneal lavage. Drain the urinary bladder. Infiltrate the area just below the umbilicus with lidocaine and epinephrine. Insert the needle two fingerbreadths below the umbilicus. Aspirate directly with a syringe attached to the needle, or insert a guidewire into the abdomen and place the peritoneal lavage catheter over the guidewire. Instill 1 L of normal saline through the catheter, and then aspirate.

DIAGNOSIS IN PENETRATING TRAUMA

The same diagnostic tools are available for evaluation of intraperitoneal injury in the patient with penetrating trauma (CT, US, and DPL). Mandatory exploration for patients sustaining a stab wound to the abdomen has yielded unacceptably high rates of nontherapeutic laparotomy,[21] yet physical exam alone can miss important intra-abdominal injuries. **Locally explore anterior abdominal stab wounds** (**Figure 263-3**) to assess for violation of the peritoneum. Patients with transabdominal gunshot wounds almost always have intra-abdominal injuries. In the hemodynamically stable patient with penetrating trauma, CT can help guide the surgeon for operative versus nonoperative management.[22]

TREATMENT

LAPAROTOMY

Laparotomy remains the gold standard therapy for significant intra-abdominal injuries. It is definitive, rarely misses an injury, and allows for complete evaluation of the abdomen and retroperitoneum. **Table 263-3**

TABLE 263-2 Criteria for Positive Diagnostic Peritoneal Lavage

>10 mL free flowing blood immediately on aspiration
>15,000 RBC/mm^3 in abdominal wounds or >25,000 RBC/mm^3 in lower chest wounds

Abbreviation: RBC = red blood cell.

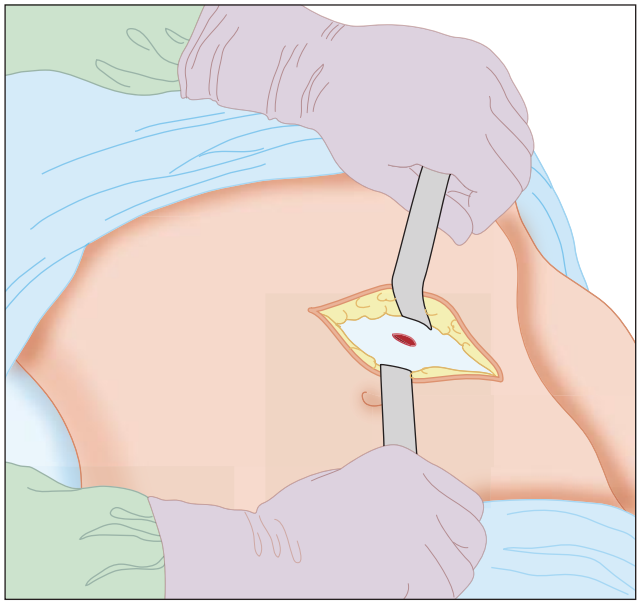

FIGURE 263-3. Local abdominal wound exploration for anterior abdominal stab wounds. This is a surgical procedure requiring expertise, proper instrumentation, and lights. Use only for anterior abdominal stab wounds. Widen the stab wound and explore down to the level of the fascia to determine if the anterior fascia and/or posterior fascia have been violated.

describes generally accepted indications for exploratory laparotomy. **All patients with persistent hypotension, abdominal wall disruption, or peritonitis need surgical exploration.** In addition, the presence of extraluminal, intra-abdominal, or retroperitoneal air on plain radiograph or CT should prompt surgical exploration. Some patients with positive DPL or FAST examination can be managed nonoperatively. In smaller medical centers or community hospitals, transfer to a trauma center may best serve such patients.

NONOPERATIVE MANAGEMENT OF BLUNT TRAUMA

Nonoperative management of trauma patients has been greatly advanced by the evolution of CT. CT can make the diagnosis of solid organ injury along with ruling out other injuries requiring surgery. Solid visceral injuries are graded according to their severity.

CT grading may not agree with intraoperative observation and does not always predict the success of nonoperative management. CT precisely reveals the condition of the internal parenchyma but not external injury anatomy. Operative grading provides an excellent external view of the organ, but may underestimate internal damage. **CT is a single snapshot in time, not a dynamic assessment.**

As patients age, the capsule of the spleen and liver weakens. Parenchymal changes may occur as well. The consequences of rebleeding increase and the failure rates of nonoperative management are much higher in the older population than in a younger population for some injuries. Accordingly, nonoperative management of even very severe injuries is the norm in children but not necessarily in adults.

Several technologic advances have increased the sophistication of nonoperative therapy. The increased resolution of helical CT can identify intraparenchymal vascular injuries (i.e., pseudoaneurysms or arteriovenous fistulae) and active extravasation of contrast. Patients without vascular injury can usually be managed nonoperatively. In patients in whom vascular injury is diagnosed, percutaneous transcatheter embolization with either stainless steel coils or Gelfoam pledgets can reliably arrest hemorrhage.

For patients with suspected abdominal trauma who present in extremis, **resuscitative endovascular balloon occlusion of the aorta** for end-stage shock is gaining attention as a way to quickly stop suspected intra-abdominal hemorrhage.[23] Resuscitative endovascular balloon occlusion of the aorta is a percutaneous method to achieve temporary occlusion of the aorta, to maintain or increase perfusion to the heart and lungs in the setting of shock from blunt and penetrating injury, and to avoid the morbidity of a thoracotomy for control of the proximal aorta. The femoral artery is accessed, typically percutaneously with US guidance. Using the Seldinger technique, a sheath is introduced, and a latex balloon is placed inside the sheath, with sheath length and balloon size based on the level of the aorta to be occluded. For resuscitative endovascular balloon occlusion of the aorta, the aorta is divided into the following three zones: I, descending thoracic aorta between the origin of the left subclavian and celiac arteries; II, between the celiac and lowest renal artery; and III, the lowest renal artery and the aortic bifurcation. The balloon is inflated to get inflow control of the aorta. For example, for massive bleeding from a pelvic fracture, the balloon can be inflated below the renal arteries providing control of bleeding until definitive surgical care or embolization is done.[24] Sixty minutes of resuscitative endovascular balloon occlusion of the aorta is tolerated and recoverable. Further studies are under way before widespread clinical application.

TABLE 263-3 Indications for Laparotomy

	Blunt	Penetrating
Absolute	Anterior abdominal injury with hypotension Abdominal wall disruption Peritonitis Free air under diaphragm on chest radiograph Positive FAST or DPL in hemodynamically unstable patient CT-diagnosed injury requiring surgery	Injury to abdomen, back, and flank with hypotension Abdominal tenderness GI evisceration High suspicion for transabdominal trajectory after gunshot wound CT-diagnosed injury requiring surgery
Relative	Positive FAST or DPL in hemodynamically stable patient Solid visceral injury in stable patient Hemoperitoneum on CT without clear source	Positive local wound exploration after stab wound

Abbreviations: DPL = diagnostic peritoneal lavage; FAST = focused assessment with sonography for trauma.

DISPOSITION AND FOLLOW-UP

Patients with significant intra-abdominal injury need admission to the surgical or trauma service for definitive surgical intervention or observation. Given the high rate of concomitant injuries, even patients who suffer minor abdominal injury may need hospitalization to manage other injuries. In patients in whom ED discharge is considered, discuss appropriate follow-up and careful instructions for return to the ED. Patients who develop fever, vomiting, increased pain, or symptoms suggestive of blood loss (e.g., dizziness, weakness, fatigue) should return promptly for reevaluation.

CHAPTER 264

Trauma to the Flank and Buttocks

Alicia Devine

INTRODUCTION AND EPIDEMIOLOGY

The number of serious retroperitoneal, intraperitoneal, or vascular injuries that can occur, many of which require operative repair, complicates the evaluation of penetrating injuries to the flank or buttocks. Imaging assists in diagnosis and can direct selective conservative management. The choice of management, conservative or operative, is based on the emergency evaluation, making the emergency physician's input essential to a correct decision and a clinically successful outcome.

PENETRATING FLANK TRAUMA

PATHOPHYSIOLOGY

The flank is located between the anterior and posterior axillary lines, bordered superiorly by the sixth rib and inferiorly by the iliac crest. Although a penetrating wound to the flank can produce intraperitoneal injury with the associated findings of peritonitis or hemoperitoneum, it is possible that a penetrating flank injury could injure only the retroperitoneal organs. A solitary injury to the retroperitoneum from a penetrating flank injury may not induce peritoneal signs initially, and reliance on physical exam findings alone could lead to a delay in diagnosis, resulting in septic or hemorrhagic shock. Essentially any intra-abdominal organ is at risk for injury from a penetrating flank wound, and injuries to the kidney, ureter, bladder, liver, spleen, gallbladder, pancreas, colon, adrenal gland, diaphragm, stomach, duodenum, lung, esophagus, heart, and vascular structures have all been reported.[1-4]

The path of a gunshot or stab wound to the flank could track in any direction. Once inside the abdominal cavity, bullets may ricochet off the bony structures of the spine and produce a unique bullet path and injury pattern. The extent of injury caused by a projectile depends on its velocity, with higher-velocity objects causing more injury than lower-velocity objects, as well as on the construction of the projectile, which affects the movement of the object once inside the abdominal cavity. The greater the surface area interface, the greater is the tissue damage. Stabbing injuries are low velocity and induce injury through direct contact with tissue.[5]

CLINICAL FEATURES

Obtain information about the mechanism of injury, how much time has passed since the event, and the nature of the weapon. In the case of a gunshot wound, determine the nature of the gun (e.g., shotgun, handgun, BB gun) and the distance between the gun and the patient at the time of the gun's discharge. **For gunshot wounds, attempt to identify an exit wound and reconstruct the bullet path.** For stab wounds, determine the size of the weapon and, if possible, estimate a measure of the depth of penetration. Perform a rectal examination because the presence of red blood in the stool may indicate bowel injury. Note any blood around the urinary meatus or blood in a Foley catheter drainage that would suggest bladder or urethral injury.

DIAGNOSIS

Patients with penetrating flank trauma who are hemodynamically unstable or who have peritoneal signs require emergent laparotomy. Patients who are not taken emergently to the operating room require further evaluation to ascertain the extent of injury and to determine if the wound has penetrated the peritoneum and caused intraperitoneal organ injury. Evaluation of flank trauma represents challenges related to its unique anatomic position and potential for retroperitoneal injury with late manifestations. Few data exist on isolated penetrating flank trauma, and most of the recommendations for management come from studies of both flank and back trauma or flank and abdominal trauma.[6] Several diagnostic modalities exist to further evaluate penetrating flank trauma, each with some degree of limitation in its ability to exclude injury. **Table 264-1** lists the diagnostic modalities available (see also chapter 263, "Abdominal Trauma"). Triple-contrast CT scan can detect the trajectory of the penetrating object and evaluate the retroperitoneum and is highly accurate in detecting injuries requiring laparotomy, but is less sensitive for the detection of injuries to the diaphragm or colon.[2,3,7,8] US has limited ability to detect hollow viscous or retroperitoneal injury and cannot be used alone in penetrating flank trauma to exclude occult injury.[9,10,11] Diagnostic peritoneal lavage can detect intraperitoneal penetration, but cannot evaluate the retroperitoneum, and has a high false-positive rate leading to nontherapeutic laparotomy. Local wound exploration has a false-positive rate of 14% to 45%.[7] Diagnostic laparoscopy is very sensitive for the detection of peritoneal violation and can help prevent the morbidity and mortality associated with unnecessary laparotomy.[11-13]

LABORATORY TESTING

Table 264-2 lists the baseline laboratory and imaging studies that should be obtained.

IMAGING

CT is the diagnostic modality of choice in hemodynamically stable patients with penetrating flank trauma.[2,3,6,7,14] Use double (PO and IV) contrast or triple (PO, IV, and PR) contrast; add rectal contrast if there is any likelihood of a rectal or sigmoid injury.[3,6,7] Fine cuts through the site of injury may be required (**Figures 264-1 and 264-2**). Free intraperitoneal fluid or air suggests peritoneal perforation. Bowel wall thickening with hematoma near the bowel or contrast extravasation from the bowel suggests bowel injury. The presence of a wound track near either the diaphragm or bowel mandates close scrutiny for injury to either of those organs.[3,6,15]

TREATMENT AND DISPOSITION

Evaluate and resuscitate patients with penetrating trauma to the flank according to standard protocols (see chapter 254, "Trauma in Adults"). Following stabilization, try to find an exit wound and reconstruct the bullet path. Obtain emergent surgical consultation. Administer broad-spectrum IV antibiotics to cover for gram-negative aerobic and anaerobic organisms for peritonitis.

Exploratory laparotomy is indicated for patients who are hemodynamically unstable or who exhibit peritoneal signs after sustaining a gunshot wound to the flank. Historically, all patients with gunshot wounds to the flank underwent exploratory laparotomy, but a more conservative approach should be taken at trauma centers when penetrating wounds are found to be tangential and there are no peritoneal signs.

In the case of high-velocity gunshot wounds, take into account the blast effect. Depending on the exact location and type of injury, consideration of the blast effect may lead to exploratory laparotomy if there is concern about bowel, bladder, or vascular integrity.

Patients with stab wounds to the flank who are hemodynamically stable and lack peritoneal signs or diffuse abdominal tenderness may be managed conservatively after triple-contrast CT scan or local wound exploration.[2,3,6,7,11,14] Patients with either gunshot or stab wounds who are managed nonoperatively will usually require admission to the hospital for observation and serial abdominal exams.

PENETRATING BUTTOCK TRAUMA

PATHOPHYSIOLOGY

The gluteal region extends from the iliac crest to the gluteal fold and is bordered by the greater trochanters. The gluteal region is divided into an upper zone and a lower zone by a line drawn at the level of the trochanters. Although any pelvic or intra-abdominal structure is susceptible to injury following a penetrating injury to the buttocks, the most common structures injured in a stab wound to the buttock are the rectum, superior gluteal artery, and iliac artery, and the most common structures injured in a gunshot wound to the buttock are the small bowel, colon, rectum, bony pelvis, and bladder. Most of the major pelvic vascular structures, the sciatic nerve, ilium, sacrum, lower colon, upper rectum, bladder, and female reproductive organs reside in the upper zone, and penetrating wounds in the upper zone have a higher risk of major injury compared to wounds in the lower zone. The lower zone contains the male bladder, prostate, urethra, and external genitalia as well as the lower part of the rectum.[1,16-18] An important component of the history is information regarding the weapon used and the patient's position at the time of injury, because this information will help determine the trajectory of the bullet or knife.

DIAGNOSIS AND TREATMENT

The evaluation of penetrating buttock wounds focuses on identification of potential injury to the lower GI and GU tract, as well as to pelvic vasculature. Perform a rectal examination to identify gross blood, and perform stool guaiac testing. Guaiac testing is not completely sensitive for GI injury; therefore, a negative guaiac test does not rule out rectal injury. Evaluate for the presence of hematuria. Assess the peripheral pulses in the lower extremities for decreased pulses or pallor as evidence of a more proximal injury. Perform a neurologic examination of the lower extremities searching for any injury to the sciatic or femoral nerve. Buttock wounds rarely cause direct damage to the sciatic plexus or femoral plexus. Injury could include transection, partial transection, or stretch injury secondary to the trauma. Table 264-2 lists the needed baseline laboratory and imaging studies.

Exploratory laparotomy is indicated for patients with hemodynamic instability or peritoneal signs. For peritonitis, obtain emergent surgical consultation and administer broad-spectrum IV antibiotics to cover for gram-negative aerobic and anaerobic organisms.

Patients with penetrating buttock injury who do not meet criteria for emergent laparotomy may be candidates for nonoperative management.[1] Selective nonoperative management uses a combination of serial exams and adjunctive modalities, including the focused assessment with sonography for trauma exam, CT, sigmoidoscopy, cystourethrogram, and angiography. Upper zone gluteal stab wounds can undergo local wound exploration to evaluate for muscle violation. Patients without muscle violation can be observed with serial exams, whereas those with muscle violation require CT and rigid sigmoidoscopy, plus cystography for hematuria.[19] Selective nonoperative management for lower zone gluteal stab wounds and all gluteal gunshot wounds is similar. CT scan, preferably with triple contrast, should be used to evaluate for injury in the stable patient (**Figure 264-3**). Obtain a cystourethrogram if there is blood on urinalysis or the wound is close to the GU tract. Perform a cystourethrogram either as a separate study or in conjunction with CT with rectal and IV contrast material, with clamping of the urethral catheter to obtain a CT cystogram.

In most cases, sufficient diagnostic workup may be obtained with CT, but rigid sigmoidoscopy is advised if there is any concern about injury to the rectum or because of the trajectory of the bullet. If the CT

FIGURE 264-3. Noncontrast abdominopelvic CT scan after gunshot wound to the buttock. This CT scan shows bullet fragments in the gluteal muscles but no pelvic injury.

demonstrates a pelvic hematoma, angiography or venography may be indicated to document a significant vascular injury; in many centers, CT angiography has replaced these techniques, but interventional angiography may be required for extensive pelvic bleeding.[1]

CHAPTER 265

Genitourinary Trauma

Matthew C. Gratton
L. Keith French

INTRODUCTION

Falls, assaults, motor vehicle crashes, and sports injuries are the most common mechanisms for blunt genitourinary injuries, whereas gunshot wounds and stab wounds are the most common causes for penetrating injuries.[1] The majority of ureteral injuries are caused by penetrating trauma.[1,2] Bladder injuries are typically caused by pelvic fracture, with urethral injuries seen in 5% to 10% of pelvic fractures.[1,3] Children are more susceptible to genitourinary injury than the general population. Children lack periadipose tissue, and kidney size is large relative to overall body size.[4] Appropriate management will minimize or prevent complications such as renal function impairment, urinary incontinence, and sexual dysfunction.

CLINICAL FEATURES

HISTORY

Obtain a detailed history to determine the time and mechanism of injury and the magnitude of forces involved. In motor vehicle crashes, seat location, use of restraints, vehicle speed, and crash details provide information about forces applied to the victim. Sudden deceleration can cause major vascular disruption and parenchymal damage to the kidneys and bladder, even in the absence of symptoms and physical findings. For penetrating trauma, obtain information about the caliber of weapon or type of knife, its length, any contamination, and whether removed intact.

An inability to urinate may be due to an empty bladder or inability to void because of pain, but can also result from bladder perforation, urethral injury, or spinal cord injury.

PHYSICAL EXAMINATION

Inspect the perineum during the secondary survey. Blood on the underwear or pants is an important finding and may suggest genital trauma. Inspect the folds of the buttocks for ecchymoses, abrasions, or lacerations, which may be related to an open pelvic fracture. Do not deeply probe perineal injuries because probing could disrupt a clot.

Rectal examination identifies sphincter tone, position of the prostate gland, and presence of blood. If the prostate is "missing" or riding high or feels boggy, assume disruption of the membranous urethra until proven otherwise. In males, examine the scrotum for ecchymoses, laceration, and testicular disruption. Palpate and inspect the penis for ecchymoses, deformity, and blood at the meatus. In females, examine the vaginal introitus for lacerations and hematomas. Lacerations and hematomas can accompany pelvic fracture. Perform a speculum examination when vaginal bleeding or hematoma is present to exclude vaginal laceration. Complications of missed vaginal injuries include infection, fistula formation, and hemorrhage.

KIDNEY INJURIES

DIAGNOSIS

Renal injury is present in up to 10% of patients with abdominal trauma.[1,3] Because of the protected position of the kidneys, most injuries are associated with other intra-abdominal injuries.[5] Flank contusions or ecchymosis, palpable mass, lower rib fractures, and penetrating wounds in the flank mandate consideration of renal injury. Renal injuries consist of lacerations, avulsions, and hematomas to the kidney itself and renal pelvis. Renal vascular injuries (avulsion, laceration, occlusion) are uncommon but must be considered in the specific diagnosis of kidney injury.[6]

URINALYSIS

Although urinalysis is a commonly ordered laboratory study for suspected renal injury, **there is no direct relationship between the presence, absence, or degree of microscopic hematuria and the severity of injury**.[1,3,5] Microscopic and dipstick urinalysis are equally reliable for detecting the presence of hemoglobinuria.[5,7] However, **renal pedicle injuries and segmental arterial thrombosis may be present without hematuria**. In blunt trauma, there is some evidence suggesting that gross hematuria has predictive value for more severe renal injury.[1,5,7] In addition, patients with a systolic blood pressure of <90 mm Hg and microscopic hematuria have a higher likelihood of significant injury.[1,5] Children with <50 red blood cells per high-powered field have a low likelihood of significant renal injury.[5]

IMAGING

The main objectives of imaging are to (1) accurately stage the renal injury, (2) recognize preexisting pathology of the injured kidney, (3) document the function of the opposite kidney, and (4) identify associated injuries to other organs.[5] Imaging guidelines are listed in **Table 265-1**. An IV contrast-enhanced CT scan of the abdomen and pelvis is the imaging "gold standard" for the stable patient with suspected renal injury.[5,8,9] Contrast-enhanced CT detects contusion, lacerations, hematomas, and perfusion abnormalities (**Figure 265-1**). Early contrast extravasation is consistent with ongoing hemorrhage. However, urinary extravasation cannot be detected until the contrast-enhanced urine is excreted into the collecting system, which usually can take up to 10 minutes. Therefore, a delayed scan of the kidney, ureter, and bladder is recommended to exclude urinary extravasation from any source. If the

TABLE 265-1 Imaging for Genitourinary Trauma

Injury	Imaging	Comments
Multisystem trauma or suspected renal parenchymal or vascular injury	Abdominal-pelvic IV contrast CT scan	Include pelvis to view entire GU tract Delayed films needed to identify urinary extravasation
Any visceral injury resulting in free intraperitoneal fluid	FAST	Identifies free fluid, but does not specify type of visceral injury and does not identify renal vascular injury
Renal artery injury	Renal angiography	Details vascular injuries
Ureteral injury	Abdominal-pelvic IV contrast CT scan	Delayed films needed to identify extravasation; obtain IV pyelogram or retrograde pyelogram if still suspicious with negative CT
Bladder injury	Retrograde cystogram	Can use plain radiographs or CT scan
Urethral injury	Retrograde urethrogram	Discuss sequencing with radiologist, because if performed prior to abdominal-pelvic contrast CT scan, can interfere with diagnosis
Scrotal/testicular injury	Color Doppler US	Contrast-enhanced US or MRI if suspicion is high and initial US is negative

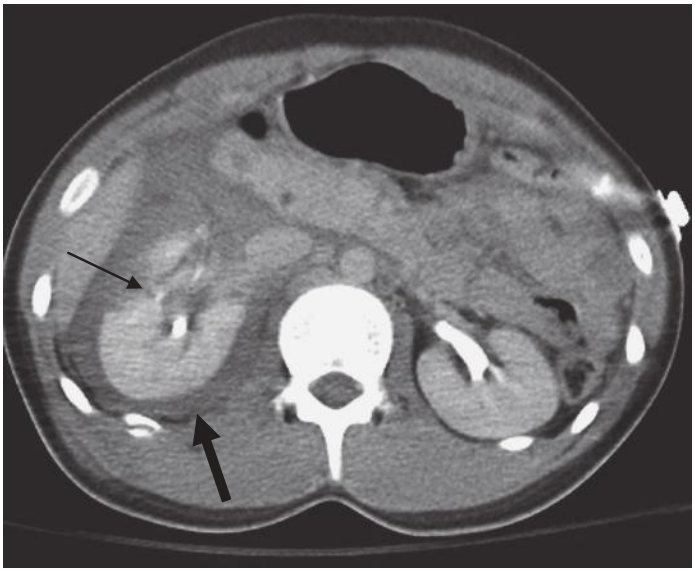

FIGURE 265-1. Renal laceration. Narrow arrow = renal laceration. Thick arrow = perinephric hematoma. [Image used with permission of Matthew C. Gratton, MD.]

kidney is normal and there is no abnormal fluid collection in the perinephric, retroperitoneal, or peripelvic areas, then the delayed scan can be omitted.

The focused assessment with sonography for trauma (FAST) examination is useful for identifying free intraperitoneal fluid, but does not specifically evaluate renal injury. FAST does not identify renal vascular injury. US examination may be useful for identifying and following postoperative fluid collections and for patients who are managed without operative intervention.[8,9]

Renal angiography can identify vascular injuries. Embolization of appropriate injuries can then be accomplished. Embolization can also be used to treat delayed traumatic arteriovenous fistulas.

GRADING OF RENAL INJURY

Grading of the renal injury is based on the American Association for the Surgery of Trauma organ injury scale (**Table 265-2**).[10] This grading system correlates with the need for operative repair and nephrectomy. In a study of 2467 patients with renal trauma, 86.5% were grade I, 3.5% grade II, 4.8% grade III, 4.0% grade IV, and 1.1% grade V. The rate of nephrectomy ranged from 0% for grades I and II to 82% for grade V.[11] Decreased kidney function is also directly correlated with renal injury grade.[12]

TREATMENT OF RENAL INJURIES

Absolute indications for renal exploration and intervention include life-threatening hemorrhage due to a renal injury; expanding, pulsatile, or noncontained retroperitoneal hematoma (thought to be from a renal avulsion injury); and a renal avulsion injury (grade V vascular injury) demonstrated on imaging studies.[5,7,8] High injury grade, high injury severity score, large blood transfusion requirement, and hemodynamic instability are predictive of the need for nephrectomy. Urinary extravasation alone is not an indication for exploration because it resolves spontaneously in the majority of cases. Extravasation from a renal pelvis or ureteral injury, however, does require repair.

TABLE 265-2 Renal Injury Scale

Grade	Description
I	Hematuria with normal anatomic studies (contusion) or subcapsular, nonexpanding hematoma; no laceration
II	Perirenal, nonexpanding hematoma or <1 cm renal cortex laceration with no urinary extravasation
III	>1 cm renal cortex laceration with no collecting system involvement or urinary extravasation
IV	Laceration through cortex and medulla and into collecting system or segmental renal artery or vein injury with hematoma
V	Shattered kidney or vascular injury to renal pedicle or avulsed kidney

Most authorities agree that grade I, II, and III renal injuries can be handled nonoperatively. Selected grade IV and V parenchymal injuries may be managed nonoperatively, although many of these patients have other indications for operative intervention.

If the trauma patient is hemodynamically stable and there is suspicion for renal injury with or without gross hematuria or if the patient has a penetrating injury, then CT imaging is indicated. If the CT scan reveals no renal pelvis, vascular, or ureteral injury and the patient remains clinically stable, then observe until the gross hematuria clears. If the CT scan reveals a renal pelvis, vascular, or ureteral injury, then surgical consultation is indicated.

Many gunshot and stab wounds to the kidneys can be treated nonoperatively. The absolute indications for operation remain those listed previously. Many patients with renal injuries have associated injuries that mandate operative intervention.

Renal Vascular Injury Renal vascular injury is identified on CT scanning and requires emergent surgical consultation in order to arrange treatment to minimize the time of renal ischemia. The optimal time to revascularization is not clear, with recommendations for timing of definitive treatment ranging from 4 to 20 hours.[6] Follow local institutional urology and trauma protocols once renal vascular injury is identified.

COMPLICATIONS

Complications that may result from renal trauma include delayed bleeding, urinary extravasation, urinoma, perinephric abscess, and hypertension and failure of the affected kidney. Delayed bleeding can occur up to a month after injury and is most commonly due to an arteriovenous fistula that has developed after a deep parenchymal laceration. Arteriovenous fistula occurs in up to 25% of cases of grade III or IV injuries that are managed conservatively.[5,13] Most can be managed with angiographic embolization, but renorrhaphy or nephrectomy may be necessary.[8,13] A urinoma may develop from a few weeks to many years after injury and may have no symptoms or may cause a feeling of abdominal discomfort, mass, or low-grade fever. Treatment is usually percutaneous drainage or ureteral stenting. A perinephric abscess can present similarly and can also be treated with percutaneous drainage. Hypertension may occur due to renal artery injury, devascularized tissue, renal parenchymal compression by clot, or by arteriovenous malformation, and may occur from days to many years after injury. Nephrectomy is the most common treatment, but medical management may be indicated.

DISPOSITION AND FOLLOW-UP

Most patients with significant renal injury are admitted on the basis of associated injuries. For patients with isolated renal trauma, few data support specific recommendations for disposition and follow-up.

Patients with isolated renal trauma and a class I injury can be separated into two groups after urology consultation. Those with a renal contusion (microscopic hematuria with normal imaging) can be discharged home as above. Patients with a subcapsular hematoma can be admitted for a short observation stay followed by a hematocrit and clinical reevaluation. Patients with gross hematuria usually need admission and require bed rest until the gross hematuria clears. Admit patients with grade II or higher injury to the hospital under the care of a trauma surgeon, general surgeon, or urologist as appropriate for the practice setting.

URETERAL INJURIES

DIAGNOSIS

Isolated ureteral injury is rare in trauma patients because the ureter is well protected in the retroperitoneum.[14,15] Approximately 80% of ureteral injuries occur from intraoperative, iatrogenic damage. Of the 20% of injuries due to external trauma, almost 90% occur as a result of

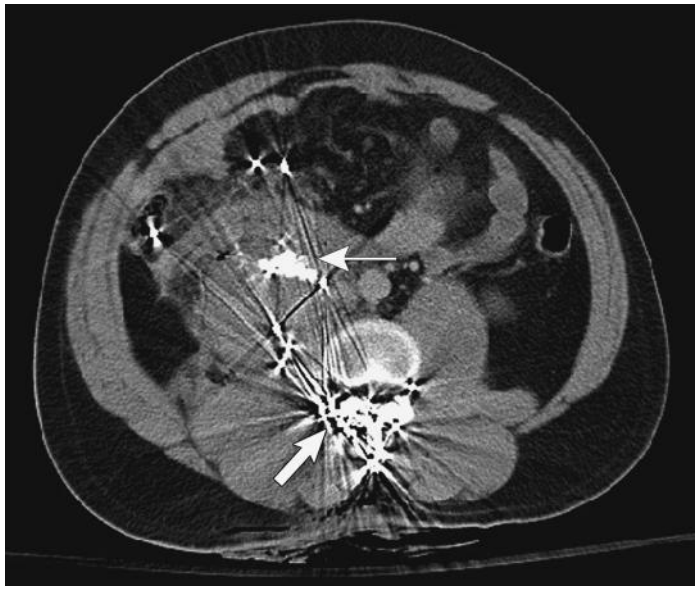

FIGURE 265-2. Ureteral injury. Narrow single arrow = contrast material that has leaked from a transected ureter. Thick arrow = multiple metallic foreign bodies with artifact (shotgun pellets).

FIGURE 265-3. Bladder rupture. Retrograde cystogram demonstrates an intraperitoneal rupture of the bladder.

penetrating trauma (81% gunshot wounds, 9% stab wounds) and 10% occur due to blunt trauma.[14,15] Because there are no history or physical examination findings that are specific for ureteral injuries, these injuries can be easily missed.[7] Approximately 70% of patients with ureteral injuries have either gross or microscopic hematuria. The absence of hematuria does not exclude ureteral injury.[2,7,14]

In the stable patient with suspicion of ureteral injury, obtain a CT of the abdomen and pelvis with IV contrast with a delayed phase. Extravasation of contrast along the course of the ureter is diagnostic for ureteral injury (**Figure 265-2**).[2,7,15] If the CT is nondiagnostic and there remains a high index of suspicion for this injury, perform IV pyelography or retrograde pyelography. If there is intraoperative suspicion of ureteral injury from the course of a missile or stab wound, then further exploration is indicated.

TREATMENT AND DISPOSITION

Treatment of ureteral injuries is operative. Partial tears can be stented, and simple lacerations can be primarily repaired over a stent. More complex injuries can be reconstructed using a variety of techniques. Complications include urinary leakage, urinoma, periureteral abscess, peritonitis, ureteral stricture, and urinary fistula. All cases require urology consultation and admission for operative management.

BLADDER INJURIES

DIAGNOSIS

Bladder injury occurs in approximately 2% of blunt abdominal trauma cases, with 70% to 97% associated with pelvic fractures.[7,16] A direct blow to a distended bladder is associated with bladder rupture. Therefore, suspect bladder injury in alcohol-intoxicated patients (bladder often distended) who are in a motor vehicle crash (potentially high-energy transfer resulting in pelvic fracture).[16] Lower abdominal pain and tenderness and gross hematuria are commonly associated findings. Lower abdominal bruising, abdominal swelling from urinary ascites, perineal or scrotal edema from urinary extravasation, and inability to void are also common findings on examination of patients with bladder injury. Bladder injury also occurs secondary to penetrating trauma, and penetrating injuries to the rectum or buttocks may also have associated bladder injury.

Gross hematuria is present in most significant bladder injuries, and gross hematuria in the setting of pelvic fracture requires investigation of the bladder with a retrograde cystogram.[3,7,16] The presence of microscopic hematuria associated with a pelvic ring fracture can indicate a bladder injury, but the exact degree of microscopic hematuria warranting cystogram in this setting is undetermined and depends on clinical judgment.[16]

A retrograde cystogram is the "gold standard" imaging study for the diagnosis of bladder rupture.[16] The diagnosis is made when contrast material is seen spilling out of the bladder into the peritoneal cavity (intraperitoneal rupture) or into the retroperitoneal area surrounding the bladder (extraperitoneal rupture). This study can be performed with plain radiographs or with CT (**Figure 265-3**).[3,16] The bladder must be filled in a retrograde fashion (through an indwelling bladder catheter) by gravity feed with enough contrast material (at least 350 mL) to distend the bladder. Obtain a postvoid film. A contrast-enhanced CT with passive bladder filling, even with a clamped catheter, is not sensitive enough to exclude bladder rupture. Sonographic diagnosis of bladder rupture is not accurate.[16]

TREATMENT AND DISPOSITION

Extraperitoneal ruptures of the bladder are most common (55%), followed by intraperitoneal (38%) and combined intra-/extraperitoneal ruptures (5% to 8%).[7] Intraperitoneal ruptures always require surgical exploration and repair.[7] Extraperitoneal ruptures can usually be managed with bladder catheter drainage alone. Approximately 85% to 90% will heal within 10 days with simple drainage, and the remainder will likely heal within 3 weeks.[3,7,16] **Table 265-3** lists conditions when operative repair may be needed for extraperitoneal rupture.[7]

Missed intraperitoneal rupture can lead to urinary ascites, local abscess, peritonitis, or sepsis.[7] If bladder neck injuries or rectal or vaginal injuries are missed, then incontinence or fistula may result.[7] Associated injury to the sacral nerve roots or pelvic nerves can damage innervation of the bladder, resulting in a neurogenic bladder or impotence.[7] Simple ruptures are less likely to produce complications but may occasionally be

TABLE 265-3 Operative Repair May Be Needed for Extraperitoneal Rupture of the Bladder

Urinary catheter does not allow appropriate drainage
Associated rectal or vaginal injury
Associated bladder neck injury
Open fixation of a pelvic fracture (to avoid contamination of the hardware)

associated with persistent bladder diverticulum, decreased bladder volume, or urinary tract infection.

Because bladder rupture is frequently associated with other injuries, admitting the patient for either operative intervention or catheter drainage under the care of a trauma surgeon, general surgeon, or urologist is the general rule.

URETHRAL INJURIES

DIAGNOSIS

Timely diagnosis and effective treatment of urethral injury are paramount to limiting long-term adverse outcomes, including impotence, stricture, urinary retention, or incontinence. Urethral injuries are less common in women primarily due to differences in urethral length (4 cm in women vs. 20 cm in men).[1] Urethral injuries are classified anatomically as either anterior or posterior, an important distinction because comorbid injuries and treatment may vary.

POSTERIOR URETHRAL INJURIES

The posterior urethra consists of prostatic and membranous portions. Because the posterior urethra is relatively well insulated by bony and soft tissues, injuries here are generally the result of major blunt-force trauma from deceleration mechanisms such as motor vehicle collisions or falls from heights. Such mechanisms lead to shearing forces applied to the prostatic-membranous urethral junction. Posterior urethral injuries may occur in about 10% of patients with pelvic fractures.[17]

ANTERIOR URETHRAL INJURIES

The anterior urethra is divided into the relatively fixed bulbar segment and the pendulous (penile) segment. Anterior urethral injuries are generally the result of direct perineal trauma, either blunt or penetrating. Trauma to the anterior urethra may be missed initially, and patients may present years later with urethral stricture. Straddle injury is the classic mechanism, although strikes or kicks to the perineum may lead to the same injury. The bulbar rather than pendulous segment is typically affected.[18] Anterior urethral trauma can also occur as a result of penile fracture. Penetrating trauma to the urethra usually occurs to the penile urethra. Evaluate for female urethral injuries in association with extensive pelvic fractures.

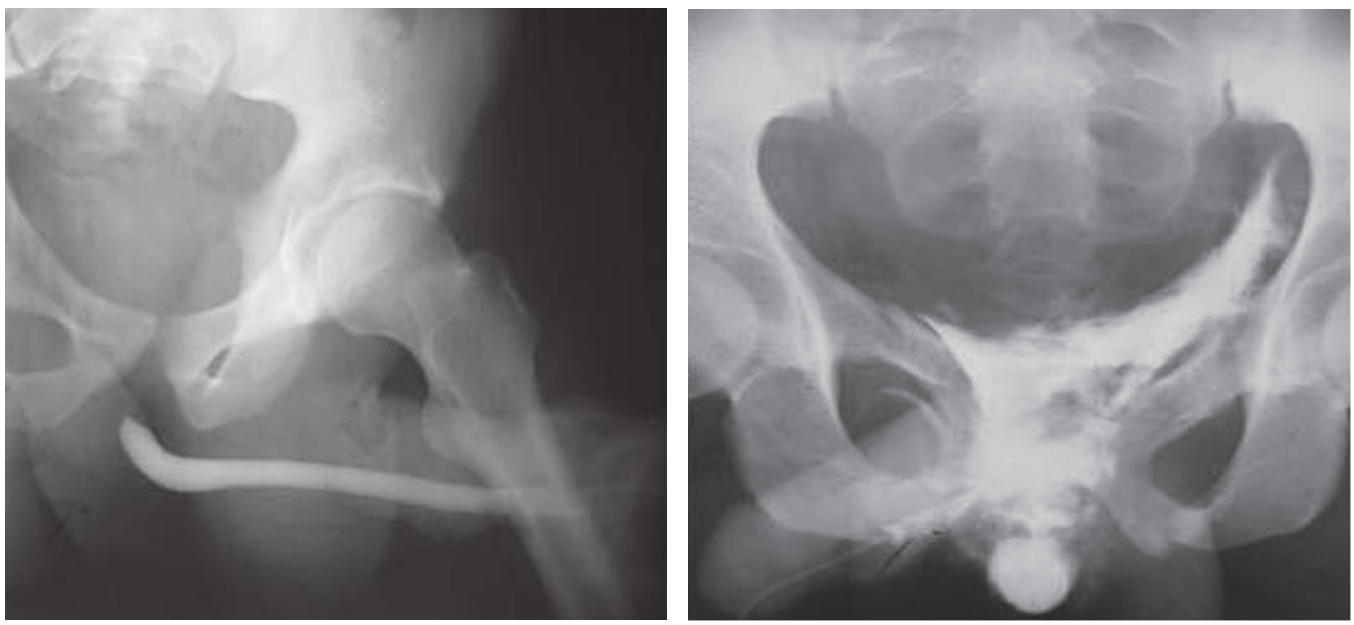
CLINICAL FEATURES

Suspect urethral injury from common mechanisms (straddle or penetrating perineal injuries), comorbid injuries (pelvic fractures), or iatrogenic complications (traumatic catheterization). Symptoms may include hematuria, dysuria, or inability to void. Rectal and perineal examination may demonstrate a perineal hematoma or high-riding prostate. Posterior urethral injury is suggested by the triad of urinary retention, blood at the meatus, and a high-riding prostate.[19] Intuitively, hematuria should be a helpful clue; however, this is neither specific nor sensitive enough to be used alone to diagnose or exclude a urethral injury.[20] Difficulty passing a Foley catheter raises concern for a urethral injury; insertion should never be a forceful process. Most female urethral injuries present with vaginal bleeding. A careful vaginal inspection is important because this may reveal findings suggestive of urethral injury, such as blood at the vaginal introitus.[19] In women, no consensus exists on the best modality to detect urethral injury because cystography or urethrography may not be adequate.[21]

DIAGNOSIS

The diagnosis of urethral injury is made by retrograde urethrogram, which should be performed before catheterization to prevent further urethral injury. If there are any signs of possible urethral injury, such as high-riding prostate, meatal blood, perineal ecchymosis, scrotal hematoma, pelvic fracture, or gross hematuria, do not insert a Foley catheter until urethral injury is excluded.[22]

Perform retrograde urethrogram by gently injecting 20 to 30 mL of contrast into the urethra and obtaining a radiograph. Extravasation identifies the existence and location of the urethral tear. In partial anterior urethral lacerations, the retrograde urethrogram reveals contrast extravasation at the site of injury and contrast material outlining the urethra proximal to the site of injury (**Figure 265-4**). In complete anterior urethral lacerations, the retrograde urethrogram reveals contrast extravasation at the site of injury without contrast proximal to the site of injury. Extravasation of contrast along fascial planes of the perineum is another indication of urethral disruption. **Performing a retrograde urethrogram before completing a CT of the abdomen and pelvis to evaluate for other life-threatening injuries can interfere with CT diagnosis and embolization treatment of pelvic arterial extravasation from pelvic fractures, so discuss the sequencing of studies with the trauma surgeon, urologist, or radiologist.**[23,24] If a Foley catheter has



A B

FIGURE 265-4. **A.** Normal retrograde urethrogram. **B.** Extravasation of contrast.

already been successfully inserted, and then a urethral injury is considered, keep the Foley catheter in place. Using a 16-gauge angiocatheter, inject contrast material at the meatus, around the urinary catheter, and then obtain radiographs in the standard fashion.[25] In males, the location and displacement of anterior pelvic fractures, if present, can predict the risk of urethral injury. For every millimeter of symphysis pubis diastasis or inferomedial pubic bone fracture displacement, the risk of urethral injury increases by 10%.[26]

TREATMENT AND DISPOSITION

Patients with urethral trauma often have multiple injuries, some of which take precedence over the urethra trauma. Prioritize treatment(s) according to standard Advanced Trauma Life Support guidelines. The treatment for male patients with posterior urethral injury secondary to pelvic fracture has generally been immediate placement of a suprapubic catheter (for bladder drainage) with delayed surgical repair (often weeks later). Suprapubic catheter placement allows for urinary drainage without urethral manipulation or disruption of a pelvic hematoma. The suprapubic catheter can be placed either percutaneously or by an open approach using a small incision. Use US guidance to aid in the percutaneous approach. Early endoscopic repair may lead to equally good potency and continence outcomes while reducing the rates of urethral stricture.[27-29]

Most penetrating injuries to the anterior urethra require surgical exploration and repair. Female urethra injuries are difficult to manage because the diagnosis is often clinical. It is more difficult to perform urethrography in women. Concomitant bladder injury needs to be excluded with CT cystography. Consider antegrade cystogram through a suprapubic tube and cystoscopy if the diagnosis remains uncertain. Because urethral injury is frequently associated with other injuries, admit the patient for either operative intervention or catheter drainage under the care of a trauma surgeon, general surgeon, or urologist.

INJURIES TO THE EXTERNAL GENITALIA

CLINICAL FEATURES

One study reported that 25% of patients sustaining injury to the external genitalia required red blood cell transfusion due to blood loss from genital injury alone, so carefully assess for signs of blood loss as well as evaluating for local injury.[30]

Penile fracture, with or without urethral injury, occurs when the corpus cavernosum ruptures after being forcibly bent, usually during sexual intercourse. A cracking sound may be heard, followed by penile pain, rapid swelling, discoloration, and visible deformity ("eggplant deformity").[31] Amputations are usually self-inflicted or result from clothing trapped by heavy machinery. Self-inflicted trauma to the penis can also result from vacuum cleaner injuries, which cause extensive injury to the glans penis and urethra. Strangulation from constricting penile rings used to enhance erections is another mechanism of injury. Penetrating injuries are less common and may also involve the urethra.

Injuries to the scrotum may occur from blunt or penetrating trauma, burns, and avulsions. More than half of all testicular trauma is a result of sporting activity.[31] Impingement of the testicles against the symphysis pubis is the primary cause of blunt testicular injuries. Resultant injury to the testicle ranges from contusion to rupture. In both conditions, the tunica vaginalis fills with blood, forming a hematocele. If the tunica albuginea is disrupted, a rupture has occurred. Traumatic dislocation of the testicle is a rare event and most commonly occurs following straddle injuries from motorcycle accidents.[32]

Symptoms after a direct scrotal blow are usually scrotal pain and swelling. Other signs may include scrotal discoloration and a tender, firm scrotal mass that fails to transilluminate, which indicates a hematocele. An empty hemiscrotum suggests testicular dislocation. An open wound to the scrotum suggests the possibility of testicular involvement. Many patients will be exquisitely tender, potentially limiting a thorough exam. Furthermore, the external signs of trauma may not correlate well with the degree of testicular injury; thus, there should be a low threshold for diagnostic imaging.[31]

DIAGNOSIS

Color Doppler US is the diagnostic modality of choice in the evaluation of scrotal/testicular trauma.[31] Although there is no advantage initially, contrast-enhanced US and testicular MRI may be useful adjuncts if the Doppler US results are inconclusive and clinical suspicion remains high for testicular injury.[32-35] CT plays an important role in the evaluation of concomitant abdominopelvic injuries. Penile injuries often result in urethral injuries; thus, consider retrograde urethrogram in this scenario. While the diagnosis of penile fracture is largely clinical, US may detect corpus cavernosum hematomas and can be an adjunct to both diagnosis and operative management.[36]

TREATMENT

Most closed testicular contusions are managed conservatively with narcotic analgesics, ice, elevation, scrotal support, and appropriate urologic follow-up. Testicular rupture requires immediate drainage and repair. The salvage rate following testicular rupture may be as high as 90% if treated promptly.[31] Any patient with penetrating scrotal trauma should undergo immediate scrotal exploration.[37] Obtain emergent urologic consultation for all confirmed or suspect penile fractures. With immediate surgical intervention, erectile function may be spared.[36]

Traumatic epididymitis is a noninfectious inflammatory condition that usually occurs within a few days after a blow to the testis. Treatment is similar to that for nontraumatic epididymitis.[38]

All penetrating trauma to the penis requires surgical consultation and, in most cases, exploration. Loss of penile skin by avulsion injury or burns is managed by split-thickness skin grafts after the denuded penis is clean and sterile. Do not reapply avulsed skin, because avulsed skin invariably becomes necrotic and infected and must be subsequently removed. Penile amputations require repair by microsurgical reimplantation if the amputated segment is deemed viable by the urologist.

Strangulation injuries can usually be managed simply by removing the constricting agent. Zipper injury to the penis is caused when the penile skin is trapped in the trouser zipper. Mineral oil and lidocaine infiltration are useful in freeing the penile skin from the zipper. Otherwise, wire-cutting or bone-cutting pliers are used to divide the median bar (or diamond) of the zipper, which causes the zipper to fall apart, freeing the penile skin. Contusions of the perineum or penis are treated conservatively with cold packs, rest, and elevation. Insert a Foley catheter if the patient is unable to void.

SPECIAL POPULATIONS

ELDERLY

As men age, they experience anatomic changes, including laxity of scrotal tissue, atrophy of the perineal muscles, and loss of collagen tissue. Changes in women are secondary to declining secretion of estrogen after menopause and include atrophy of the cervix and uterus, atrophy of the walls of the vaginal canal, decrease in vaginal length and width, and decrease in vaginal lubrication.[39] These changes predispose the elderly to complex injuries of the external genitalia even with a minor mechanism of injury. Compared to younger trauma patients, trauma to the genitourinary system in the elderly patient tends to be more common from blunt mechanisms and tends to result in higher rates of bladder and urethral injuries.[40]

The presence of a **penile prosthesis** can transform a minimal blunt trauma genital injury into a complicated surgical issue for the patient.[41] Extrusion and rupture of penile prostheses predispose patients to infection and complications of wound healing. This becomes a special concern in diabetic patients who are more likely to have prostheses. Obtain urologic consultation for any patient who has sustained trauma to the genitalia with a prosthesis in place (see chapter 95, Complications of Urologic Procedures and Devices).

PREGNANT WOMEN

With pregnancy, women experience physiologic changes that predispose them to more severe injury in both blunt and penetrating trauma to the genitalia. During pregnancy, venous outflow from the perineal area is

slowed because of the pressure on the vena cava from the enlarging uterus. Slowed blood flow to the area can cause edema of the vulva. The increased level of progesterone during pregnancy also contributes to fluid retention and edema of the genitalia. Engorgement of the perineum predisposes pregnant patients to increased risk of hemorrhage from penetrating trauma to this anatomic region.

CHILDREN

Roughly 33% of males worldwide are circumcised.[42] The aim of circumcision is to excise sufficient foreskin (both penile shaft and inner preputial epithelium) to leave the glans uncovered. Complications of circumcision are more common in children than in neonates. Several different techniques and devices are employed to perform circumcision, each with its own complication profile. Early complications of circumcision include bleeding, infection, pain, and inadequate skin removal.[42] Bleeding is the most common complication, occurring in 1% of patients.[43] Direct pressure alone is adequate to stop bleeding in most scenarios, although in some instances, the application of pressure alone is insufficient to control local hemorrhage and other methods of hemostasis must be employed. Circumferential dressings may cause urinary retention and even necrosis of the distal penis if blood flow is compromised.

The clinical evaluation of prepubescent females with blunt urogenital trauma may underestimate the severity of injuries when compared with examination under anesthesia. Consider consultation for examination under anesthesia for accurate diagnosis and to minimize psychological sequelae of examination.[44] In boys, nonsexual trauma to the external genitalia most commonly occurs between ages 6 and 12 years. Sports accidents, kicks, and falls are the typical mechanisms, and scrotal and penile lacerations or testicular contusions are the most common injuries.[45]

CHAPTER 266

Trauma to the Extremities

James Heilman

INTRODUCTION AND EPIDEMIOLOGY

Isolated trauma to an extremity with associated vascular injury has nearly a 10% rate of mortality or limb loss.[1] Injuries involving the lower extremities are more common than injuries involving the upper extremities. The two most commonly injured blood vessels are the femoral and popliteal vessels.[2] Penetrating trauma with early shock from proximal arterial hemorrhage is more likely to lead to mortality. Blunt distal extremity trauma with associated distal vascular injury is more commonly involved in early limb loss and amputations.

Advances in diagnostic imaging[3] and surgical management have dramatically reduced the rate of limb loss and disability due to limb ischemia.[4] The extent of injury to extremity nerves, bones, and soft tissues now determines if the limb can be surgically salvaged. Identifying and detecting which injuries require surgical evaluation and/or imaging are essential skills for emergency physicians.

PATHOPHYSIOLOGY

Gunshot and knife wounds are the two most common causes of penetrating trauma. Stab wounds have a more predictable pattern of injury, making them more straightforward to manage. Gunshot injuries are more difficult to evaluate due to the extent of tissue damage and wider range of patterns of injury. More sophisticated vascular surgical repair techniques of arterial injuries,[5] advances made during military conflicts, improved imaging, and other factors have led to a decreased rate of limb amputations and limb disability associated with penetrating trauma.[6]

CLINICAL FEATURES

Perform the primary trauma survey, immediate resuscitation, and secondary survey before focusing on injuries to the extremities. Apply direct pressure, pressure dressings, or a tourniquet to any actively bleeding extremity (see chapter 254, "Trauma in Adults," and "Tourniquets"). Do not get distracted or deviate from the initial trauma management because associated injuries to other areas of the body are common with penetrating injuries. After identifying an injury during the secondary survey, thoroughly evaluate the affected extremity for vascular integrity, nerve function, skeletal injury, and soft tissue injury. The rapid evaluation of extremities for associated arterial injury is critically important for the management of these injuries. Note any hard or soft signs of vascular injury (**Table 266-1**). Use a Doppler flow device to detect a pulse if distal pulses cannot be palpated.

Thoroughly evaluate nerve, tendon, and muscle function during the physical exam (**Table 266-2**). Pain on palpation or movement of bony structures or obvious deformities suggests an underlying fracture. Note any intra-articular hematomas or other signs of joint injury. Measure soft tissue lacerations and other associated injuries with a tape measure or ruler. Accurately describe injuries to consultants because measurement of the injury may change management in some situations.[7]

ANKLE-BRACHIAL INDEX

In the absence of hard signs, determine the ankle-brachial index for any injured extremity along with the nonaffected extremity for comparison. An ankle-brachial index reading of <0.9 is considered abnormal and is concerning for associated arterial injury. The ankle-brachial index reliably detects occlusive arterial injury with accuracy as high as 95%, but the true sensitivity and specificity have varied in clinical studies.[8,9] Use caution in relying on a normal ankle-brachial index to rule out arterial injury, because it does not detect nonocclusive arterial injuries such as intimal flaps, focal narrowings, small pseudoaneurysms, and arteriovenous fistulas in up to 10% of cases.[10]

DIAGNOSIS

Diagnosis of associated injuries depends on a complete history and physical exam of the involved extremity. If any hard signs of vascular injury are present, then consult vascular surgery immediately. If there are any soft signs of vascular injury and/or if the ankle-brachial index is <0.9, then order imaging tests to evaluate for associated vascular

TABLE 266-1 Clinical Manifestations of Extremity Vascular Trauma

Hard signs
Absent or diminished distal pulses
Obvious arterial bleeding
Large expanding or pulsatile hematoma
Audible bruit
Palpable thrill
Distal ischemia (pain, pallor, paralysis, paresthesias, coolness)
Soft signs
Small, stable hematoma
Injury to anatomically related nerve
Unexplained hypotension
History of hemorrhage
Proximity of injury to major vascular structures
Complex fracture

TABLE 266-2 Clinical Examination of the Nerves of the Extremities

Nerve	Test of Motor Function	Test for Sensation
Axillary (C5-C6)	Arm abduction	Lateral aspect of shoulder
	Arm internal, external rotation	
Musculocutaneous (C5-C6)	Forearm flexion	Lateral forearm
Radial (C5-C8)	Forearm, wrist, and finger extension	Dorsoradial hand, thumb
Median (C6-T1)	Wrist flexion, finger adduction	Volar aspect of thumb and index finger
Ulnar (C7-T1)	Finger abduction	Volar aspect of little finger
Femoral (L1-L4)	Knee extension	
Obturator (L2-L4)	Hip adduction	
Superior gluteal (L4-S1)	Hip abduction	
Sciatic (L4-S3)	Knee flexion	
Deep peroneal (L4-S1)	Ankle and great toe dorsiflexion	
Superficial peroneal (L5-S1)	Foot eversion	
Tibial (L5-S2)	Ankle plantar flexion	
Posterior tibial (L5-S2)	Great toe plantar flexion	
Spinal L4		Medial calf
Spinal L5		Dorsal foot
Spinal S1		Lateral plantar foot

injuries, or transfer to an institution with vascular care capability (**Figure 266-1**).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for injuries associated with penetrating trauma to the extremities includes arterial or venous injury, nerve damage, tendon lacerations, fractures, soft tissue injury, degloving injuries, damage to joint capsule, bullet embolization of artery, or vein and compartment syndrome.[11]

LABORATORY TESTING

No specific laboratory testing is indicated for isolated penetrating extremity injuries; in certain cases, type and screening and a CBC may be indicated. If the patient has soft signs of vascular injury or an ankle-brachial index <0.9, then obtain a creatinine to determine renal function in patients with risk for preexisting renal disease. Underlying renal insufficiency creates potential for contrast-induced nephropathy when performing CT angiography. See chapter 88, "Acute Kidney Injury" for discussion of radiocontrast-induced nephropathy.

IMAGING

Plain Radiographs Obtain anteroposterior and lateral radiographs of extremities with suspected fracture, joint injury, or retained bullet or other foreign body fragments. Oblique views may add value if the physician has a strong clinical suspicion of retained foreign body and it is not shown on anteroposterior and lateral views. Obtain radiographs of the joint above and below the site of injury. Evidence of air in the joint or an intra-articular fracture on the radiograph demonstrates that joint involvement has occurred.

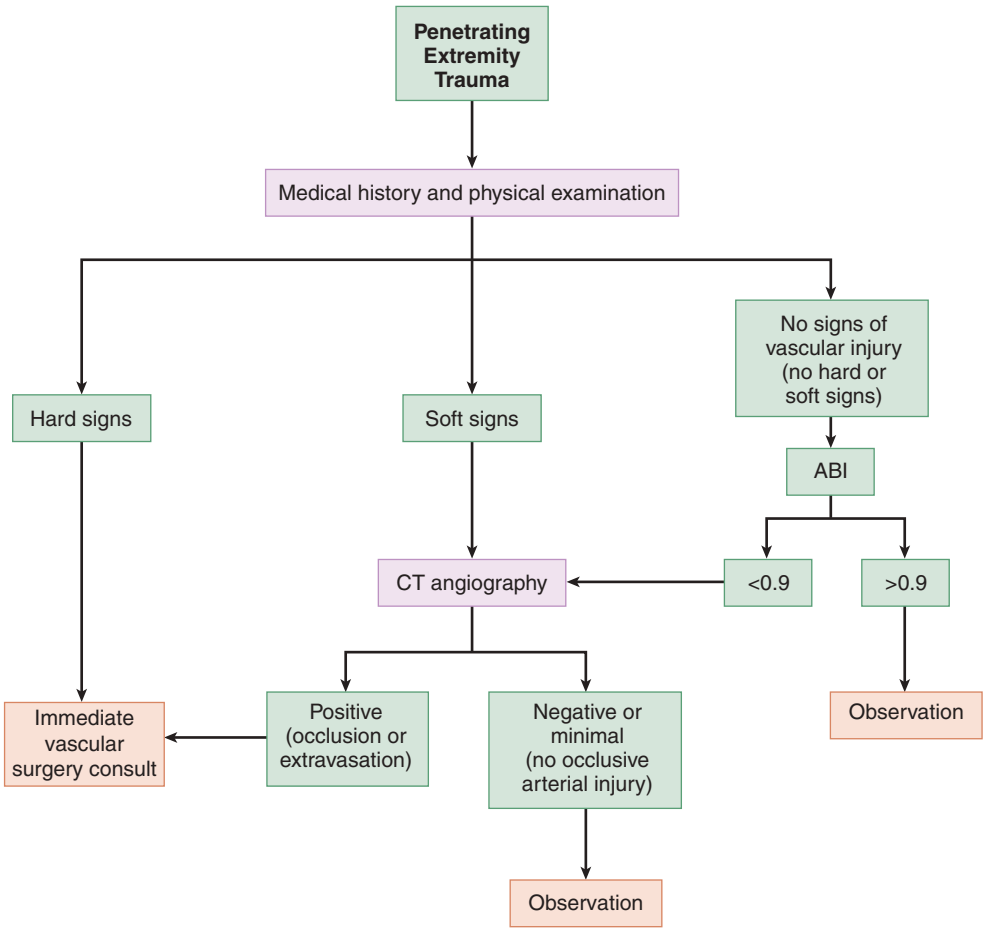

FIGURE 266-1. Algorithm for penetrating extremity trauma. ABI = ankle-brachial index.

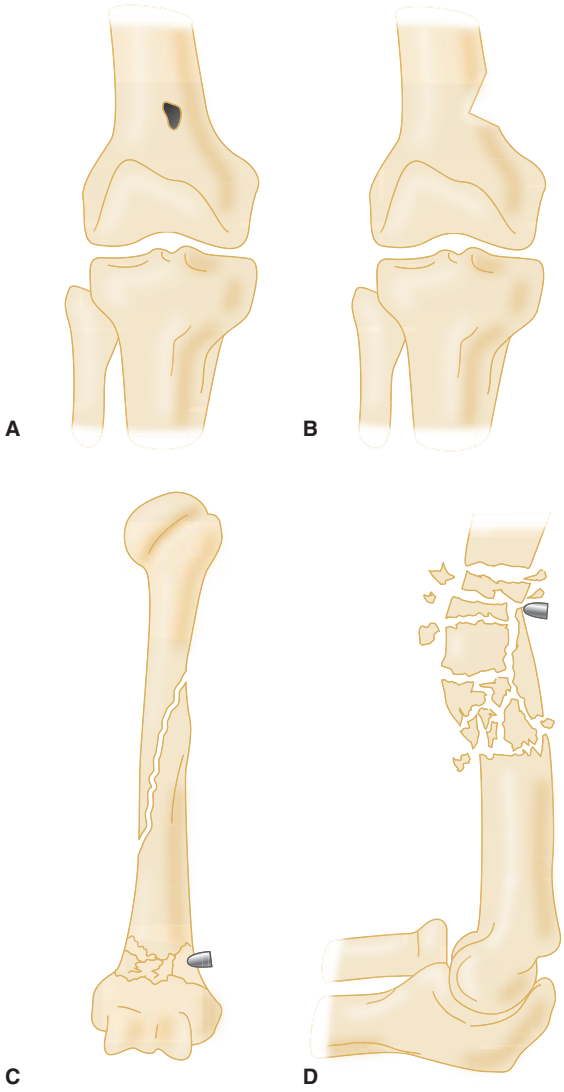

FIGURE 266-2. Fracture patterns created by bullets: drill-hole (**A**), unicortical (**B**), distant spiral (**C**), comminuted (**D**).

There are four types of fracture patterns associated with low-energy gunshots[12] (**Figure 266-2**). The drill-hole wound track pattern appears in the more porous and lower density cancellous bone. This pattern is most common in the distal femur, pelvis, and proximal humerus. Unicortical fractures appear in the metaphyses of long bones and occur only due to tangential impact with the bone. Comminuted fractures occur most frequently in diaphyseal bone; multiple bone fragments are common. The fourth type of fracture is the distal spiral fracture, and this occurs most commonly in the femur. There is controversy in the literature over whether this fracture is caused by the bullet itself or associated with falls that occur after the gunshot injury is sustained.[13]

For shotgun or blast injuries, obtain radiographs of the extremity and joint distal to the injury in order to detect any pellets that have embedded into the bone, remain in the soft tissues, or have potentially entered into a joint capsule (**Figure 266-3**).

CT Angiography CT angiography is the primary diagnostic study for the evaluation of vascular injuries to the extremities.[2] CT angiography is noninvasive, provides higher resolution images, and is less expensive when compared to catheter angiography. It provides three-dimensional reconstruction with minimal artifact. CT angiography also assists in the evaluation of extravascular injuries such as fractures, foreign objects, or joint involvement.[14] Studies comparing CT angiography to catheter angiography have demonstrated that the CT angiography sensitivity and specificity rates for identifying clinically significant arterial injuries are

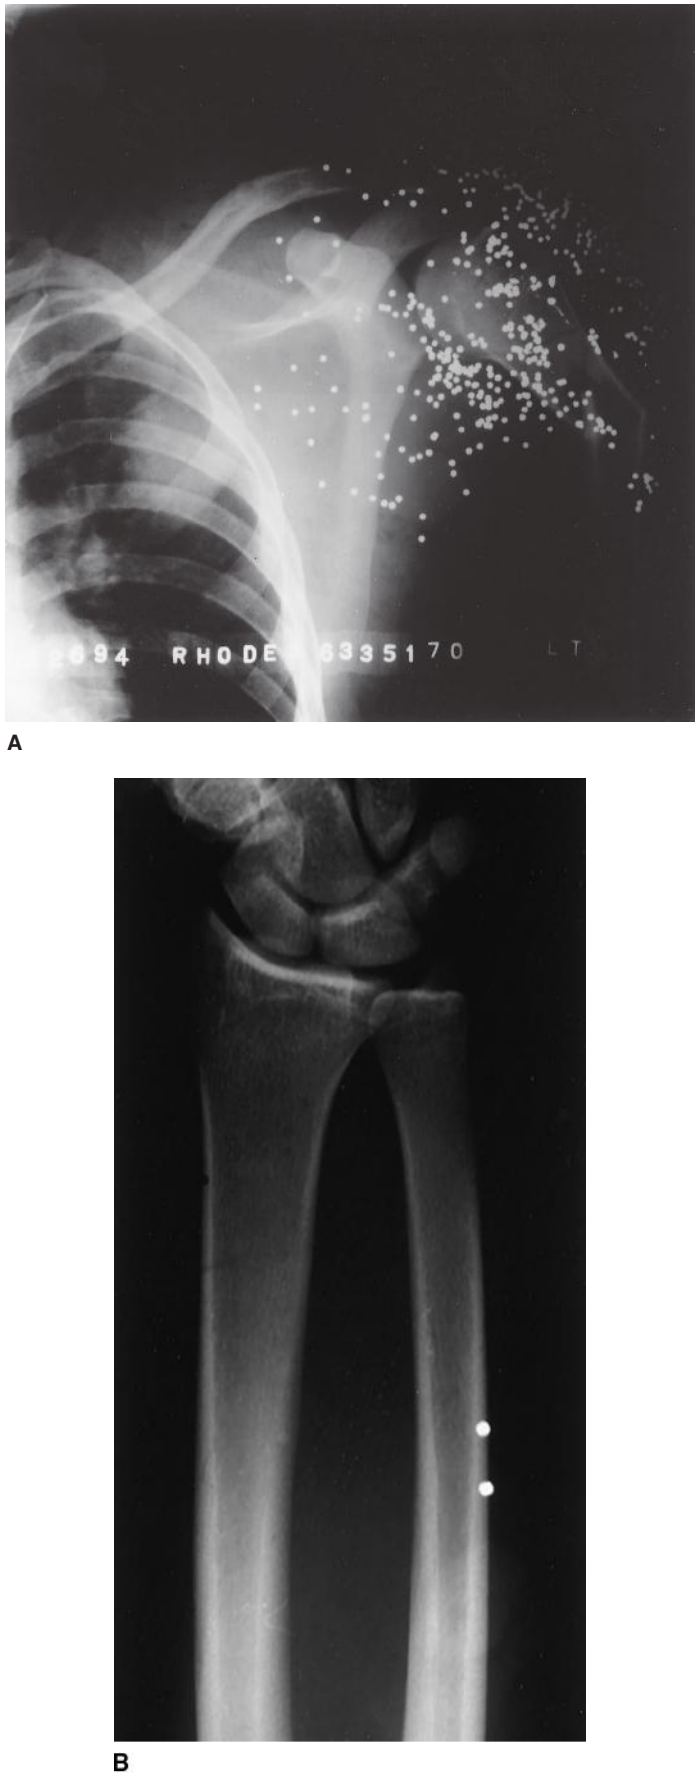

FIGURE 266-3. **A.** Gunshot wound to the shoulder and axilla. **B.** Embedded pellet of shotgun in the distal ulna, illustrating the importance of obtaining images of the extremity distal to such injuries.

equivalent to those with conventional catheter angiography.[15-18] Limitations of CT angiography include scatter artifact interference caused by bullets, poor visualization of tibial vessels, and the inability to perform any therapeutic interventions during the study.

Ultrasonography Color flow duplex ultrasonography has a sensitivity that ranges from 50% to 100% for evaluating vascular injuries.[19,20] Given this mixed evidence of accuracy, color flow duplex ultrasonography should not be used as the primary diagnostic study to rule out vascular injuries associated with penetrating trauma to extremities.[10]

TREATMENT

CONTROL OF BLEEDING

Patients with venous trauma can bleed profusely. Control bleeding with direct pressure, pressure dressing, or a tourniquet. Avoid clamping vessels in an attempt to control bleeding, as this risks nerve damage. Nerves are bundled with vascular structures and can be easily damaged by blind clamping or ligation during the initial trauma resuscitation.

ARTERIAL INJURY

Penetrating injuries to the extremities that involve any associated arterial injury are critically important to recognize early. Figure 266-1 outlines the approach to these injuries.

FRACTURES AND JOINT INJURIES

Penetrating trauma can cause joint sepsis and destruction, rapid chondrolysis, and loss of anatomic contours. These can lead to serious long-term consequences, including posttraumatic degenerative arthritis and partial or total loss of flexibility. Treat bone fractures from penetrating trauma as open fractures. Surgically debride the injury and admit the patient for IV antibiotics, such as a cephalosporin plus gentamicin. Synovial joint fluid is an organic acid, which causes lead bullets to become soluble in the joint and can cause systemic lead toxicity.[21] If a patient has an obvious bony or joint capsule injury, obtain consultation to evaluate the injury.

WOUND MANAGEMENT

Careful wound management is critical to prevent infection after penetrating injuries. The most important component of wound management is irrigation. Copiously irrigate with saline or tap water (500 to 1000 mL) at high pressures (15 to 20 pounds per square inch). Antiseptic solution does not decrease infection rate and may actually be harmful.[22]

Heavily contaminated wounds may require more fluid and/or more pressure. If the wound is older than 3 to 4 hours, gently scrub the wound. Despite the importance of irrigation and wound management, there are many other factors that play a role in infection risk and proper healing, including bacterial inoculum, tissue devitalization, blood supply, time to presentation and treatment, presence of foreign bodies, and host immune status.

WOUND CLOSURE

The decision to close associated open wounds depends on the time that has elapsed since the injury and the degree of contamination. If there is minimal contamination and the wound is well irrigated, it can be closed. It is important to arrange close follow-up in 24 to 48 hours in order to check for developing wound infection. Extremity wounds with retained foreign bodies, major tissue destruction, or contamination should be closed after a delay of 72 to 96 hours. Do not routinely administer antibiotics for uncomplicated extremity gunshot and knife wounds because there is an approximately 2% rate of infection in these injuries.[23] However, antibiotics may be beneficial for treating hand injuries, joint or bony involvement, immunocompromised patients, and wounds with significant contamination.[24]

SOFT TISSUE FOREIGN BODIES

Plain radiographs will detect glass, metal, bone, or gravel. Wood and other organic material may be missed on plain films, and US is better at identifying these objects. CT scanning is the best modality for identifying both radiolucent and opaque foreign bodies. Several factors impact whether the foreign body should be removed. The benefit of exploring the wound and removing the substance must be weighed against the associated damage to surrounding tissues and the increased risk of infection. Organic material is more reactive and has a higher rate of infection than metal or glass. A bullet generally should not be removed unless the bullet has potential to migrate into surrounding vital structures or if it is in the joint capsule.

DISPOSITION, FOLLOW-UP, AND DISEASE COMPLICATIONS

Hard signs of arterial injury require immediate surgical consultation, and such patients will need further imaging, surgery, and hospital admission. All other patients with penetrating extremity trauma should undergo a period of observation with associated serial examinations to detect any delayed or missed injuries. There is no consensus on the required observation time required, but a minimum of 24 hours is reasonable.[17]

Wound healing may be complicated by infections, missed nerve injuries, tendon or joint injuries, delayed vascular injury, and compartment syndrome. Discuss return precautions with patients before discharge. State these precautions as clearly as possible. Recommend that patients return to the ED for increasing pain, numbness, weakness, redness, or pus drainage from the wound site. Ensuring follow-up with the appropriate surgical service, a primary care provider, or the ED is essential, especially in uninsured patients or patients transported long distances from home, as well as for other high-risk populations.

SPECIAL CONSIDERATIONS/SPECIAL POPULATIONS

Uninsured, African American, and Latino populations have higher traumatic injury mortality when compared to the general population. Increased mortality has been demonstrated in the uninsured and the nonwhite populations for lower extremity vascular injuries.[25] Ensure appropriate follow-up and outline clear return precautions. If reliable follow-up cannot be arranged, then consider a longer period of ED or hospital observation.

SECTION 22

Injuries to Bones and Joints

CHAPTER 267

Initial Evaluation and Management of Orthopedic Injuries

Jeffrey S. Menkes

INTRODUCTION

Musculoskeletal trauma involves injury to one or more of the following structures:

Bone: A unit of the skeleton composed of the hardest variety of connective tissue. Bones give shape and support to the body. In addition to surrounding and protecting vital organs, they serve as points of attachment for the muscles of the limbs, making movement possible.

Joint: The area where two or more bones articulate with one another. Joints are usually classified in terms of the amount of motion permitted at the articulation. Most joints of the extremities are synovial joints, which allow the greatest amount of motion.

Ligament: A bundle of connective tissue forming part of the fibrous capsule surrounding a joint and attached to it. Every joint of the extremities is reinforced by two or more ligaments, whose purpose is to stabilize the joint by confining its movements to specific planes and preventing movement beyond physiologic limits.

Tendon: The fibrous structure connecting a voluntary muscle to bone, cartilage, or ligaments. Tendons enable muscles to effect motion in the joint or body area to which they are attached.

Orthopedic injuries to these structures include the following:

Fracture: A disruption of bone tissue. Fractures may be caused by: (1) an application of force exceeding the strength of the bone, (2) repetitive stress, or (3) an invasive process that undermines the bone's integrity.

Dislocation: Complete disruption of a joint, such that the articular surfaces of the bones that comprise the joint are no longer in contact with one another.

Subluxation: Partial disruption of a joint, in which some degree of contact between the articular surfaces remains.

Fracture-dislocation or fracture-subluxation: Disruption of a joint combined with fracture of at least one of the bones involved in the articulation.

Strain: A tearing injury to muscle fibers resulting from excessive tension or overuse.

Sprain: A tearing injury to one or more ligaments of a joint, which occurs when the joint is forced beyond the limits of its normal planes of motion.

PATHOPHYSIOLOGY OF FRACTURES

Properly assessing and treating bony injuries in the ED requires an understanding of the physiologic processes by which fractures are created and by which they heal. Practical knowledge of fracture pathophysiology may provide the index of suspicion needed to diagnose an injury that might otherwise be missed. It also may help prevent or minimize complications and sometimes may form the basis for advising the patient regarding the outlook for recovery of function.

TYPES OF FRACTURES

Although fractures are sometimes classified in terms of the mechanism that created them, they also may be described in terms of the physiology involved.

"Common" Fractures Most fractures are the result of significant trauma to healthy bone. The bony cortex may be disrupted by a variety of forces, including a direct blow, axial loading, angular (bending) forces, torque (twisting stress), or a combination of these.

Pathologic Fractures Fractures that result from relatively minor trauma to diseased or otherwise abnormal bone are termed pathologic fractures. In such cases, a preexisting process has weakened the bone and rendered it susceptible to fracture by forces that, under normal circumstances, would not disrupt the cortex. Common examples of such injuries are fractures through metastatic lesions, fractures through benign bone cysts, and vertebral compression fractures in patients with advanced osteoporosis. Numerous other disease processes may render an individual susceptible to pathologic fracture. Because these injuries often are not associated with a history of significant trauma, subtle pathologic fractures may go undetected unless there is a clinical index of suspicion.

Stress Fractures Bone may undergo a "fatigue" fracture by being subjected to repetitive forces before the bone and its supporting tissues have had adequate time to accommodate to such forces. An example is a metatarsal shaft fracture in unconditioned foot soldiers ("**march fracture**"). Radiographs often are negative early in the clinical course of stress fractures. The initial diagnosis may be presumptive, based solely on the history and findings of point tenderness or localized swelling. Days or weeks may pass before the fracture line or new bone formation becomes visible radiographically.

Salter (Epiphyseal Plate) Fractures Fractures involving the physis, the cartilaginous epiphyseal plate near the ends of the long bones of growing children, were originally classified by Salter and Harris[1] and are commonly called *Salter fractures*. New bony material needed for the elongation of bones during growth is provided by specialized cells within the physis. When growth is completed, the physis transforms from cartilage into bone, ultimately fusing with the bone surrounding it, and disappearing as a distinct entity. By definition, Salter fractures cannot occur in fully grown adults.

Damage to the epiphyseal plate during a child's growth may destroy part or all of its ability to produce new bone substance, resulting in aborted or deformed growth of the limb. The potential for growth disturbance from an epiphyseal plate injury is related to the number of years the child has yet to grow (the older the child, the less time remains for deformity to develop) and to the pattern of the fracture line through the epiphyseal area. Classification of Salter fractures and their clinical implications are discussed in the section Describing Radiographs in this chapter.

FRACTURE HEALING

An understanding of the short- and long-term aspects of bone healing helps decision making regarding fracture reduction, treatment modality, and the prognosis for regaining function or being left with residual deformity. Fracture healing consists of three phases: inflammatory, reparative, and remodeling, each of which blends into the next, with some degree of overlap between them.[2] When a fracture occurs, the microvessels crossing the fracture line are severed, depriving the damaged bone ends of their blood supply. As a result, the bone ends gradually necrose, triggering a classic inflammatory response in which neutrophils, macrophages, and lymphocytes migrate to the area. The proteins and peptides (collectively

termed *cytokines*) released by these cells promote revascularization.[3] This early phase is brief but creates the tissue environment for the most predominant aspect of fracture healing, the reparative phase.

Granulation tissue soon begins to infiltrate the area.[4] Within the granulation tissue are specialized cells capable of forming collagen, cartilage, and bone—the ingredients of callus. Callus gradually surrounds the fractured ends and stabilizes them, becoming more densely mineralized with time.

Meanwhile, the necrotic edges of the fragments are removed by osteoclasts, cells whose function is to resorb bone. That is why some "hairline" fractures do not appear on a radiograph until days after injury. Invisible initially, the diagnostic fracture line appears only after necrotic bone has been resorbed from the area.

The final phase of bone healing, the remodeling phase, is the longest, sometimes lasting years. Remodeling is the tendency of bone gradually to regain its original shape and contour. During this phase, superfluous portions of callus are resorbed, and new bone is laid down along the natural lines of stress. These layers, easily visible on radiographs of normal bone, are the bony trabeculae. The formation of trabecular bone is a physiologically efficient process providing maximum strength relative to the amount of bone material used.

The anticipated degree of remodeling after a fracture is related to a number of factors. Predictors of satisfactory remodeling include youth, proximity of the fracture to the end of the bone (but not involving the epiphyseal plate), the amount of angulation, and the extent to which the direction of angulation coincides with the plane of natural joint motion.

Clinical decisions regarding the aggressiveness of fracture reduction are directly linked to knowledge of bone-healing physiology. Some angulation near the end of a long bone, for example, may be more acceptable than the same amount of angulation near the midshaft. In the wrist, dorsal or volar angulation has a better prognosis than does ulnar or radial angulation because the natural plane of wrist motion is dorsal to volar. Mild angulation in a 2-year-old child may be left to remodel on its own, whereas the same amount of angulation in an adult may require correction.

ORTHOPEDIC EMERGENCIES

OPEN FRACTURE

An open fracture is a fracture associated with overlying soft tissue injury, creating communication between the fracture site and the skin. Although this term may convey the image of grossly exposed bone, the term is equally applicable to any puncture wound extending to the depth of an underlying fracture. Such puncture wounds may be created by external forces or may occur from within, when a sharp bone fragment transiently protrudes through the skin before receding back beneath the surface.

A potential major complication of open fracture is osteomyelitis. Once established, osteomyelitis may result in months or years of pain, disability, medical therapy, surgical procedures, and, in some cases, amputation. Although osteomyelitis may sometimes be unavoidable, it is less likely when treatment is prompt and meticulous.

Open fractures are usually classified by their severity, based on the extent of overlying tissue disruption, lack of bone coverage, kinetic energy of the injuring force, and evidence or likelihood of significant contamination. Irrespective of these factors, any open fracture should be promptly and carefully treated.

SUBLUXATION AND DISLOCATION

Subluxation is a condition in which the articular surfaces of a joint are nonconcentric to any degree. Dislocation is the most extreme form of subluxation. A joint is dislocated when the articular surfaces of the bones that normally meet at the joint are completely out of contact with one another. The urgency of reducing a dislocation is based on several factors. One is the potential for neurologic or circulatory compromise. The neurovascular bundle passing close to the affected joint may become "kinked" around the dislocation. This may result in neurologic or vascular deficit that might be temporary if the deformity is reduced promptly but irreversible if treatment is delayed. Another consideration is that the longer a joint has been dislocated, the more difficult it may be to reduce and the less stable the reduction is likely to be. This is probably due, at least in part, to edema, muscle spasm, and other tissue changes that increase over time.

Dislocation of the hip also carries the potential for avascular necrosis of the femoral head. The necrosis occurs because much of the blood supply to the femoral head is delivered through vessels that emerge from the acetabulum. When the joint is dislocated, circulation to the femoral head is disrupted. At some point, the vascular insult becomes irreversible, and bony necrosis results. Although aseptic necrosis may occur despite the clinician's best efforts, its likelihood increases with the delay until reduction.

NEUROVASCULAR INJURY

Any injury associated with neurologic or vascular compromise should be addressed as soon as possible. The longer such a deficit goes untreated, the longer it is likely to persist and the greater the possibility that it will be irreversible. In some cases, reducing a deformity by means of longitudinal traction is all that is necessary to restore circulation or nerve function.

PREHOSPITAL CARE

PRELIMINARY SPLINTING

Effective splinting of an injured extremity is important for several reasons: (1) it reduces pain, (2) it reduces damage to nerves and vessels by preventing them from being compressed between the fracture fragments or being stretched by angulation at the fracture site, (3) it reduces the chance of inadvertently converting a closed fracture to an open one should a sharp bone fragment poke its way through the skin, and (4) it reduces the pain associated with patient transport by minimizing motion of the fracture fragments.

PREHOSPITAL SPLINTING DEVICES

Many splinting modalities are available to EMS personnel. These may range from sophisticated devices, such as vacuum splints containing small beads that conform to the extremity when air is removed, to simpler techniques such as cardboard or pillow splints, or padded IV boards.

Sling and Swath For injuries of the wrist or forearm, consider using a sling to supplement the splint, because optimal immobilization includes the joint above and the joint below the fracture, and a sling helps keep the elbow at rest.

For suspected injuries to the shoulder, humerus, or elbow, a sling-and-swathe arrangement works well. This method involves applying a sling, then binding the affected arm to the thorax with a gauze wrap. An exception to this principle is immobilization of patients with suspected anterior dislocation of the shoulder. Many patients with this injury have difficulty adducting the forearm, and forcibly binding it to the thorax may be painful. A simple sling is adequate in such cases. Injuries to the ankle may be immobilized in a pillow or well-padded cardboard splint. If a fracture of the tibial shaft or knee is suspected, the device should extend well above the knee to immobilize the joint above and the joint below the fracture.

Splints Some injuries warrant special splints, such as a winch-mechanism traction apparatus for femoral shaft fractures. Although such a device does not immobilize the hip (the joint above the fracture), the traction component makes this unnecessary. If a traction device is not available, then both the hip and knee should be immobilized. One method of accomplishing this is to bind the legs together, then bind the patient to a backboard from ankles to thorax with folded sheets or towels beneath the lower legs (but not the feet) to ease pressure on the heels.

Other types of splints exist, but their use is controversial. Inflatable plastic splints, for example, may be used for injuries to the ankle or wrist but sometimes are used inappropriately for fracture of the humerus or femur. Because these devices normally do not extend sufficiently proximally, they provide inadequate immobilization for such injuries. Also, overinflating the device may impair circulation. **If the inflatable splint cannot be dented by moderate thumb pressure, it is probably overinflated.** Inflatable splints should not be applied over clothing, because wrinkles in the clothing may cause pressure sores in swollen and vulnerable tissue.

Also controversial are nonmalleable aluminum splints, because they are based on the "one size fits all" principle, which some clinicians interpret as

"this size fits none." Malleable aluminum splints are preferable, as they can be made to conform more closely to the contour of the extremity, even accommodating some degree of deformity. If used, aluminum splints of either type should be well padded, because their hard surface may cause pressure sores. Like any splint, they should immobilize the joint above and the joint below the fracture when used for long-bone injuries. For example, an above-knee splint is indicated for suspected fracture of the tibial shaft. Aluminum splints should be removed promptly once a fracture is diagnosed or ruled out. If a fracture is confirmed, replace the splint with an alternative immobilization dressing before the patient leaves the ED, because aluminum splints may cause pressure sores even when padded.

Military Antishock Trousers Another controversial device is military antishock trousers. This device may be used during ambulance transport of patients with already diagnosed pelvic ring fracture, or for patients with a clinically apparent femoral fracture when a traction device is not at hand, as the device immobilizes the joints above and below the fracture. Some EMS systems also advocate its use for patients with bilateral femur fractures even when traction is available, because of the anatomic difficulty of applying two traction splints. However, military antishock trousers are cumbersome to apply, their efficacy is not firmly established, and they can possibly contribute to compartment syndrome, fluid and electrolyte imbalance, and circulatory impairment.[5,6]

REDUCING DEFORMITY IN THE FIELD

Many EMS programs do not recommend prehospital reduction of deformity for an injured extremity, as injudicious manipulation may convert a pure dislocation to a fracture-dislocation. Even if a fracture had already existed, there would be no way to prove it was not caused by the manipulation. One circumstance in which prehospital reduction of obvious fracture to the shaft of a long bone may be justified is a nonpalpable distal pulse. In the absence of a common standard, the indications for reduction of deformity by prehospital personnel remain at the discretion of the supervising EMS program.

CLINICAL FEATURES

The importance of a careful history and physical examination cannot be overstated. Orthopedic diagnosis is sometimes thought of as being as simple as taking a radiograph of the painful area. Although imaging is an important adjunct, it is not the ultimate diagnostic resource. **The pain of a fracture or a dislocation may be referred to another area.** For example, patients with disruption of the sternoclavicular joint or fracture of the humeral shaft may complain only of shoulder pain. If the radiograph is based solely on where the patient reports discomfort, then the injured part might not be included on the film. **Imaging decisions should be based not only on the chief complaint, but also on systematic palpation, observation of subtle deformity or significant point tenderness, and mechanism of injury.**

Some fractures or dislocations may be demonstrated only by special radiographic views, which are not part of the standard series for that body part. Such views will never be ordered unless the clinician has already formulated a presumptive diagnosis based on the history and physical findings.

Some injuries might not be radiographically apparent on the first day, regardless of what views are taken. Common examples are fracture of the scaphoid, nondisplaced fracture of the radial head, and stress fracture of a metatarsal. The classic radiographic signs accompanying these injuries, such as the fat-pad sign of the elbow, are not always conveniently present, but mechanism, history, and findings suggesting the injury often are. CT or MRI may allow early diagnosis of fractures that are not radiographically evident. However, such tests are not always available or feasible on the day of injury. In such cases, the diagnosis of fracture may be purely clinical until 7 to 10 days post-trauma, when enough bony resorption has occurred at the fracture site to reveal a lucency on plain radiographs.

HISTORY

The value of the history in cases of orthopedic trauma is often underestimated. Knowing the precise mechanism of injury may be the key to diagnosing some fractures or dislocations. For example, a history of shoulder injury combined with the complaint of dysphagia may be the only clue to the existence of posterior sternoclavicular dislocation. This entity, which causes pressure on mediastinal structures, often can be demonstrated only by CT and may result in severe complications if treatment is delayed. **Table 267-1** provides other examples of mechanisms that may lead the clinician to suspect, or presumptively treat for, specific injuries. This is by no means a definitive or exhaustive list. Some of the mechanisms described may produce injuries other than those mentioned. Conversely, the injuries may be produced by mechanisms in addition to those listed.

TABLE 267-1 Mechanisms Associated With Particular Orthopedic Injuries

Mechanism	Possible Injury
Bilateral compression of the shoulders	Anterior or posterior sternoclavicular dislocation
Direct blow to the medial clavicle	Posterior sternoclavicular dislocation
Fall, landing on the apex of the shoulder	Acromioclavicular separation
Direct blow to the anterior shoulder, fall on the outstretched arm, seizure or electroconvulsive muscular activity	Posterior dislocation of the shoulder
Sudden traction force to a toddler's arm	Subluxed radial head (sometimes misdiagnosed as brachial plexus injury because of pseudoparalysis of the arm)
Fall, landing on the outstretched arm or with the elbow beneath the body	Fracture of the radial head (may be occult on initial x-ray)
Forced dorsiflexion of the wrist	Fracture of the scaphoid, lunate dislocation, perilunar dislocation, Colles fracture
Striking the knee against the dashboard in a high-speed collision	Posterior dislocation of the hip
Landing flat on the feet from a height	Calcaneus fracture; tibial plateau fracture; acetabular fracture; vertebral compression fracture, usually lumbar
Ankle inversion force	Fracture of any of the three malleoli, fracture of the base of the fifth metatarsal
Rotatory ankle force	Fracture of any of the three malleoli, disruption of the anterior tibiofibular ligament with proximal fibular fracture (Maisonneuve's injury)
Inversion or medial or lateral stress to the forefoot; axial load on the metatarsal heads with the ankle plantarflexed	Midfoot dislocation (Lisfranc's injury)

Some musculoskeletal injuries or conditions may not necessarily be associated with a history of direct trauma. Occult fracture of the hip in an osteoporotic individual, occult stress fracture of a metatarsal in someone who has recently done an unusual amount of walking, and slipped capital femoral epiphysis in a preteenager or young adolescent are examples of injuries in which symptoms may be gradual and insidious in onset, unrelated to an isolated traumatic event. **Exquisite tenderness to palpation or pain on weightbearing or passive range of motion suggests the possibility of an occult or easily missed fracture.** Depending on the index of suspicion, further studies, such as a bone scan or MRI, may be indicated to exclude significant pathologic conditions before the patient is allowed to resume weightbearing.

History taking should not necessarily be limited to orthopedic issues. Depending on the situation, a general medical history should be obtained because it may have implications for further workup, the potential for complications, or ultimate prognosis for recovery of function. Relevant issues may include a history of heart disease or neurologic disease, taking anticoagulant medication, falling due to syncope or transient hemiparesis, or an unsteady baseline gait that cannot withstand further impairment.

PHYSICAL EXAMINATION

Essential components of the examination for musculoskeletal trauma are (1) inspection for swelling, discoloration, or deformity; (2) assessment of active and passive range of motion of the joints proximal and distal to the injury; (3) palpation for tenderness or deformity; and (4) assessment of neurovascular status.

Inspection and Range of Motion Gross deformity along the shaft of a long bone is pathognomonic for fracture. Deformity at a joint, loss of range of motion, and severe pain at rest suggest the presence of a dislocation or fracture near the joint. An exception is posterior dislocation of the shoulder, which, although intensely painful, might not be accompanied by obvious deformity, although the humeral head may be palpable posteriorly.

Palpation When gross deformity is not present, presumptive diagnosis strongly depends on findings noted on palpation. Palpation may disclose areas of bony step-off and the precise location of point tenderness.

The palpation examination should be done systematically and consistently from one patient to the next. The area palpated should extend well beyond the location of pain described by the patient, as the pain may be referred. For example, when an injured patient complains of shoulder pain, palpation should begin at the sternoclavicular joint, then proceed along the clavicle onto the acromioclavicular joint, then onto the humeral head and along the entire humeral shaft. In addition, the scapula should be palpated for tenderness, and the posterior aspect of the shoulder should be palpated for any unnatural prominence or fullness that might suggest posterior dislocation of the humeral head. Injury to any of these areas may be reported by the patient as "pain in the shoulder." Only a meticulous palpation examination may protect the clinician from being misled by referred pain and missing a crucial diagnosis.

Neurovascular Assessment When injury involves an extremity, as opposed to the vertebral column, sensorimotor testing should be performed on the basis of peripheral nerve function, rather than nerve root and dermatomal distribution (**Figure 267-1**). In the upper extremity, the radial, median, and ulnar nerves should be tested. When the shoulder is anteriorly dislocated, two additional nerves, the axillary (supplying sensation to the lateral aspect of the shoulder) and the musculocutaneous (supplying sensation to the extensor aspect of the forearm), also should be checked. In the lower extremity, examination of the saphenous (sensory only), peroneal, and tibial nerves should be performed. Neurologic deficit is important to document early, particularly before the patient has undergone any significant manipulation or reduction maneuvers.

Assess vascular status early. **The sooner circulatory compromise is identified and addressed, the better the chance of avoiding tissue ischemia or necrosis.** Injuries such as dislocation of the knee (tibiofemoral joint), fracture-dislocation of the ankle, and displaced supracondylar fracture of the elbow in children may be associated with vascular disruption, with resulting circulatory impairment.

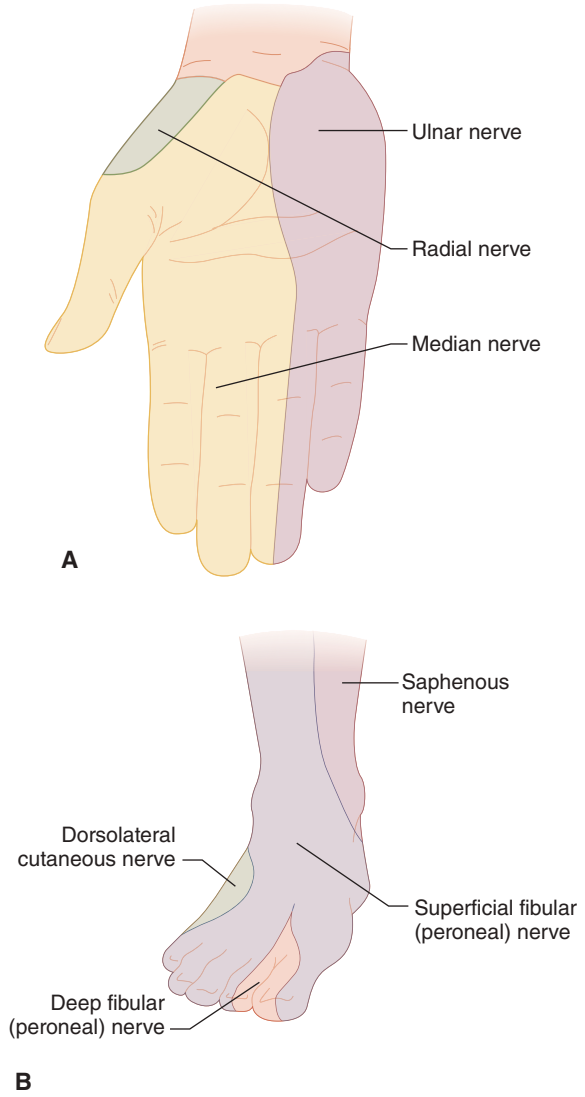

FIGURE 267-1. **A.** Peripheral sensory nerve distribution of the hand. **B.** Peripheral sensory nerve distribution of the foot.

DIAGNOSIS

IMAGING

The joints above and below a fracture should generally be imaged because injury at the proximal or distal joint may coexist with long-bone fractures. Injuries that may require special views or advanced imaging modalities in order to be visualized include acromioclavicular separation, fracture of the scaphoid, posterior shoulder dislocation, and sternoclavicular dislocation.

The use of bedside US has been reported for pediatric clavicle and forearm fractures and long-bone fractures. However, US for these purposes is operator dependent and has not replaced traditional diagnostic imaging.[7-10]

Children who have sustained trauma at or near a joint may need comparison studies of the opposite extremity to differentiate fracture lines from normal epiphyseal plates or ossifying growth centers. This is particularly true of the pediatric elbow, which typically exhibits six ossification centers sequentially as the child grows.

Although the clinician may be tempted to base diagnostic and treatment decisions on the radiologist's report, this is not advisable for at least two reasons. First, **a negative radiologic report does not exclude significant injury.** Fracture of the radial head, scaphoid, or metatarsal shaft, for example, may be undetectable on radiographs initially, even when special views are taken. Second, the terminology used by radiologists to describe malposition of fracture fragments or disrupted joints often differs from the terminology used by orthopedists. Because the emergency physician may confer with an orthopedist regarding the initial management of a patient, and because this interaction commonly involves describing the radiographic appearance of an injury, it is important that the two physicians "speak the same language."

DESCRIBING RADIOGRAPHS

As more hospitals convert from film-based to digital imaging, orthopedic consultants are increasingly likely to be able to examine a patient's imaging studies by remote access. In the absence of such technology, proper management of the patient may depend on the emergency physician's ability to convey the radiographic appearance of the injury to the consultant. In such cases, the narrative often will influence the orthopedist's decision regarding the need for hospital admission and whether surgical versus nonsurgical management is warranted. In essence, the emergency physician should be able to transmit a virtual copy of the radiograph by means of verbal description.

There are a number of ways to characterize the appearance of fractures. The method presented below is intended to be the most practical from the standpoint of communicating with an orthopedic consultant.

Open Versus Closed Although not a radiologic finding per se, whether a bony injury is open or closed is an important consideration and should be conveyed to the orthopedist at the outset. The implications of open fracture are of such significance that this factor alone may determine the patient's immediate care or ultimate disposition.

Location of the Fracture **Typical reference points used by orthopedists to describe the location of a fracture along the shaft of a long bone are the midshaft, the junction of the proximal and middle thirds, and the junction of the middle and distal thirds.** Any fracture more proximal or distal than these locations may be described in terms of its distance, in centimeters, from the bone end.

When a fracture extends into the adjacent joint, it is termed intra-articular. Intra-articular fractures have special significance because disruption of the joint surface may warrant surgery to restore the joint's contour and prevent subsequent traumatic arthritis. This feature of a fracture line, if present, constitutes important information.

Anatomic bony reference points should be cited when applicable. A fracture just above the condyles of the distal humerus or femur, for example, is termed a supracondylar fracture. A fracture running from the greater to the lesser trochanter of the proximal femur is an intertrochanteric hip fracture, whereas a fracture just below the trochanters is subtrochanteric, a fracture just above them is said to involve the femoral neck, and a higher fracture just below the femoral head is referred to as subcapital. The area at or proximal to the coronoid process of the ulna is the olecranon and should be referred to as such, rather than simply the "proximal ulna." Other bony landmarks include the radial head at the elbow, radial styloid at the wrist, and the greater tuberosity of the humeral head. Numerous additional examples exist.

Orientation of the Fracture Line The most common orientations of fracture lines are illustrated in **Figure 267-2**. Torus and greenstick fractures occur almost exclusively in young children, whose bones are more pliable than those of adults. Note the segmental fracture, which is commonly described incorrectly as a comminuted fracture. To an orthopedist, the term *comminuted* implies splintering or shattering. A single, large, free-floating segment of bone between two well-defined fracture lines is a segmental fracture.

Displacement and Separation The term *displacement* may be used in either of two ways. In the broadest sense, it pertains to any deviation from anatomic position or alignment. Used more precisely, displacement refers to the extent to which fracture fragments are nonconcentric or offset from each other. The magnitude of displacement may be expressed in terms of direct measurement (e.g., 4-mm displacement) or in terms of the percentage of the width of the bone (e.g., 50% displacement, complete displacement). The direction of displacement is based on the position of the distal fragment relative to the proximal fragment.

Displacement should not be confused with separation, which is the distance two fragments have been pulled apart. **Figure 267-3** illustrates principles of displacement and separation.

Shortening Shortening, expressed in millimeters or centimeters, is the amount by which a bone's length has been reduced. Shortening may occur by impaction (telescoping of the fragments into one another) or by the overlap of two completely displaced fragments (**Figure 267-4**). The latter is referred to by some orthopedists as *overriding*. Because a radiograph affords no depth perception, a fracture that appears impacted on one view needs to be visualized at an angle 90 degrees from the first to differentiate it from a fracture whose ends are completely displaced and overriding. Depending on the location of the fracture and the age of the patient, shortening may have long-range functional implications and may have to be corrected by closed manipulation or by surgery.

Angulation Angulation is described in terms of two parameters: degree and direction (**Figure 267-5**). Quantifying the angulation is relatively simple. One need only estimate the amount of "unbending" (expressed in degrees) that would be needed to make the fragments parallel.

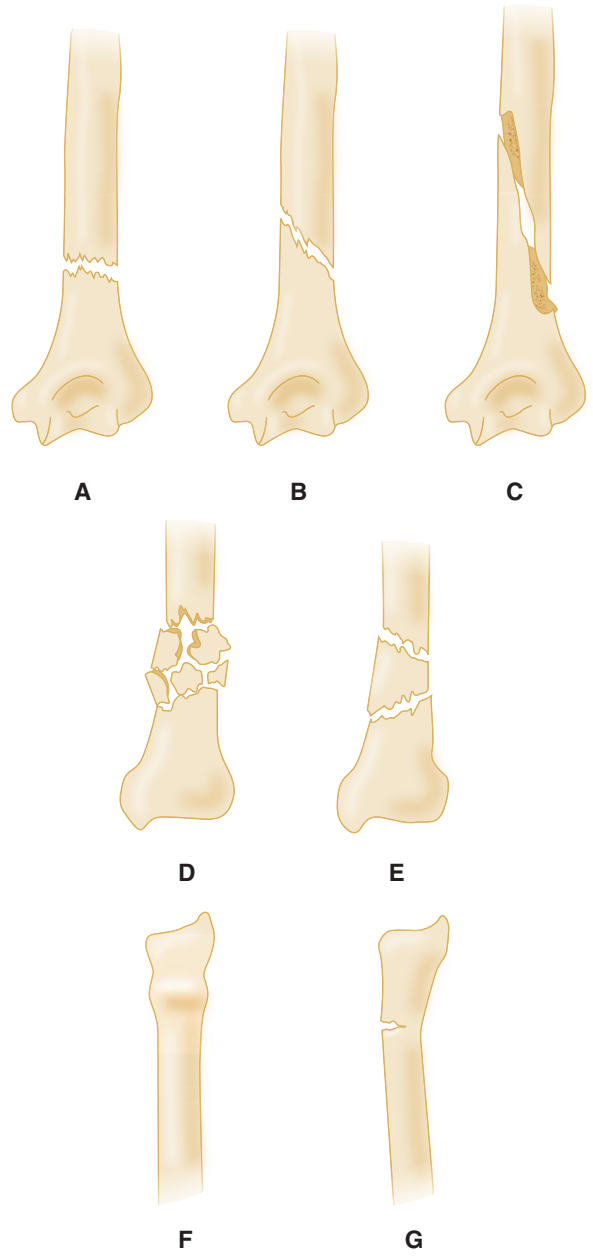

FIGURE 267-2. Fracture line orientation. **A.** Transverse. **B.** Oblique. **C.** Spiral. **D.** Comminuted. **E.** Segmental. **F.** Torus. **G.** Greenstick.

Conveying the direction of angulation may be more difficult because the terminology is less consistent among clinicians. In general, when a fracture is near the midshaft of a long bone, the direction of angulation is the direction of the apex of the angle formed by the two fragments. (**Figures 267-5A** and **267-5B** illustrate 30 degrees of dorsal angulation.) When a fracture is near the end of a bone, however, angulation is described in terms of the direction the terminal fragment is deviated. Thus **Figure 267-5C** also shows 30 degrees of dorsal angulation, even though the apex of the angle formed by the fragments is pointing in the opposite direction from that in the preceding figures. **If there is a possibility of ambiguity in the description, specifying the *direction of deviation of the distal fragment* usually can resolve it.**

Depending on the anatomic area involved, direction of angulation may be expressed as anterior or posterior, lateral or medial, radial or ulnar, or dorsal or volar.

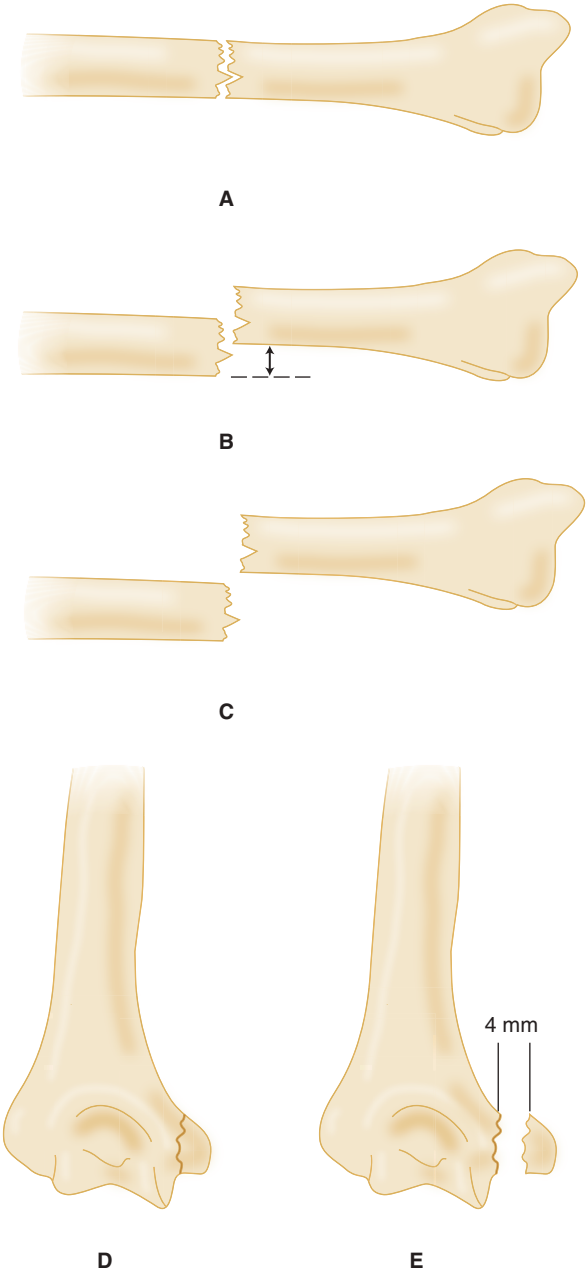

FIGURE 267-3. Fracture displacement and separation. **A.** No displacement, slight separation. **B.** Fifty percent dorsal displacement. **C.** Complete dorsal displacement. **D.** Nondisplaced, no separation. **E.** A 4-mm separation.

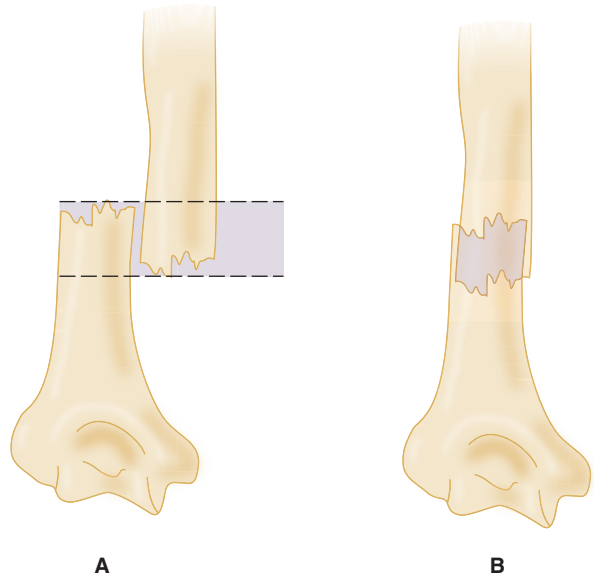

FIGURE 267-4. Shortening at fracture site. **A.** Complete displacement with overriding. **B.** Impaction. In both cases, the width of the shaded area represents the amount of shortening.

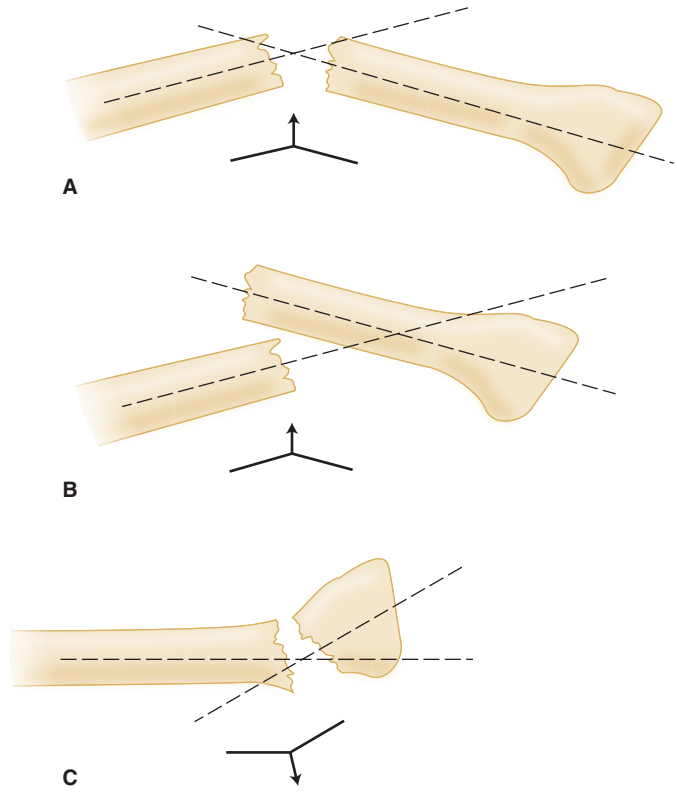

FIGURE 267-5. Fracture angulation. All figures depict 30-degree dorsal angulation. **A, B.** Direction is based on the apex of the angle drawn below the figures. **C.** Direction is based on the direction of the terminal fragment.

Rotational Deformity Rotational deformity—that is, the extent to which the distal fracture fragment is twisted on its own axis relative to the proximal fragment—is generally not apparent on radiographs. This element of fracture description depends on physical examination. Its detection is particularly important in the phalanges of the fingers, where, if rotational deformity goes unrecognized and uncorrected, the injured finger will permanently be malaligned when the hand is closed.

Fracture Combined With Dislocation or Subluxation Injuries near a joint may involve dislocation or subluxation combined with a proximate fracture. An example is fracture of one or more ankle malleoli, together with partial or complete displacement of the talus from beneath the tibia. These are significant injuries, often requiring surgical intervention. If, in describing the injury, the clinician emphasizes the fracture component but expresses the dislocation or subluxation as mere "displacement," then the full severity may not be appreciated by the orthopedist. Such injuries should be described as fracture-dislocations or fracture-subluxations.

Salter-Harris Fractures Salter and Harris classified fractures involving the epiphyseal plate at the end of the long bone of a growing child into

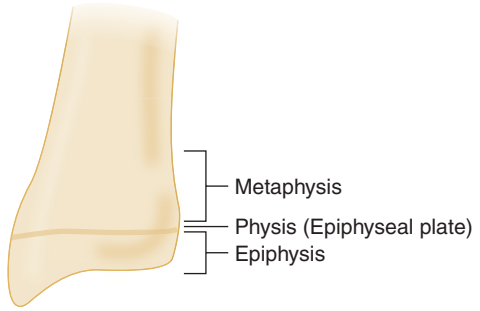

FIGURE 267-6. Epiphyseal anatomy in the growing child.

five types based on the pattern of the fracture line. Because the type generally correlates with the potential for future growth disturbance (and, consequently, with the aggressiveness of the treatment warranted), the ability to identify the fracture type based on its radiographic appearance is important.

Perhaps the easiest way to remember the Salter-Harris classification system is to think of these injuries not in terms of where the fracture line runs, but in terms of what has been *broken off.* **Figure 267-6** illustrates the anatomy involved. **Table 267-2** lists the five types of Salter-Harris fractures, which are illustrated in **Figure 267-7**. The potential for growth disturbance is least for type I and increases with the classification number, with the worst prognosis being associated with type V injuries.

Type I and type V Salter fractures may be radiographically undetectable. Type I injuries usually involve no transverse displacement and little or no separation of the epiphysis from the rest of the bone. Also, the lucent fracture line is not visible within the equally lucent epiphyseal plate. Diagnosis of acute Salter type I fractures is usually presumptive, based on the presence of swelling and tenderness in the region of the physis.

Type V injuries may be evident only retrospectively, when growth disturbance first begins to appear. At the time of initial presentation, however, a history of a significant axial loading force, coupled with significant tenderness in the area of the epiphyseal plate, should suggest the possibility of a type V injury. Such injuries should be immobilized and referred for orthopedic follow-up.

TREATMENT

CONTROL PAIN AND SWELLING

Initiate measures to reduce swelling early. Severe swelling not only intensifies the pain of injury but also may delay the application of a definitive immobilization dressing and may make the skin more susceptible to pressure sores. Although sometimes regarded as trivial modalities, the application of cold and elevation are often quite effective in keeping swelling to a minimum or at least halting its progression. Jewelry, watches, or rings that may cause compression or constriction as an extremity swells should be removed.

Give analgesics as necessary. If the patient is relatively comfortable at rest, medication may not be required. **Even narcotic analgesics may have minimal effect on the pain of movement or manipulation unless combined with other CNS–acting agents.**

TABLE 267-2 Description of Salter-Harris Fractures

Salter Type	What Is Broken Off
I	The entire epiphysis
II	The entire epiphysis *along with* a portion of the metaphysis
III	A portion of the epiphysis
IV	A portion of the epiphysis *along with* a portion of the metaphysis
V	Compression injury of the epiphyseal plate (nothing is "broken off")

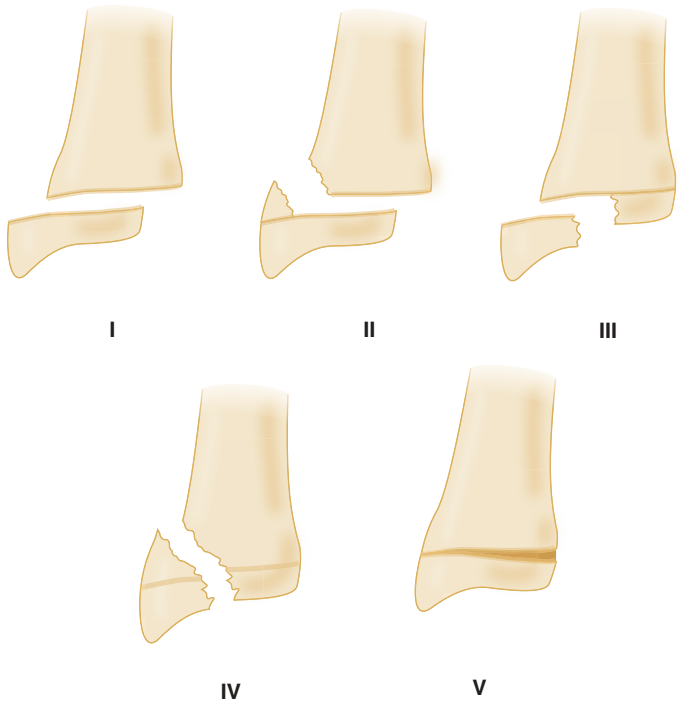

FIGURE 267-7. Epiphyseal plate fractures based on the classification of Salter and Harris.

WITHHOLD ORAL INTAKE

Any patient who might be a candidate for prompt surgical fixation, manipulation, or any other procedure under general anesthesia or procedural sedation should not be allowed to eat or drink from the moment of arrival until the need for, and timing of, such a procedure has been ascertained.

REDUCE FRACTURE DEFORMITY

The long-term purpose of reducing significant deformity associated with fractures is restoration of normal appearance and function of the extremity. However, there are also short-term benefits to reducing deformity early: (1) alleviating pain, (2) relieving the tension on nerves or vessels that may be stretched as they pass along the deformity, (3) eliminating or significantly minimizing the possibility of inadvertently converting a closed fracture to an open one when the skin is tented by a sharp bony fragment, and (4) restoring circulation to a pulseless distal extremity.

After the patient has been appropriately sedated, deformity at or near the midshaft of a long bone is usually reduced with gradual, steady, longitudinal traction. Any rotational deformity should be corrected only after the angular component has been addressed and should be performed while traction is maintained.

The nearer a deformity is to a joint, the more difficult it may be to correct and the more specialized the reduction maneuver may have to be. **When deformity is associated with circulatory deficit, a true emergency exists, and the anticipated delay until reduction should be considered.**

REDUCE DISLOCATIONS

The techniques used to reduce specific dislocations are discussed in subsequent chapters. In general, prereduction radiographs are advisable when there has been significant trauma, unless time is crucial because circulation is threatened. Radiographs are needed because dislocations

and fracture-dislocations may have a similar appearance on physical examination, but the techniques used to treat them may be very different.

Of course, there are circumstances in which the potential benefits of a prereduction radiograph may be outweighed by the associated expenditure of time and money. For example, a prereduction radiograph may be omitted in a patient with a history of multiple recurrent dislocations of the shoulder who presents with history, signs, and symptoms typical of another recurrence in the absence of significant trauma.

After a reduction maneuver, postreduction radiographs are valuable for confirming the success of the procedure, as well as for providing documentation, in the event that the joint redislocates after the patient is discharged from the ED.

INITIAL MANAGEMENT OF OPEN FRACTURES

Open fractures warrant prompt and meticulous attention. The most important elements in the treatment of open fractures, aside from tetanus prophylaxis that applies generally to any wound, are irrigation, debridement, and antibiotics as soon as is practical.[11]

Early administration of antibiotics can prevent or reduce the clinical consequences of bacterial contamination in open fractures.[12,13] Consequently, initiate antibiotic therapy promptly in the ED. There is no standard antibiotic regimen. An accepted approach, but by no means the only regimen in use, is a first-generation cephalosporin, with the addition of an aminoglycoside when the wound is >10 cm with severe soft tissue injury and loss of bone coverage.[14,15] Some studies advocate the use of ciprofloxacin as an alternative to a cephalosporin.[16] When there is significant contamination by plants or soil, consider the addition of penicillin (or metronidazole, clindamycin, or vancomycin for penicillin-allergic patients) for anaerobic coverage. Aerobic and anaerobic wound cultures may be obtained before antibiotics are administered, although the value of pretreatment cultures for open fractures is controversial.[17]

To lower the infection rate, not only antibiotics but also generous irrigation and adequate debridement are necessary to reduce bacterial contamination and colonization.[18] The purposes of debridement and irrigation are (1) to expose the wound in order to allow better identification of the limits of injury and facilitate inspection for foreign material; (2) to identify and remove clots, debris, and nonviable tissue; and (3) to reduce bacterial contamination and make the wound more resistant to the effects of any residual contamination. (See chapter 40, Wound Preparation, for complete discussion of wound irrigation.)

Debridement and irrigation of minor wounds overlying a fracture sometimes may be performed in the ED. When tissue damage is moderate or severe, debridement and irrigation are typically performed in the operating room.

ORTHOPEDIC CONSULTATION IN THE ED

In many cases, such as fracture of the hip, the need for hospital admission and/or orthopedic consultation in the ED is obvious. In some situations, however, differences of opinion may exist regarding whether the patient needs to be seen by an orthopedist in the ED or whether the patient may be treated in preliminary fashion and referred for definitive orthopedic management. Even patients with injuries that ultimately may require surgical repair, such as an unstable ankle fracture, sometimes may be immobilized and discharged with a referral for prompt orthopedic follow-up.

COMPARTMENT SYNDROME

In cases of known or suspected compartment syndrome, obtain prompt orthopedic consultation. Emergency surgical intervention may be required to try to avert permanent tissue damage and muscle contracture. The physiology and potentially catastrophic consequences of compartment syndrome are described in the section Complications later in this chapter and in chapter 278, Compartment Syndrome.

IRREDUCIBLE DISLOCATION

The emergency physician sometimes may be unable to reduce a dislocation, even with the aid of a nerve block or procedural sedation. Although technique is certainly a factor, there may be other reasons closed reduction cannot be accomplished, such as the interposition of soft tissues within the joint or the presence of an associated fracture. Orthopedic consultation should be sought in such cases. Timely reduction, which sometimes can be achieved only surgically, may help minimize the complications (and shorten the duration of pain) resulting from a dislocated joint.

CIRCULATORY COMPROMISE

Circulatory deficit due to musculoskeletal injury warrants prompt orthopedic consultation. Even if circulation has been restored by the emergency physician through the correction of deformity, the orthopedist may wish to investigate the integrity of the involved vessels and should at least be contacted to discuss the case.

OPEN FRACTURE

Some open fractures need to be treated aggressively in the operating room. Other types, such as those involving the phalanges, often may be irrigated in the ED and referred for follow-up. If there is any question, a discussion with the orthopedist may result in a mutually agreeable plan of care.

INJURIES REQUIRING SURGICAL INTERVENTION

Whereas some musculoskeletal injuries require operative intervention as soon as possible, others may be treated on a delayed basis. In many cases, orthopedists differ in their preferred approach to the timing of surgery. Orthopedic consultation, at least by telephone, is indicated in cases of musculoskeletal injury that the emergency physician believes may require operative fixation or repair. The orthopedist may then exercise the option to admit the patient or to see the patient in timely follow-up and schedule any necessary surgery at that time.

SPLINTING MATERIALS AND TECHNIQUES

Immobilization is indicated not only for fractures, but also for dislocated joints that have been reduced. When a joint becomes dislocated, the ligaments that had provided its stability are disrupted, and the joint is susceptible to redislocation until healing has occurred.

The materials most commonly used for orthopedic immobilization are plaster of Paris (calcium sulfate) and fiberglass fabric combined with a polyurethane resin. Fiberglass has the advantages of being lightweight, fast setting, and resistant to damage by moisture. However, it is not as malleable as plaster, so it might not conform as well to the contour of the limb. This may be an issue when the purpose of the dressing is not only to provide immobilization but also to maintain the position of the fragments once a displaced fracture has been reduced.

Whether plaster or fiberglass is used for immobilization depends on a number of factors, including the emergency physician's preference, the philosophy of the orthopedic community, the needs of the patient, and the hospital's resources.

PRINCIPLES OF SPLINTING

The chemical reactions that cause plaster or fiberglass to set are initiated by contact with water. The higher the water temperature, the faster the materials harden. However, these reactions are exothermic, meaning they liberate heat. The faster the setting process, the more heat is generated. Therefore, the temperature to which the skin ultimately is exposed will be the additive result of the water temperature and the heat released by the chemical reaction. For this reason, severe burns may occur when plaster or fiberglass has been immersed in mildly hot water, even though the temperature of the water itself would not be sufficient to cause such burns. Although there is no universally prescribed ideal water temperature, a safe practice is to make the water room temperature. If steam is visible, the water is certainly too hot.

To avoid irritation and to minimize the potential for pressure sores, plaster or fiberglass dressings should include several layers of padding over the skin. When non-prepadded longitudinal plaster splints are used, cast padding has to be applied separately. The padding does not necessarily have to be circumferential. Several layers of longitudinal padding will effectively

protect the skin as long as they exceed the width and length of the splinting material. The best way to ensure this is to fashion the dry splint first, then measure the padding over it. Longitudinal splints may be fashioned from fixed-length plaster strips, from plaster rolls normally used to create circumferential casts, or from prepadded material with plaster or fiberglass enclosed. The splint should be long enough to provide the leverage needed to immobilize the injured joint. To immobilize the elbow, for example, a splint should begin distal to the wrist and extend high up the lateral arm, almost to the level of the humeral neck. To immobilize the ankle effectively, a splint should extend from beneath the metatarsal heads to the proximal calf. If the fracture is along the midportion of a distal extremity (i.e., the forearm or the lower leg) rather than at a joint, the splint should be long enough to immobilize the joint above and the joint below the fracture.

NON-PREPADDED PLASTER

When a splint is fashioned from plaster rolls, determine the length of the splint by measuring out a single layer along the extremity according to the principles described previously. Then, on a flat surface, unroll the plaster back and forth over itself to make a multilayered splint. If fixed-length plaster strips are used instead of rolls, the only way their length can be customized is to shorten them, so an adequate length should be selected at the outset and trimmed as necessary. In either case, the splint should be at least 12 layers thick for an adult. Even more layers should be used for children, who typically remain as active as possible and have little regard for protecting the dressing.

When the dry splint has been prepared, measure out several layers of padding over it, making the padding longer and wider than the plaster. After setting the padding aside, grip each end of the splint and immerse it in water, keeping it submerged until bubbling stops (indicating that water has been fully absorbed into the interstices of the material). Then withdraw the splint and remove the excess water by sliding the compressed thumb and index finger along the length of the plaster on each edge. (Use a stripping motion, rather than crumpling or wringing out the dressing, or much of the plaster may be lost.)

The next step, frequently overlooked, is to lay the splint on a flat surface and massage the layers into one another so that they fuse together. This creates a strong dressing that is solid on cross-section. A splint whose separate layers are still visible on cross-section is much weaker.

The padding should now be laid on the plaster and the dressing applied to the extremity, with the padded surface against the skin. When two plaster segments are used, as for a thumb spica or a posterior ankle mold with an additional transverse "sugar tong" component, no padding should be interposed between the segments. Rather, they should be molded into each other where they overlap. An assistant can hold the splint against the extremity while it is wrapped in place with gauze bandage. The assistant should use the palms, rather than the fingertips, when holding the splint in place. Hardened finger dents may cause irritation or even pressure sores. When a compressive effect is desired, an elastic bandage may be wrapped over the gauze. (If an elastic bandage is wrapped directly onto plaster without an interposed layer of gauze, it will set into the plaster and may lose most of its compressive function.)

While the plaster is setting, the affected joint may need to be held in a particular position. Again, use the palms, rather than the fingers, for reasons already described. Once the setting process is well under way, the position of a joint should not be changed, or the dressing may crack and become functionally useless. If the joint has gradually migrated from the desired position, the clinician must decide to accept the current position or remove the dressing and start over. There is no need to feel hesitant about the latter course. Patients generally appreciate a desire for perfection by their clinician.

PREPADDED MATERIAL

Some plaster or fiberglass splinting products are manufactured with the immobilization material already enclosed in padding, either as strips of predetermined length or as rolls from which splints may be cut to the desired length. Precut strips come packaged in air-tight foil. When a roll is used, the cut end is sealed with a tight clip to protect the exposed material. (Even when not immersed in water, fiberglass may set within 10 to 15 minutes, simply from exposure to moisture in the air.)

Prepadded material is fast and convenient to use because the layers are already in place and the padding need not be applied separately. However, the potential disadvantages are that the thickness of the dressing cannot be customized, and the material does not lend itself to applying two overlapping segments, because they cannot be molded into each other to create a sturdy dressing. If these issues are not a consideration, then prepadded material is a reasonable choice.

TYPES OF IMMOBILIZATION DRESSINGS

The more common immobilization dressings used in the ED are discussed next and are summarized in **Table 267-3**.

TABLE 267-3 Immobilization Devices and Uses

Immobilization Technique	Clinical Application
Shoulder immobilizer	Clavicle fracture Acromioclavicular separation Shoulder dislocation (postreduction) Humeral neck fracture
Sling	A variety of upper-extremity injuries, in conjunction with other immobilization techniques; may be used alone for nondisplaced or clinically suspected fracture of the radial head.
Long-arm gutter	Elbow fracture other than nondisplaced radial head fracture Reduced elbow dislocation
Sugar-tong	Wrist or forearm fracture
Short-arm gutter	Metacarpal or proximal phalanx fracture. (Ulnar gutter for fourth or fifth ray; radial gutter for second [index] or third [middle] ray.)
Thumb spica	Scaphoid fracture (proven or suspected) Thumb metacarpal or proximal thumb phalanx fracture
Knee immobilizer	Fracture or reduced subluxation of patella Knee dislocation, postreduction (temporary) Tibial plateau fracture Knee ligament injury Suspected meniscal tear (provided the knee can be fully extended)
Posterior ankle mold (consider above-the-knee extension and/or adjunctive use of ankle sugar-tong for unstable ankle injuries)	Ankle dislocation or fracture-dislocation Unstable ankle fracture (high distal fibular fracture or medial and/or posterior malleolar fracture) Widened medial mortise (indicates disruption of stabilizing medial structures) Metatarsal fracture (alternative immobilization dressings may be used)
Ankle stirrup	Simple ankle sprain Stable lateral malleolus fracture (below the superior border of the talus) without other ankle involvement (no medial swelling or tenderness, posterior malleolus intact)
Hard-soled shoe	Toe fracture Some metatarsal fractures (see the section Hard-Soled Shoe later in this chapter)
Short-leg walking boot	Some toe or foot contusions or fractures where weightbearing is allowed[19]

FIGURE 267-8. Shoulder immobilizer.

FIGURE 267-10. Long-arm gutter splint.

Shoulder Immobilizer This is a removable Velcro®-fastened device that keeps the arm in "sling position" but allows less mobility than a sling (**Figure 267-8**). A wide band wraps around the thorax. Two cuffs are attached to the thoracic piece: one on the lateral side, which grasps the upper arm, keeping the shoulder adducted; and one anteriorly, which holds the wrist to the chest, keeping the shoulder internally rotated. This dressing is suitable for fractures about the shoulder girdle, including clavicle and well-positioned humeral neck fractures, and for reduced shoulder dislocations.

A shoulder immobilizer is also commonly used for acromioclavicular separations, although from a mechanical standpoint, the ideal dressing for this injury is one that exerts upward pressure on the elbow and downward pressure on the clavicle to bring the clavicle and acromion back into alignment. Commercial versions of such dressings exist, but they are cumbersome to apply and uncomfortable to wear, leading to noncompliance. A shoulder immobilizer (or sling and swathe) is an acceptable alternative dressing.

Arm Sling Although it does not provide rigid immobilization, a sling (**Figure 267-9**) may be used as an adjunct to other splinting techniques for a variety of upper extremity injuries to enhance comfort, reduce motion, and provide some degree of support and elevation to the upper extremity. In some cases, as for nondisplaced fracture of the radial head, it may be used alone, without the need for supplementary immobilization.

Clavicle Strap (Figure-of-Eight Bandage) The figure-of-eight clavicle strap is mentioned only as a historical note. This dressing had long been considered the appropriate immobilization method for fracture of the clavicle, but in fact it is fairly ineffective at maintaining alignment of the fracture fragments and produces no difference in clinical outcome compared with a simple sling.[20] In addition, the clavicle strap may be awkward to apply, may require frequent readjustment, may cause problems related to pressure on the brachial plexus, and is often uncomfortable for the patient. A shoulder immobilizer or sling is a much better choice.

FIGURE 267-9. Arm sling.

Long-Arm Gutter Splint A long-arm gutter splint immobilizes the elbow (**Figure 267-10**). The upper extremity is placed in "sling position" (elbow flexed about 90 degrees and palm facing the abdomen). The splint begins on the ulnar surface of the hand at the metacarpal heads and extends along the ulnar surface of the forearm, past the elbow, to a spot high on the lateral surface of the upper arm just opposite and below the axillary crease. It should be supplemented with a sling.

The most common error associated with fashioning this dressing is insufficient length. If the splint is not carried far enough above the elbow, it will not exert enough leverage to prevent motion of that joint.

The long-arm gutter is useful for injuries about the elbow, including displaced radial head fracture, supracondylar humeral fracture, and reduced dislocation of the elbow.

Sugar-Tong Splint The sugar-tong is a splint that prevents motion of the wrist and elbow, including pronation-supination (**Figure 267-11**). The upper extremity is placed in "sling position," as described in the preceding section Long-Arm Gutter Splint. The splint begins on the extensor aspect of the hand at the level of the metacarpal heads and runs along the extensor aspect of the forearm, around the elbow and humeral condyles, onto the flexor aspect of the forearm, and ultimately to the palmar aspect of the hand, ending at the level of the metacarpal heads. It is wrapped in place with gauze and often topped off with an elastic compression bandage. It should be supplemented with a sling.

Proper length of the sugar-tong dressing is important. Too short a splint will fail to immobilize the wrist. If the dressing is too long, it will impair motion of the metacarpophalangeal joints, leaving them stiff and making the fingers more susceptible to swelling due to immobility.

The sugar-tong splint is appropriate for fractures about the wrist or distal forearm. Some orthopedists use it as a definitive dressing after reduction of wrist fractures.

Cock-Up Wrist Splint (to Be Avoided) A cock-up splint extends from the distal forearm to the proximal portion of the hand and maintains the wrist in a dorsiflexed position. **It should not be used for fractures of the wrist or carpals** because injuries to those areas usually are caused by forceful dorsiflexion, and a cock-up splint reproduces the position of injury, imposing considerable pain in the process. Generally, fractures about the wrist are immobilized in neutral position. Colles fractures may sometimes be immobilized in palmar flexion after reduction.

FIGURE 267-11. Sugar-tong splint.

Cock-up splints may be useful in some situations not related to trauma, such as to immobilize the wrist for tendinitis or to support it in the case of wrist drop due to radial nerve palsy. In such instances, passive dorsiflexion of the wrist is indicated to preserve grip strength.

Short-Arm Gutter Splint A short-arm gutter splint immobilizes the wrist and the ulnar or radial half of the hand (**Figure 267-12**). The ulnar gutter, for example, extends along the ulnar surface of the hand and forearm, beginning just proximal to the tip of the fifth finger and ending high on the forearm. It should be wide enough to encompass the fourth and fifth rays (phalanges and metacarpals) on the extensor and flexor aspects of the hand. The splint is wrapped in place so that the fourth and fifth fingers are bound together, with a thin layer of padding between them to prevent maceration of the skin. The metacarpophalangeal joints and interphalangeal joints are positioned in gentle flexion. The dressing may be supplemented with a sling.

FIGURE 267-12. Short-arm ulnar gutter splint.

FIGURE 267-13. Thumb spica splint.

The short-arm ulnar gutter is useful for fracture of the proximal phalanx of the ring or little finger or for fracture of the fourth or fifth metacarpal (including the common "boxer's fracture"). The counterpart of this splint, the short-arm radial gutter, is designed in similar fashion but extends along the radial surface of the hand and forearm and is used for comparable injuries of the index or middle rays. It can be fashioned with a hole that allows the thumb to pass through, or by splitting the distal end so the two halves can be run along the extensor and volar aspects of the index and middle rays while the thumb remains free.

Thumb Spica Splint A thumb spica immobilizes the wrist and the thumb (**Figure 267-13**). The term *spica* applies to any dressing that encompasses a main trunk plus one or more of its branches—in this case, the forearm plus the thumb. It is used for fracture of the scaphoid or for fracture of the thumb metacarpal or proximal phalanx.

A thumb spica may be fashioned from one wide splint that runs along the thumb and radial aspect of the wrist and forearm, but an even more effective dressing can be made from two separate non-prepadded plaster splints. The wrist piece runs along the extensor aspect of the hand and forearm, beginning at the metacarpal heads and ending just short of the antecubital crease. The more narrow thumb piece, approximately 2 in. wide, extends from the tip of the thumb, along the outer aspect of the thumb metacarpal, and onto the extensor aspect of the forearm, well overlapping the first splint. Along their area of contact, the two splints are molded into each other, with no padding between them, to form a sturdy dressing. The plaster is wrapped in place with gauze, and a compression wrap may be added at the clinician's discretion. The dressing may be supplemented with a sling.

This technique is not suitable for prepadded splints with plaster or fiberglass already enclosed, as the two pieces cannot be molded into one another, which compromises the structural integrity of the dressing. When prepadded material is used, a single wide splint encompassing the thumb must suffice.

While the dressing is setting, optimal position may be achieved by keeping the wrist in neutral position and having the patient oppose the tips of the thumb and index finger in the form of an "OK" sign. This preserves thumb-to-index pinch function, so as to minimize the patient's incapacitation. The neutral position of the wrist also avoids reproducing the position of injury in the case of scaphoid fracture, which is typically caused by forced dorsiflexion.

Knee Immobilizer The knee immobilizer is a removable circumferential device that extends from the thigh to just above the ankle (**Figure 267-14**). The splint contains longitudinal struts that, in some cases, may be repositioned as needed, and is secured with Velcro® straps.

A knee immobilizer maintains the knee in extension, the position of maximum stability. The device is useful for a variety of injuries, including fracture of the lateral or medial tibial plateau, fracture of the patella, meniscal injuries (provided the knee is not locked in partial flexion), and ligamentous strains or tears.

Use of an immobilizer for more than a few days in the elderly or for more than a week or two in young patients may result in painful stiffness

FIGURE 267-14. Knee immobilizer.

FIGURE 267-15. Posterior ankle mold.

of the knee joint. For that reason, orthopedic follow-up should occur within approximately 7 days. If immobilization is indicated beyond that point, the orthopedist may replace the original device with a cast brace or other orthosis that allows controlled and progressive range of motion.

Motion and Strength Exercises for the Knee Joint stiffness and instability due to quadriceps weakness may occur rapidly when the knee is immobilized. **Patients wearing an immobilizer should be encouraged to remove the device periodically and perform the following exercises:**

1. Passive flexion: While sitting on a flat surface, grasp the ends of a towel draped beneath the sole of the foot and pull upward, creating as much knee flexion as possible without undue pain.
2. "Gravity-assisted" flexion: While sitting on the edge of a bed or chair, support the knee in extension, with the well foot beneath the ankle of the injured extremity, then gradually lower the supporting foot so the injured knee "drops" into flexion. When tolerance is reached, bring the knee back into extension.
3. Quadriceps strengthening: While lying supine with a pillow beneath the knee, actively bring the knee to full extension in a straight leg raise, then relax.

Each of these exercises should be performed as multiple repetitions several times a day.

Posterior Ankle Mold The posterior ankle mold is used to immobilize the ankle (**Figure 267-15**). It begins beneath the metatarsal heads, runs along the plantar aspect of the foot, and continues up the back of the lower leg, ending at high calf. The splint is used for fractures or severe sprains of the ankle. Support may be supplemented by a transverse sugar-tong component running down the lateral side of the lower leg, beneath the heel, and up the medial side. Where the two components overlap, they are molded together. (Non-prepadded plaster should be used in this situation). The transverse component helps minimize inversion and eversion of the ankle. Even more stability is provided by continuing the posterior splint past the back of the knee to the high posterior thigh, using wider splinting material for this area. With the knee slightly flexed, rotational motion at the ankle also will be prevented.

While the dressing is setting, the ankle should be maintained in a position as close as possible to neutral dorsiflexion—that is, at 90 degrees to the leg. This may facilitate regaining range of motion after the dressing is removed. Because most patients with ankle injuries tend to keep the ankle plantarflexed, the clinician usually will have to counteract this by exerting gentle pressure with a palm beneath the metatarsal heads. An exception to the 90-degree principle is immobilization for rupture of the Achilles tendon. Patients with this injury should be immobilized in plantar flexion to reduce tension on the tendon.

Ankle Stirrup Easier to apply and less cumbersome for the patient than a posterior mold, the ankle stirrup (**Figures 267-16A** and **267-16B**) is useful for stable ankle sprains and for stable lateral malleolus fractures. The ankle stirrup is essentially an air-padded "sugar-tong" splint held in place by Velcro® straps. Unlike the posterior mold, this device is intended for use in conjunction with weightbearing. It limits inversion more effectively than taping but allows normal plantarflexion and dorsiflexion. This feature and the graduated compressive effect of the air-filled bladders may result in less swelling and edema, less joint stiffness, and a faster return to comfortable ambulation than is typically observed after rigid immobilization.[21]

The stirrup may be removed for purposes of bathing or when not bearing weight. If the patient does remove the splint temporarily, a common error when reapplying it is to fail to unwrap the straps completely—specifically, to leave the straps attached posteriorly, so that the splint is "hinged like a book" along its posterior aspect. This may result in the foot persistently slipping forward and out of the splint. The clinician may wish to instruct the patient that the proper way to reapply the splint is to unwrap the straps all the way around, so that the sides fall apart bilaterally, with the heel pad acting as the "hinge" on the plantar aspect (**Figure 267-17**). The foot may then be positioned on the lower pad, and the sides reapplied to the medial and lateral aspects of the ankle and lower leg. The final step is to rewrap the straps around the dressing.

Motion and Strength Exercises for the Ankle Exercises to restore range of motion, stability, and balance should be started as soon as possible after an ankle injury.

A

B

FIGURE 267-16. A, B. Ankle stirrup.

1. Active dorsiflexion and plantarflexion: When performed supine with the foot well elevated, this exercise may also enhance lymphatic drainage, thereby reducing swelling.
2. Passive dorsiflexion: One method for performing this exercise is to stand with the palms braced against the wall, then to bend the knee toward the wall while keeping the heel flat on the floor.

FIGURE 267-17. Technique for applying ankle stirrup.

3. Eversion, dorsiflexion, and plantarflexion against resistance: This exercise may be accomplished by manually applying a counterforce with a stretchable elastic cord (commercially available). Standing on the toes is another means of resistive plantarflexion.

Each of these exercises should be performed as multiple repetitions several times a day.

Hard-Soled Shoe A hard-soled shoe is a removable "sandal" with wrap-around sides usually secured with Velcro® and a flat, nonflexible sole (**Figures 267-18A** and **267-18B**). This device is intended to allow weight-bearing by patients with toe fractures or certain types of metatarsal fractures. The firm sole prevents the toes from bending and provides support for the forefoot. Although immobilization dressings may be warranted for some metatarsal fractures, the hard-soled shoe is an accepted treatment modality for fracture of the second, third, fourth, or proximal fifth metatarsal.[22,23]

Pneumatic Walking Brace The pneumatic walking brace is a device that provides firm support about the foot, ankle, and lower leg. It is available in high-top or short-top varieties. The high-top walker (**Figure 267-18C**), which extends almost to the knee, is suitable for injuries such as moderate to severe ankle sprains or for stable fractures of the foot or ankle. Short-top walkers extend just above the ankle joint and may be used for phalangeal or stable metatarsal fractures.

The term *pneumatic* refers to the fact that the inner lining of the brace is inflatable. Though non-pneumatic models are available, the pneumatic component has at least two advantages. It provides added compression, which helps reduce swelling and pain, and allows the walker to conform more closely to the contour of the extremity, which enhances immobilization.

ADJUNCTS TO AMBULATION

CRUTCHES

Crutches should be used by patients who can bear little or no weight on an injured lower extremity. Ideal crutch height is one hand width below the axilla. The grip bar should be adjusted to a height at which the elbows are mildly flexed while supporting the body weight. The patient should be instructed to bear the pressure of the pads against the sides of the thorax rather than in the axillae, or brachial plexus injury (crutch palsy) might result.

Any of several crutch gaits may be prescribed. The most common is the three-point gait, in which the patient keeps the injured extremity off the ground, advances both crutches simultaneously, then brings the well leg to a point between the crutches ("swing-to" gait) or just past them ("swing-through" gait). Alternatively the patient may use a two-point gait, in which one crutch and the opposite extremity are advanced together followed by the other crutch and extremity, or a four-point gait, in which one crutch is

A

B

C

FIGURE 267-18. **A, B.** Hard-soled shoe. **C.** Pneumatic walking brace.

advanced, then the opposite extremity, then the other crutch, then the remaining extremity. The two- and four-point gaits are slower in forward progression than the three-point gait but require less arm and wrist strength. They should be used only for patients who are able to bear some weight on the injured extremity. To ascend stairs, the patient advances the well extremity up to the next step, followed by the crutches and the injured extremity. To descend stairs, the crutches are lowered first.

WALKERS AND CANES

Most elderly or infirm patients do not have the strength needed to use crutches safely. For them, a walker or a cane is more suitable. Unfortunately, these devices are more appropriate for partial weightbearing than for nonweightbearing conditions. Elderly patients who can bear no weight at all on an injured extremity may require initial bedrest or use of a wheelchair and subsequent rehabilitation.

The technique for using a walker is essentially intuitive, with the patient simply lifting it and placing it a short distance ahead and then advancing toward it. In contrast, the technique for using a cane tends to be counterintuitive. Many patients instinctively hold a cane on the same side as the injured extremity. In fact, when the cane is held in the hand on the well side, less strength is required to maintain balance, resulting in a less awkward gait. The patient should be instructed to advance the cane (held on the well side) and the injured extremity simultaneously, and then advance the noninjured extremity to meet them.

DISCHARGE INSTRUCTIONS

Elevation of the injured part usually helps minimize pain and swelling. Elevation must be above the level of the heart to be effective. Patients with an injured lower extremity often sit at home or at work with the foot

resting on a stool or chair, thinking they are complying with instructions. The patient should understand that the benefits of elevating a lower extremity can be achieved only in a recumbent or near-recumbent position, with the leg supported higher than the rest of the body.

Patients discharged in a lower-extremity plaster dressing should be cautioned not to rest the heel on the floor or any other hard surface during the first day, as plaster takes about 24 hours to fully set. During this time, prolonged pressure on the heel might create an indentation that could cause significant discomfort or even a pressure sore. This is not a consideration with fiberglass, which sets almost immediately.

If an upper-extremity sugar-tong dressing has been applied, the patient should be instructed to work the fingers (wiggle or wave) as much as possible to minimize stiffness and swelling. The sugar-tong splint should extend to, but not beyond, the metacarpal heads, so as to allow full flexion of the metacarpophalangeal joints.

Patients should be advised to monitor the fingers or toes for excessive swelling, decreased sensation, or cyanosis and to be alert for a significant increase in pain. Any of these signs or symptoms warrants a return to the ED or prompt evaluation by the follow-up physician.

When crutches, a cane, or a walker is supplied, instruction for use should be provided, and the patient's ability to navigate with such aids should be verified.

COMPLICATIONS

Complications associated with musculoskeletal injury may be early or delayed and may occur minutes, days, weeks, or even months later.

NEUROLOGIC DEFICIT

Neurologic injury resulting from long-bone fracture or joint dislocation is usually due to traction or pressure on a peripheral nerve or a nerve plexus. Such complications usually manifest themselves early. Recovery may take hours, days, or weeks. Sometimes, the injury is irreversible. Prompt reduction of deformity often may prevent, eliminate, or mitigate the effects of neurologic involvement, but it is not a guarantee against permanent deficit.

VASCULAR INJURY

Peripheral vessels that run close to a joint sometimes may be compressed or disrupted when the joint becomes dislocated, as, for example, with dislocation of the ankle or knee (tibiofemoral joint). Loss of peripheral pulses or poor to absent capillary refill calls for expeditious reduction of deformity. Even after reduction, evidence of significant vascular injury may be delayed. Patients who experience tibiofemoral dislocation, for example, often undergo routine postreduction angiography to verify the integrity and patency of the popliteal vessels, regardless of whether a circulatory deficit has been observed clinically.

COMPARTMENT SYNDROME

After a fracture or a direct blow to an extremity, there may be extravasation of blood, swelling of muscle tissues, and impairment of venous flow within one or more fascial compartments. The resulting increase in pressure within the limb may lead to circulatory compromise, neurologic damage, and muscle necrosis, known collectively as *compartment syndrome*. This is a surgical emergency, and early recognition is crucial. Compartment syndrome is discussed further in chapter 278, Compartment Syndrome.

DELAYED AND LATE COMPLICATIONS

Patients who have sustained a fracture may be at risk for pulmonary fat embolus, usually originating from the marrow of a large bone, such as the femur. If fat embolism occurs, it is typically within the first few days after injury, rather than the first hours. This event may have a variable effect on pulmonary function, ranging from mild distress to severe or even fatal respiratory failure.

The most delayed complications of fracture include nonunion, malunion (healing with deformity), joint stiffness, traumatic arthritis, avascular necrosis of bone, and, in the case of open fracture, osteomyelitis.

DISPOSITION AND FOLLOW-UP

There is no universally prescribed follow-up interval for specific injuries. Orthopedists differ in their opinions regarding how soon patients should be seen. In general, patients with unreduced fractures or injuries that may require surgical intervention should be seen within a few days.

Sometimes the situation may be discussed with the follow-up physician and an appointment arranged while the patient is still in the ED. Alternatively, the emergency physician may instruct the patient to contact the follow-up physician or clinic as soon as possible. If the name of the injury is written on the discharge instruction sheet, the patient can convey it at the time of the call. This information may help the follow-up physician decide when the patient should be seen.

CHAPTER 268

Injuries to the Hand and Digits

Moira Davenport
Peter Tang

ANATOMY

The hand consists of 27 bones: 14 phalangeal bones, 5 metacarpal bones, and 8 carpal bones arranged in five rays of metacarpals and phalanges having its base at the carpometacarpal (CMC) articulation (**Figure 268-1**).

The carpal bones are made up of two rows, each with four bones. The bones are concave volarly and are bridged by the flexor retinaculum. This forms the carpal tunnel through which the median nerve and the nine long flexor tendons of the fingers pass (flexor pollicis longus [FPL]; flexor digitorum profundus [FDP] from the index, middle, ring, and small fingers; and flexor digitorum superficialis [FDS] from the index, middle, ring and small fingers) (**Figure 268-2**).

The index and middle finger CMC articulations have relatively little mobility, whereas the thumb, ring, and small finger CMC articulations have greater mobility at the CMC joint, which allows grasping and adaptive movements of the hand. More metacarpal deformity can be accepted in the great mobility CMC joints.

Multiple soft tissue structures support the bones and joints of the hand: capsules and ligaments provide stability, whereas muscles/tendons of the hand and forearm generate mobility (Figures 268-2, 268-3, and 268-4). The collateral ligaments of the metacarpophalangeal (MCP) joints are tightest in flexion in the index through small fingers (to allow stability in grasp), while the collateral ligaments of the MCP thumb are tight in flexion and extension (which also provide stability for the thumb in all positions) (Figure 268-3). The collateral ligaments of the interphalangeal (IP) joints are also tight throughout the entire range of motion.

INTRINSIC HAND MUSCLES

The intrinsic muscles of the hand are those that have both their origins and insertions within the hand. They consist of the thenar and hypothenar muscles, the adductor pollicis, the interossei, and the lumbricals (**Figures 268-3, 268-4, and 268-5**).

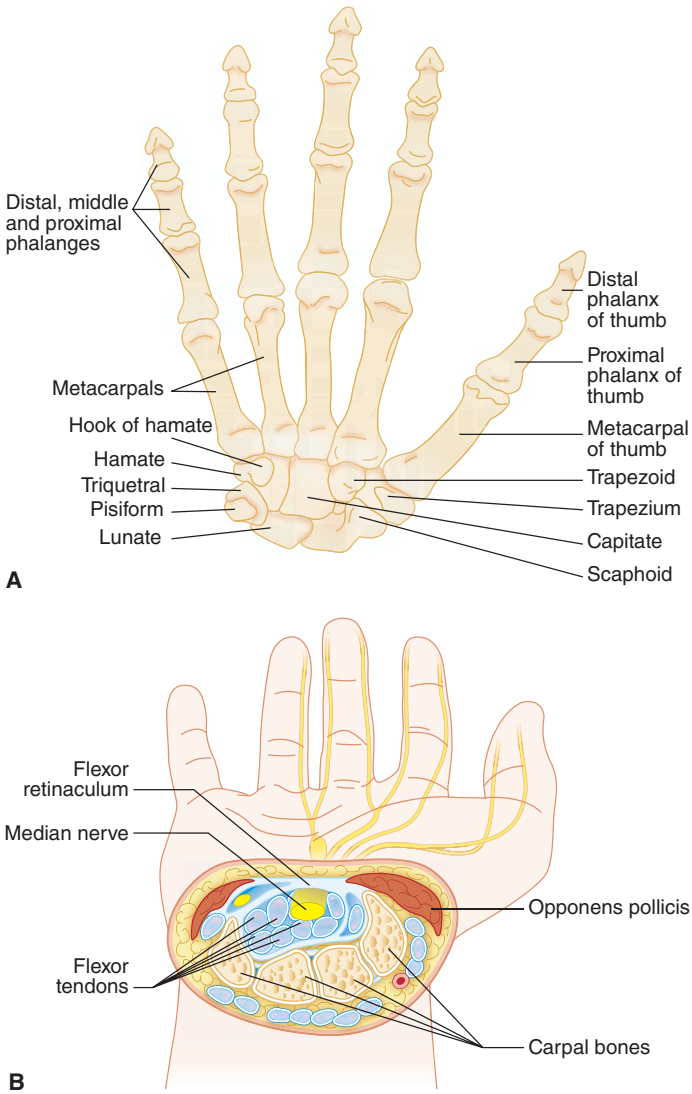

FIGURE 268-1. **A.** Bones of the hand and wrist. **B.** Carpal tunnel.

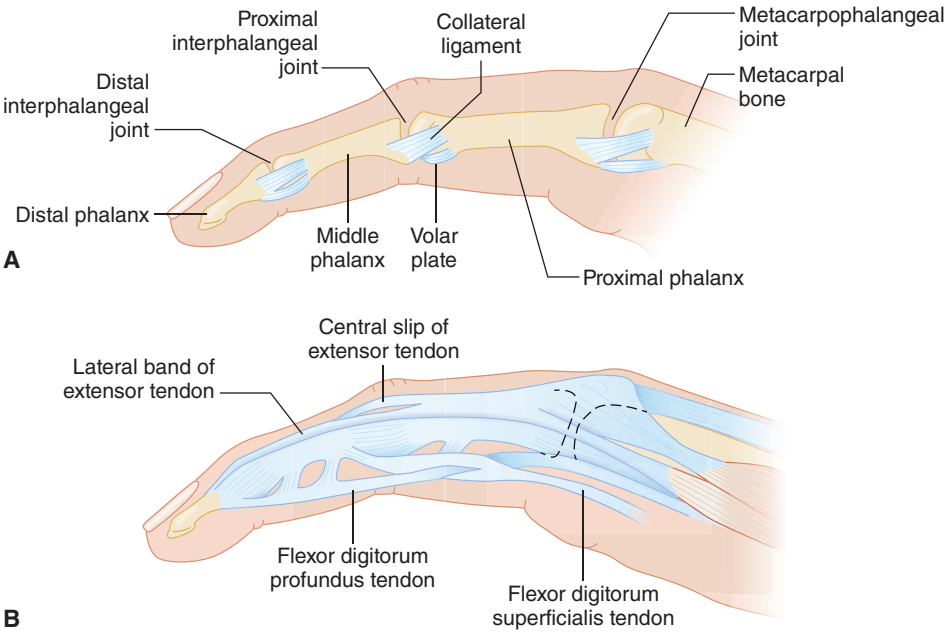

FIGURE 268-2. Joints, ligaments, and tendons of the digits.

The **thenar muscles** (from superficial to deep: abductor pollicis brevis, opponens pollicis, and flexor pollicis brevis) originate in the flexor retinaculum and carpal bones and insert on the radial base of the thumb proximal phalanx and the radial aspect of the first metacarpal. The motor branch of the median nerve innervates all three muscles except for the deep head of the flexor pollicis brevis, which is innervated by the ulnar nerve. The adductor pollicis is innervated by the ulnar nerve and originates from the capitate and second and third metacarpals and inserts on the ulnar base of the thumb proximal phalanx.

The **hypothenar muscles** include, from superficial to deep, the abductor digiti minimi, the flexor digiti minimi, and the opponens digiti minimi. These muscles, innervated by the ulnar nerve, originate in the flexor retinaculum and carpal bones and insert at the ulnar base of the small finger proximal phalanx and the ulnar aspect of the fifth metacarpal.

There are seven **interosseous muscles**, all innervated by the ulnar nerve (Figure 268-5). The three palmar and four dorsal interossei lie between the metacarpal bones and originate from them. The palmar interosseous muscle and the palmar portion of the dorsal interosseous muscle have an insertion into the extensor hood. The palmar interosseous muscle adducts the index, ring, and small finger to the midline, which is designated as the middle finger. The dorsal portion of the dorsal interosseous muscle has a tendinous insertion into the base of the proximal phalanx. The dorsal interosseous muscles abduct the fingers away from the midline.

The **lumbrical muscles** (Figure 268-3) do not attach to bone. They arise from the FDP tendons in the palm, course radially near the MCP joints, and attach to tendons or expansions, reinforcing the interosseous lateral band on the radial side of the digit. They flex the MCP joints while extending the IP joints.The median nerve innervates the radial two lumbricals, and the ulnar nerve innervates the ulnar two. The lumbricals flex the MCP joint and extend the IP joints of the index to the small fingers. Lumbrical muscles also play a critical role coordinating the flexor and extensor systems of the digits.

EXTENSOR AND FLEXOR TENDONS

The **extensor tendons** course over the dorsal side of the forearm, wrist, and hand (Figure 268-4). Nine extensor tendons pass under the extensor retinaculum and separate into six compartments. In the dorsum of the hand, the extensors digitorum communis are connected by junctura (**Figure 268-6**). **Based on this anatomy, finger extension may still be possible with a complete tendon laceration that is proximal to the juncture.** In the finger, the extensor mechanism divides into a central slip that attaches to the middle phalanx and into two lateral bands that join with the tendons of the lumbrical and interosseous muscles, which then attach to the dorsal base of the distal phalanx as the terminal tendon.

The **flexor tendons** (flexor carpi radialis, flexor carpi ulnaris, and palmaris longus) course over the volar side of the forearm, wrist, and hand, and primarily flex the wrist. The remaining nine tendons (four FDP, four FDS, and the FPL) pass through the carpal tunnel (Figure 268-1). The FPL goes to the base of the distal phalanx of the thumb. The other four digits have two tendons each (Figure 268-2). The FDS inserts into the volar, proximal half of the middle phalanx and flexes all the joints it crosses, including the proximal interphalangeal (PIP) joint and MCP joints. The FDP runs deep to the FDS until the level of the MCP joint, at which point it bifurcates. The FDP inserts at the volar base of the distal phalanx and acts primarily to flex the distal interphalangeal (DIP) joint as well as all the PIP and MCP joints. Unlike the extensor tendons, the flexor tendons are enclosed in synovial sheaths, making them prone to deep space infections.

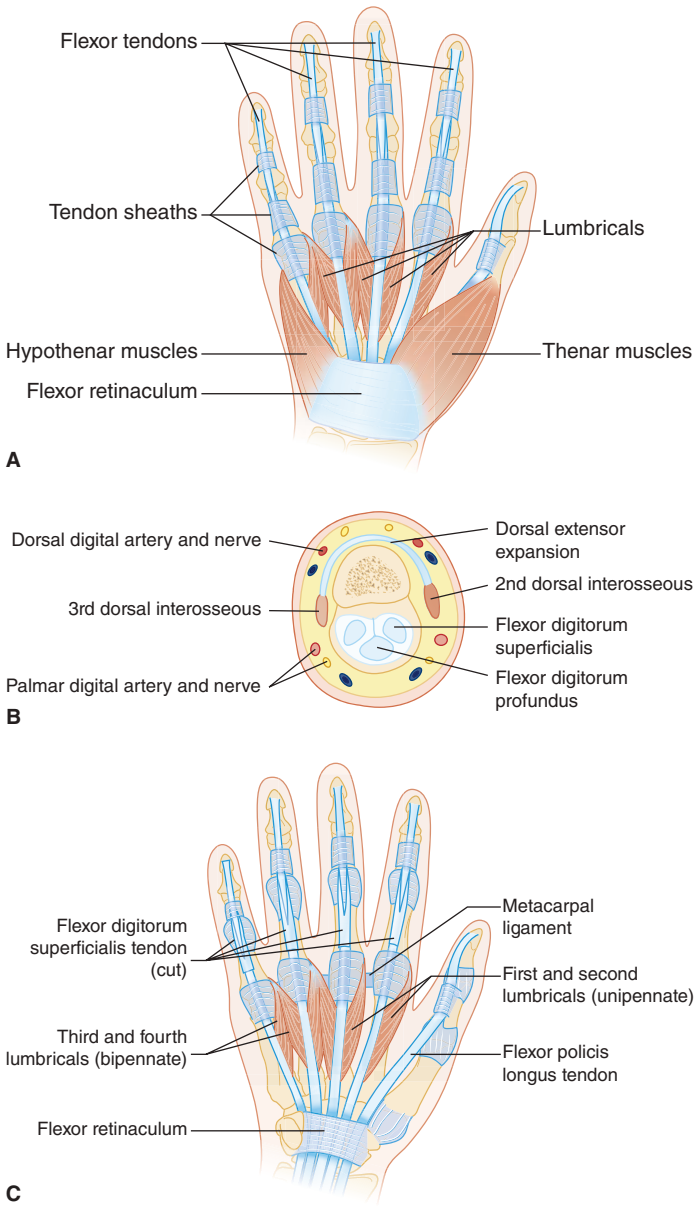

FIGURE 268-3. **A.** Palmar (volar) view of the hand showing the relationship of the some of the intrinsic muscles, and flexor tendons and sheaths. **B.** Cross-sectional view of digit at the middle phalanx. **C.** Lumbricals.

VASCULAR SUPPLY

The hand and digits are perfused by the radial and ulnar arteries. The radial artery forms the deep palmar arch, whereas the ulnar artery forms the superficial palmar arch. The common digital arteries (in the second, third, and fourth web spaces) arise from the superficial palmar arch (**Figure 268-7**) and provide blood supply to the fingers. The blood supply to the thumb arises from the princeps pollicis, which is the radial artery as it turns into the palm. The radialis indicis, which is on the radial side of the index finger, arises from the radial artery or the princeps pollicis.

NERVE SUPPLY

The radial, ulnar, and median nerves innervate the hand (**Figure 268-8**). In the hand, the median and ulnar nerves have mixed motor and sensory function. The superficial radial nerve (C5-T1) provides sensation to the dorsal radial aspect of the hand. The ulnar nerve (C7-T1) supplies sensory function to the small finger and the ulnar volar half of the ring finger and motor function to the hypothenar muscles, ulnar two lumbricals, interossei, adductor pollicis, and deep head of the flexor pollicis brevis. The median nerve (C5-T1) supplies sensory function to the thumb, index, middle, and radial volar half of the ring fingers, and motor function to the abductor pollicis brevis, opponens pollicis brevis, and superficial head of flexor pollicis brevis. As the digital nerves course across the palm, they are superficial structures and thus are easily injured. Digital nerve sensation and two-point discrimination should be routinely assessed when evaluating lacerations of the palm (**Figure 268-8**). **Normal two-point discrimination is 5 mm.** Consult a hand specialist if the extent of injury is uncertain. In the digits, the digital nerves divide into volar and dorsal branches to supply sensation to the fingers. Knowing the location of these nerves is important to properly perform a digital block (Figure 268-3, cross-sectional view).

CLINICAL FEATURES

Do not allow a visually striking hand injury to delay the identification and treatment of other potentially life-threatening injuries. After hemorrhage control, assessment involves a detailed history, general hand examination, testing of nerves and tendons, anesthesia, and direct wound inspection. Compare with the uninjured hand, especially to identify partial motor or sensory deficits.

HISTORY

The history should include the time and cause of injury as well as the position of the hand at the time of injury. Ask about the possibility of associated crush, burn, injection, or chemical exposure. When applicable, determine the type and amount of chemical to which the patient was exposed. Document the patient's occupation, avocations, prior hand injuries, and hand dominance to determine the functional impact of the injury.

PHYSICAL EXAMINATION

Detail the extent of injury by documenting the vascularity, status of the skin, posture of the fingers, and presence of deformity or active bleeding. Ask the patient to demonstrate the hand position at the time of injury. **Injuries with the digits in flexion may result in retraction of the cut end of the tendon when the digit is examined in extension.** Check bilateral grip strength. Compare motor, sensory, and tendon function of both hands to assess baseline function. Test range of motion and strength against resistance. Have the patient make a clenched fist to observe the orientation and rotation of the middle and distal phalanxes. All phalanges should be oriented parallel to each other with the nails positioned in the same plane and be pointing toward the scaphoid when the fist is clenched. Circulation is assessed by regional pulses and capillary refill.[1] Doppler assessment can also help assess digital artery flow.

NERVE TESTING

To test the **median nerve**, have the patient flex the IP joint of the thumb against resistance, which tests FPL function. Alternatively, hold the index or middle finger PIP and MCP joints in extension and have the patient flex the DIP joint, which tests FDP function of the index and middle fingers. **The "OK" sign** will reveal the ability to flex the IP joint of the thumb and the DIP joint of the index finger. To test the motor branch of the median nerve, position the thumb in palmar abduction with the palm up. Have the patient resist a force directing the thumb toward the palm, and assess the motor power while palpating the belly of the abductor pollicis brevis muscle to ensure it is contracting. It is important to note that a laceration at the level of the wrist or distal forearm may have intact FDP function of the index and middle fingers and FPL function to the thumb because these muscles have been innervated at the proximal forearm. A median nerve injury at the level of the wrist or distal forearm can only be determined by examining two-point

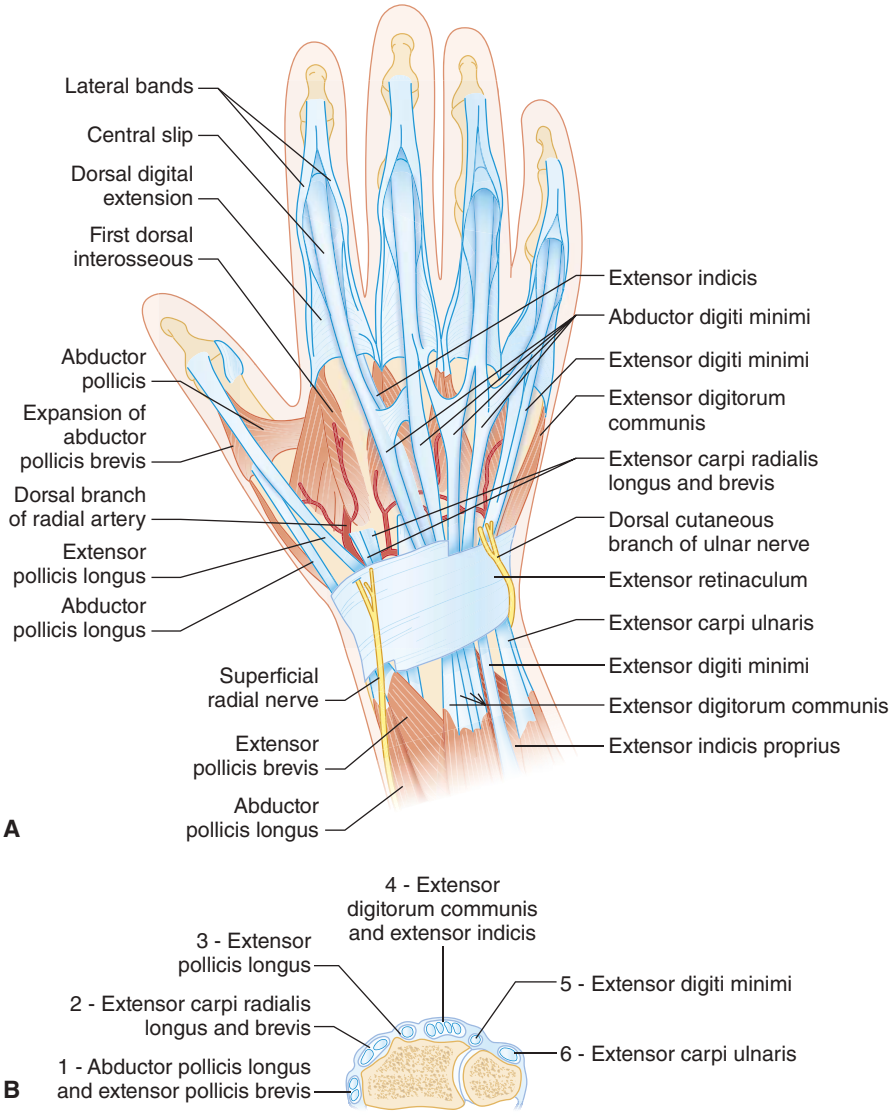

FIGURE 268-4. **A.** Dorsal view of the hand showing the extensor tendons and retinaculum, and intrinsic musculature. **B.** Cross-sectional view with the six extensor compartments.

discrimination in the three and a half radial digits or motor branch integrity to the thenar muscles.

To assess ulnar nerve integrity, have the patient spread the fingers apart (finger abduction) and assessing the motor power by resisting a force pushing the index and small fingers to midline. Alternatively, have the patient cross the fingers. To test thumb adduction (**the ulnar nerve innervates the adductor pollicis muscles**), have the patient hold a piece of paper with the volar pulp of the thumb against the radial side of the PIP joint of the index finger. If the patient can maintain the key pinch of the paper against resistance then the adductor pollicis is relatively strong. If the patient cannot hold the paper and uses the FPL and flexes the IP joint to compensate for the weak adductor pollicis this is a positive Froment's sign and indicates ulnar nerve pathology. All these reviewed maneuvers for the ulnar nerve test intrinsic muscles so that an ulnar nerve injury at the level of the wrist would be revealed by these test maneuvers.

To test the **radial nerve**, have the patient hyperextend the finger MCP joints against resistance, which will test the extensor digitorum communis tendons. One way to test this is to have the patient put the palm on a table, with fingers flat and hyperextended, and then lift each digit straight up and extend up from the table while keeping the palm flat. Finger resistance can also be checked in this extended, upright position. During this maneuver, it is important to keep the finger MCP joints in hyperextension because the interossei extend the IP joints of the fingers (but flex the MCP joints), and failure to keep the digit in full extension can mislead the examiner into believing the radial nerve is intact. The interossei cannot hyperextend the finger MCP joints. By extending the thumb against resistance, the extensor pollicis longus integrity is confirmed. If a patient has a posterior interosseous nerve (which innervates the majority of the extensor muscles) palsy, the patient will be unable to hyperextend his or her fingers, but may be able to extend the wrist in a radial direction because the extensor radialis longus and extensor radialis brevis are innervated by the radial nerve proper before the posterior interosseous nerve branches.

Sensation is determined by two-point discrimination. **Normal two-point discrimination is 5 mm at the volar fingertips. Older patients may have 6 mm of two-point discrimination.** Compare both injured and contralateral fingers to establish a reasonable baseline, because patients may have preexisting compressive neuropathies such as carpal and cubital tunnel syndrome or previous nerve injuries. Examine the radial and ulnar sides of each finger to determine which digital nerve is injured. Hand specialists recommend repeating two-point discrimination testing two to four times on each side of the digit, because patients can guess sensation correctly by chance. At least 80% accuracy is considered acceptable. Less than 80% or indeterminate accuracy suggests the possibility of digital nerve injury. **A sensory deficit also implies a potential digital artery laceration because of the close proximity of the two**.

TESTING OF TENDONS

Assess full range of motion of each tendon against resistance and compare with the uninjured side. It is important to test resistance because **up to 90% of a tendon can be lacerated with preservation of range of motion without resistance**. In addition, the juncturae tendinum contributes to digital extension, so patients with lacerations to the extensor digitorum communis may be able to extend the digit but may not have the same motor power. **Pain along the course of the tendon during resistance testing suggests a partial laceration even if strength appears adequate.** Test FDP function by checking flexion of the DIP joint against resistance while holding the PIP and MCP joints in extension. Test the FDS by having the patient flex the PIP joint against resistance while the remaining fingers are held in full extension. When the rest of the fingers are in extension, the FDP of the tested finger cannot fire and the FDS function is isolated. If the test is not performed this way, PIP joint flexion may be due to the FDP because this tendon also traverses the PIP joint, whereas the FDS does not.

To determine whether the central slip is intact, perform the **Elson's test**. Hold the PIP joint of the affected finger in flexion (therefore tightening the central slip and loosening the lateral bands) and ask the patient to extend the finger at the PIP. The examiner should resist extension; if the DIP is loose, then Elson's test is negative, meaning the central slip is intact and the extension force is being transmitted to the central slip. If the DIP is rigid and the PIP does not extend, Elson's test is positive, meaning the central slip is not intact and the extension force is being transmitted through the lateral bands to the terminal tendon to the DIP joint. The contralateral finger should be examined.

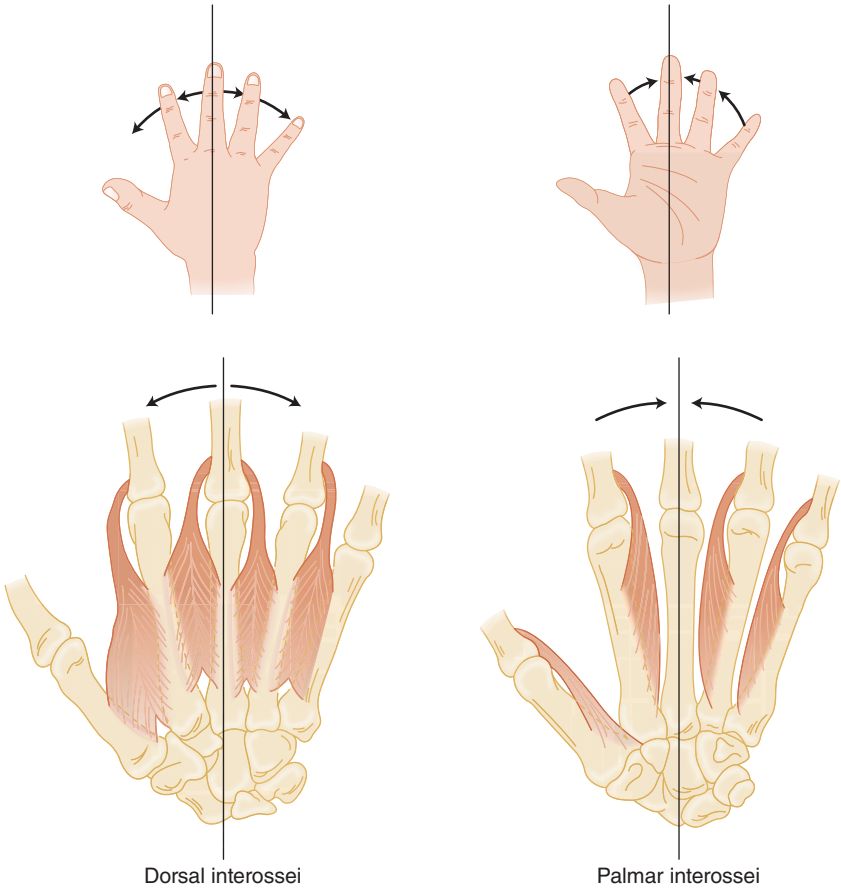

FIGURE 268-5. Origins, insertions, and actions of the palmar and dorsal interossei.

Sometimes the patient can overpower the examiner and should be asked to decrease the extension force on the finger. Lastly, if the patient resists PIP flexion due to pain, a digital block can be placed and the test repeated.

ANESTHESIA AND DIRECT WOUND EXAMINATION

Anesthesia and direct wound inspection are necessary because partial tendon lacerations or intra-articular injuries are not always readily apparent. Perform the initial motor and sensory exam before anesthesia. **If pain limits the motor exam, a digital block can be performed and then motor function reassessed.** A bloodless field can be facilitated by milking the digit proximally and then applying a local tourniquet or Penrose drain around the base of the digit. The tourniquet should not be stretched to more than 150% of its length and can be held in place with a hemostat. The digit can be milked by wrapping another Penrose drain circumferentially around the entire digit, going from distal to proximal, or by reconfiguring a 4 × 4-inch gauze dressing into a narrow band and wrapping that circumferentially around the entire digit. Only moderate compression should be used to avoid compression injury to the digit. **Do not leave the tourniquet in place for >20 minutes.** Irrigate contaminated wounds copiously with normal saline, and administer antibiotics. Cephalosporins are often the first choice, but tailor antibiotic selection to the particular contaminant. Administer tetanus toxoid as needed.

RADIOGRAPHS, CONSULTATION, AND DISPOSITION

Radiologic evaluation should include at a minimum posteroanterior (PA), lateral, and oblique projections of the hand. Similar projections are used for the digits, except that the radiographic beam is centered over the affected digit(s), so that true PA and lateral views should be obtained of the affected digit. Actual or suspected injuries of tendons and nerves should be referred to a hand specialist. Whether consultation is provided in the ED or in follow-up (1 to 3 days) depends on local resources. Injuries requiring immediate and delayed follow-up by a hand surgeon are listed in **Tables 268-1 and 268-2**, respectively.

Table 268-3 provides guidelines for immobilization and follow-up for specific hand injuries referred for delayed hand surgery evaluation. Often, the skin can be closed and the hand splinted in the position of function. The wound can be extended and explored at follow-up, with definitive repair performed by the hand specialist. **Most hand specialists prefer to do definitive repair of the acute injuries as soon as possible so patients should be informed to seek evaluation immediately and *not* in 2 weeks, as is often instructed.** Also, some diagnoses may be missed in the acute stage when patients are in pain and a thorough exam is difficult. Thus, early referral to a hand specialist verifies the diagnosis and can detect other injuries. Although most injuries involving <20% of the tendon are not surgically repaired, hand specialist follow-up and rehabilitation are still necessary to accurately determine the extent of injury, minimize scarring and tendon contraction, and minimize neuroma formation.

For patients with hand or digit lacerations that are sutured in the ED, and when there is no suspicion of neurovascular or tendon injury, follow-up evaluation and suture removal in the ED should always include repeat hand examination to make sure that significant injuries have not been missed.

FLEXOR TENDON INJURIES

The most common cause of flexor tendon injury is laceration. Flexor tendon lacerations can be subtle. A hand surgeon should repair all flexor tendon lacerations. Temporary stabilization and loose closure may be performed in the ED but should occur within 12 hours. Definitive treatment can occur up to 4 weeks after the injury but as soon as possible is best. In general, flexor tendon lacerations of <25% do not

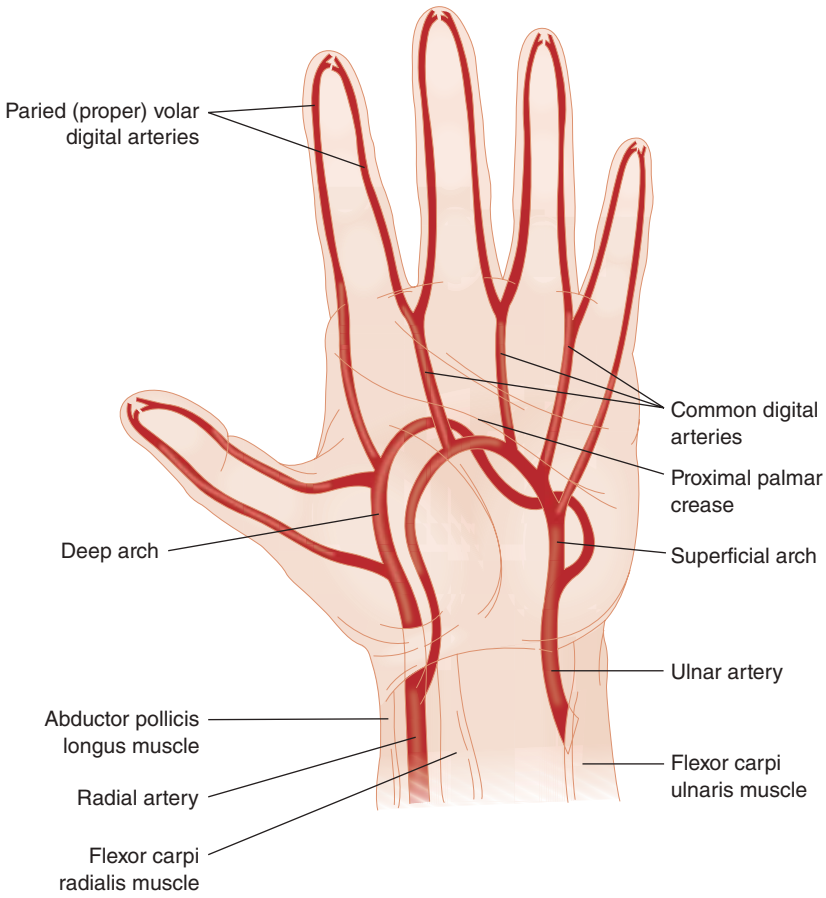

FIGURE 268-7. The dual blood supply to the hands and digits.

need to be repaired, but it is difficult to make this assessment in the ED. A distal-to-proximal five-zone (I to V) classification system for flexor tendon injuries has been developed based on location, treatment considerations, and prognosis (**Figure 268-10**).[2]

ZONE I

Zone I is distal to the insertion of the FDS so that injuries involve the FDP alone. Patients with such injuries lose flexion at the DIP joint.

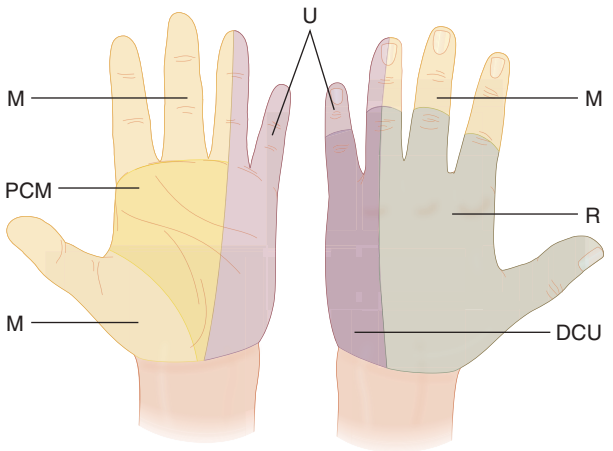

FIGURE 268-8. The cutaneous nerve supply in the hand. DCU = dorsal cutaneous branch of ulnar nerve; M = median nerve; PCM = palmar cutaneous branch of median nerve; R = superficial radial nerve; U = ulnar nerve.

ZONE II

Zone II involves the portion of the digital canal occupied by both FDS and FDP tendons (Figure 268-5). This zone is known as *no man's land* because injury in this zone has historically resulted in poor outcomes. This is due to the narrow fibro-osseous tunnel that consists of the metacarpals/phalanges. Lacerations in this zone are common, and partial lacerations are more common than complete injuries.

ZONE III

Zone III extends from the distal edge of the carpal tunnel to the proximal edge of the flexor tendon pulley system. The lumbrical muscles originate from the FDP tendons in this region. Outcomes are generally favorable.

ZONE IV

Zone IV is at the level of the carpal tunnel. The area must be explored carefully because many vital structures traverse this region. Isolated injuries are the exception.

ZONE V

Zone V involves injuries to tendons proximal to the carpal tunnel. Injuries here tend to be severe and often involve multiple tendons as well as the median or ulnar nerve (i.e., "spaghetti wrist"). Examine and test all major structures.

EXTENSOR TENDONS

The extensor tendons are the most common site of tendon injuries because of the superficial nature of the tendons on the dorsum of the hand. A separate zone classification system (I to VIII) for extensor tendon injuries has been developed for assessing injury patterns, repair techniques, and rehabilitation[3] (**Figure 268-11**). There is growing opinion that extensor tendon injuries should now be repaired operatively as well, although ED repair has often been the standard of care. In general, extensor tendon lacerations <25% do not need repair.

EXTENSOR ZONE I

Zone I involves the area over the distal phalanx and DIP joint. Injury can occur from blunt or sharp trauma. Complete laceration or rupture

TABLE 268-1 Immediate Hand Surgery Consultation Guidelines

Vascular injury with signs of tissue ischemia or poorly controlled hemorrhage
Irreducible dislocations
Grossly contaminated wounds
Severe crush injury
Open fracture
Compartment syndrome
High-pressure injection injury
Hand/finger amputation

Ligamentous injuries with instability

TABLE 268-3 Immobilization for Common Hand Injuries

Injury	Splint
Ligamentous injuries	
Thumb MCP ulnar collateral ligament rupture	
Partial tears	Thumb spica, IP free to flex
Complete or equivocal	Thumb spica (presurgical repair)
Tendon injuries	
Mallet finger	Dorsal splint, full extension at DIP
Flexor tendon laceration	Dorsal splint, 30-degree wrist flex, 70-degree MCP flexion, 30- to 45-degree PIP flexion (presurgical repair)
Dislocations	
DIP joint	Dorsal splint, full extension
PIP joint	
Stable/postreduction	Dorsal splint, 30-degree PIP flexion
Unstable/postreduction	Dorsal splint, 30-degree PIP flexion
MCP joint	Buddy-taping
Carpometacarpal joint	Dorsal-volar splint
Thumb IP joint	Dorsal splint, full extension
Thumb MCP joint	Thumb spica
Fractures	
Distal phalanx	Volar or hairpin splint not immobilizing PIP
Middle/proximal phalanx	
Stable/nondisplaced	Buddy taping/dynamic splinting
Unstable/displaced	Radial/ulnar gutter, 90-degree MCP flexion, <15- to 20-degree PIP flexion, <5- to 10-degree DIP flexion
Thumb proximal phalanx	Thumb spica
Metacarpal	
Index, middle	Radial gutter, 20-degree wrist flexion, 90-degree MCP flexion, PIP left mobile
Ring, small	Ulnar gutter, 20-degree wrist flexion, 90-degree MCP flexion, PIP left mobile
Thumb metacarpal	
Extra-articular	Thumb spica
Intra-articular	Thumb spica for initial immobilization (presurgical repair)

Abbreviations: DIP = distal interphalangeal; IP = interphalangeal; MCP = metacarpophalangeal; PIP = proximal interphalangeal.

Note: Hairpin splint: metal backed splint with foam padding; dynamic splint: spring-loaded splint that allows some motion at unaffected joints while protecting the injured joint, usually available from a hand surgeon or occupational therapist.

of the tendon at this level will result in the inability to extend the DIP joint. This injury is often called a **mallet finger** (**Figure 268-12**), and it is the most common tendon injury in athletes. This injury has been classified as type I if there is tendon-only rupture, type II if there is a small avulsion fracture, and type III if >25% of the articular surface is involved. Type I can be treated with the DIP joint immobilized in continuous full extension for 6 to 10 weeks. For the best outcome, **no** flexion of the DIP joint is permitted for the duration of splinting. Thus, instruct patients not to take off the splint. If they do remove the splint to clean the finger and the splint, the DIP should be held in extension. The DIP **cannot** be allowed to fall into flexion. Splints for the mallet finger can be a Stax or aluminofoam splint as long as the splint holds the DIP in full extension (**Figure 268-13**).

Type II injuries can be treated the same way if on x-ray the splinted finger in extension shows congruency with the rest of the noninjured articular surface of the distal phalanx on the distal articular surface of the middle phalanx. Other indications for surgery include an open injury and >30% to 50% articular fracture involvement. Chronic untreated mallet finger may result in a **swan-neck deformity** (**Figure 268-14**). This occurs when the lateral bands are displaced dorsally, resulting in increased extension forces on the PIP joint.

EXTENSOR ZONE II

Zone II involves the area over the middle phalanx. Injuries are usually a result of laceration. Injuries to this area are treated similarly to zone I injuries.

EXTENSOR ZONE III

Zone III involves the area over the PIP joint. The central tendon is the most commonly injured structure. Complete disruption of the central tendon may result in the volar displacement of the lateral bands, causing them to be flexors, along with the unopposed FDP. Additionally, the extensor hood retracts, causing extension of the DIP joint, resulting in the **boutonnière deformity** (**Figure 268-15**). Controversy exists regarding whether treatment of zone III injuries should be conservative or operative. Closed injuries are initially treated with the PIP joint immobilized in continuous extension for 5 to 6 weeks and should be followed closely by a hand specialist.

EXTENSOR ZONE IV

Zone IV involves the area over the proximal phalanx. These injuries have clinical findings similar to zone III injuries. These injuries are often less likely to have long-term morbidity because the joint is not involved and the tendon at this level is broad and flat.

EXTENSOR ZONE V

Zone V involves the area over the MCP joint. Open injuries to this area should be considered human bites until proven otherwise. Wounds from human bites should have delayed repair following hospital admission for a course of broad-spectrum IV antibiotics. This injury may require operative washout. Clean, nonbite wounds can be repaired primarily using mattress sutures to reapproximate tendon edges.

EXTENSOR ZONE VI

Zone VI involves the area over the dorsum of the hand. Because the tendons in this area are so superficial, even minor-appearing lacerations may be associated with one or more tendon injuries. If the laceration is proximal to the juncturae tendineae, the patient may be able to extend the involved MCP joint, because extensor forces are transmitted to the juncturae from adjacent extensor tendons. Injuries to zones VI, VII, and VIII typically require advanced suture techniques.[4]

EXTENSOR ZONE VII

Zone VII involves the area over the wrist. Repair can be difficult because of the presence of the extensor retinaculum. This thick, fibrous structure on the dorsum of the wrist contains 12 extensor tendons and six synovial-lined retinacular compartments. Due to the anatomic complexity of this region, operative repair is needed.

EXTENSOR ZONE VIII

Zone VIII involves the area of the distal forearm. Injuries to this area require a thorough exploration to identify all injured structures. The tendons frequently retract into the forearm and must be retrieved and repaired. After repairs in zones V through VII, splinting should occur with the wrist in 15-degree extension, the MCP joint in 15-degree flexion, and the IP joint in 15-degree flexion in the involved and adjacent digits.

LIGAMENTOUS INJURIES AND DISLOCATIONS

Soft tissue injuries to the hand are extremely common. Accurate diagnosis and treatment are important to avoid complications such as joint luxation, loss of motion, chronic pain, and deformity.

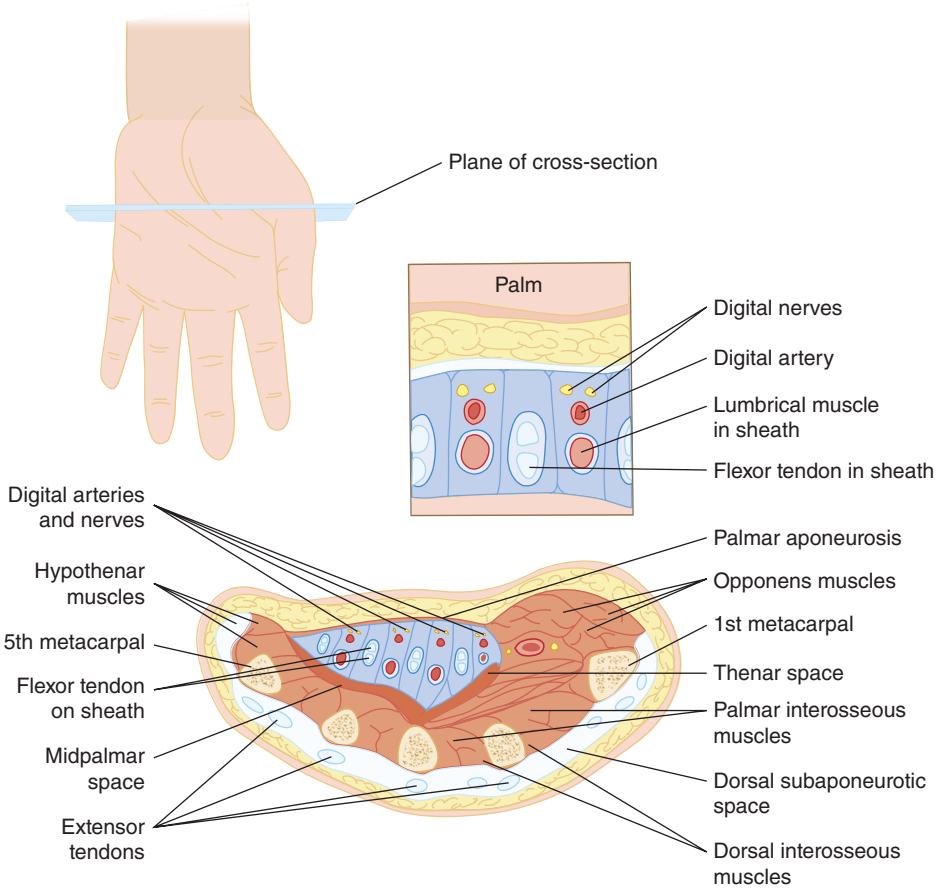

FIGURE 268-9. Relationship of nerves, arteries, tendons, and muscles at the level of the metacarpals.

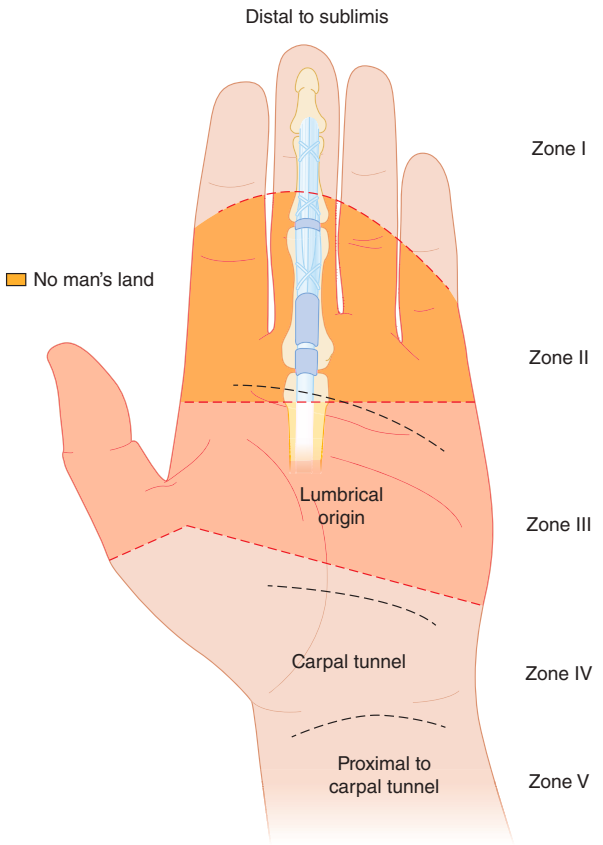

FIGURE 268-10. Flexor tendon zones and no man's land.

DISTAL INTERPHALANGEAL JOINT

Dislocations of the DIP joint are uncommon because of the firm attachments of the skin and subcutaneous tissue to the underlying bone by osteocutaneous fibers. Additional stability is provided by the flexor and extensor tendons. When dislocations do occur, they are usually dorsal. Longitudinal traction and hyperextension followed by direct dorsal pressure to the base of the distal phalanx usually accomplish reduction. Attempts at reduction should be made after a digital nerve block or other means of anesthesia has been performed. **Irreducible cases may be due to the entrapment of an avulsion fracture, the profundus tendon, or volar plate.**

PROXIMAL INTERPHALANGEAL JOINT

Dislocations of the PIP joint are common hand injuries. The mechanism is usually due to axial load and hyperextension. Dorsal dislocation occurs when the volar plate ruptures. Lateral dislocations occur when one of the collateral ligaments ruptures with at least a partial avulsion of the volar plate from the middle phalanx. The digit is usually ulnarly deviated because the radial collateral ligament is six times more likely than the ulnar collateral ligament to rupture. Volar dislocations are rare. Dorsal dislocations are reduced in the same manner as dorsal DIP joint dislocations. Active motion and strength should be tested following reduction. If testing is normal, splint the joint at 30-degrees of flexion for 3 weeks. **If the joint is irreducible or there is evidence of complete ligamentous disruption, operative repair is required.**

METACARPOPHALANGEAL JOINT

Dislocations of the MCP joint are usually due to hyperextension forces that rupture the volar plate, causing dorsal dislocation. Subluxation is more common than dislocation. In subluxation, the joint appears to be hyperextended 60 to 90 degrees, and the articular surfaces are still in contact. Reduction here does not involve hyperextension because it might convert a subluxation into a complete dislocation. **Reduction is performed by flexing the wrist to relax the flexor tendon and then applying pressure over the dorsum of the proximal phalanx in a distal and volar direction.** After reduction, splint the MCP joint in flexion. Multipart dislocations appear less deformed because of the number of disrupted structures. Because the volar plate is interposed in the MCP joint space, closed reduction is usually not possible. Volar dislocations are rare and usually require operative reduction.

CARPOMETACARPAL JOINT

Dislocations of the CMC joint are uncommon because the joint is supported by strong dorsal, volar, and interosseous ligaments and is reinforced by the broad insertions of the wrist flexors and extensors. The cause is usually a result of high-speed mechanisms such as motor vehicle crashes, falls, crushes, or clenched fist trauma. If a dislocation occurs, it is usually dorsally oriented and associated with fracture(s). **Reduction of dorsal CMC joint dislocations can be attempted after regional anesthesia is administered. Traction and flexion with simultaneous longitudinal pressure on the metacarpal base should reestablish normal anatomic alignment.** Early referral after reduction is needed to determine if further fixation is needed. Volar CMC joint dislocations are exceedingly rare and should be referred to a hand specialist.

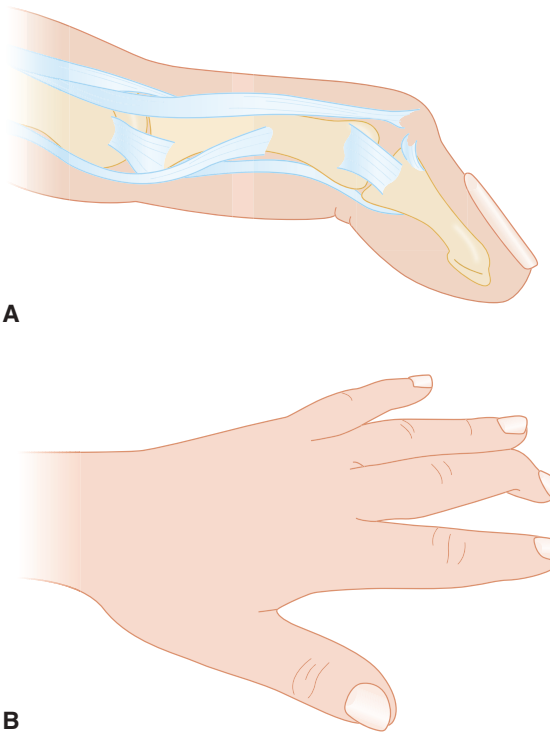

FIGURE 268-12. **A.** Mallet finger. **B.** Clinical appearance.

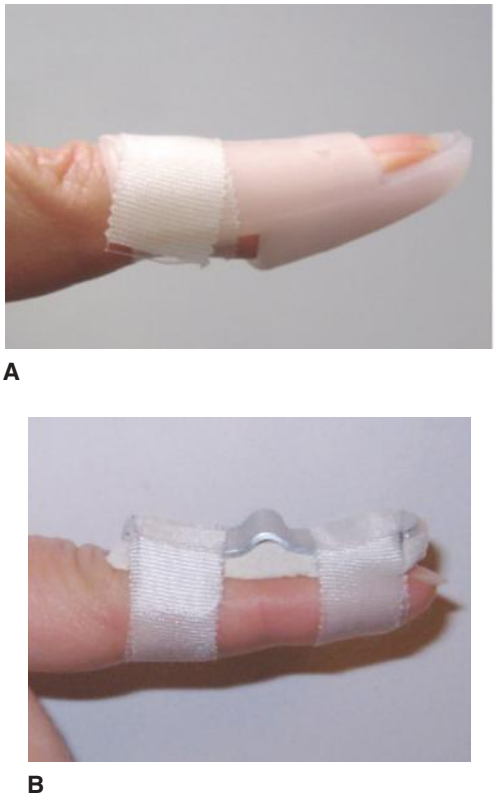

FIGURE 268-13. **A and B.** Splinting for mallet finger.

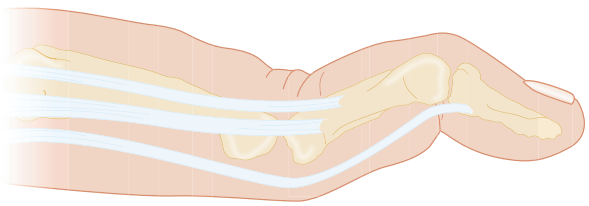

FIGURE 268-14. Swan neck deformity.

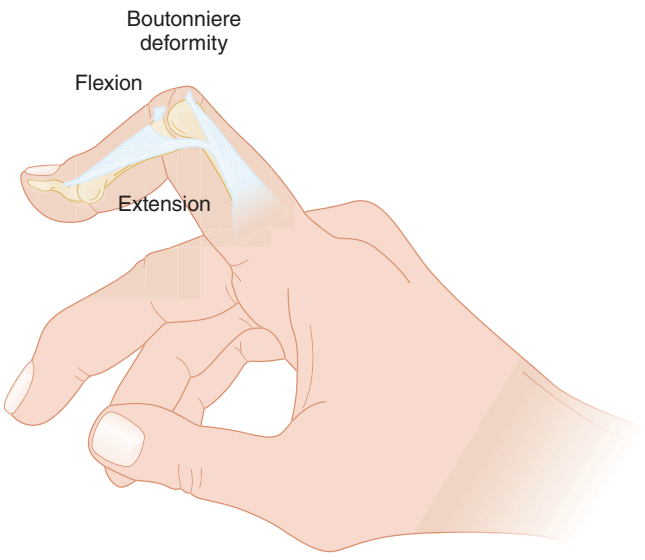

FIGURE 268-15. Boutonnière deformity.

THUMB INTERPHALANGEAL JOINT

Dislocations of the thumb IP joint are rare but, if present, are usually open. The mechanism is typically hyperextension with rupture of the volar plate. Reduction is similar to that of the IP joints of the other digits. After reduction, the joint should be immobilized in 15 to 20 degrees of flexion for 3 weeks.

THUMB METACARPOPHALANGEAL JOINT

Dislocations of the MCP joint of the thumb are usually dorsal and result from a hyperextension force causing rupture of the volar plate. The dislocation may be simple or complex. Reduction, after radial nerve block, is accomplished with pressure directed distally on the base of the proximal phalanx with the metacarpal flexed and abducted.

THUMB METACARPOPHALANGEAL (ULNAR) COLLATERAL LIGAMENT RUPTURE

Rupture of the ulnar collateral ligament (**gamekeeper's thumb**, **skier's thumb**) occurs when the mechanism causes radial deviation (abduction) of the MCP joint. The tear usually occurs at the insertion into the proximal phalanx. Often significant injury to the dorsal capsule and volar plate occurs. **Hand surgery referral is recommended for all patients with suspected complete tears of the ulnar collateral ligament of the thumb**, signs of which are pain, ecchymosis of the thumb MCP, and weakness of pinch. The diagnosis is made with stress testing of the ulnar collateral ligament. The examiner tests the thumb MCP joint, both in full extension and 30-degree flexion, by stabilizing the metacarpal with one hand while applying lateral (radial) stress on the proximal phalanx with the other. **More than 30 to 35 degrees of radial angulation or 10 to 15 degrees more than the contralateral thumb indicates complete rupture and requires surgical consultation.** If patients are discharged from the ED, a thumb spica splint should be applied and urgent orthopedic follow-up arranged. Repair is best accomplished within 1 week. **Radial collateral ligament rupture** is not as common, and the mechanism is forced adduction. Examination with the same parameters applied in the ulnar direction is used to make the diagnosis of a complete radial collateral ligament rupture.

THUMB CARPOMETACARPAL JOINT

Isolated thumb CMC joint dislocation is rare compared with the more common Bennett's fracture dislocation (see below). These are easy to reduce but unstable after reduction. After reduction, a thumb spica splint should be applied. These injuries should have a surgical referral for a decision on operative repair.

FRACTURES

DISTAL PHALANX

Fractures of the distal phalanx usually result from crush or shearing forces. The fractures can be classified as tuft, shaft, or intra-articular. Tuft fractures can be associated with nail bed lacerations. Fractures at the base may be associated with flexor or extensor tendon involvement. Generally, fractures of the distal phalanx are treated as soft tissue injuries with protective splinting.

PROXIMAL AND MIDDLE PHALANX

The proximal phalanx has no tendinous attachments, so fractures frequently result in apex volar angulation from the forces of the extensor and interosseous muscles. For the middle phalanx, the FDS tendon inserts on the proximal volar half and the extensor tendon inserts at the proximal base. Therefore, fractures at the base of the middle phalanx demonstrate apex dorsal angulation, and fractures at the neck result in apex volar angulation. A direct blow mechanism usually causes a transverse or comminuted fracture, whereas a twisting mechanism will more often result in a spiral fracture. Most often, such fractures are stable and nondisplaced and can be treated with early protected motion by buddy taping. Unstable fractures amenable to closed reduction can be splinted from the MCP to the DIP joint with the MCP joint in 70 degrees of flexion and the IP joints in extension. Midshaft transverse fractures, spiral fractures, and intra-articular fractures often require internal fixation.

METACARPAL (SECOND TO FIFTH) FRACTURES

The second and third metacarpals are relatively immobile, and fractures require anatomic reduction. The ring and fifth metacarpals have 15- to 20-degree anteroposterior motion, which allows for some compensation for malunion. Metacarpal fractures are categorized as head, neck, shaft, or base fractures.[5] The presence of a metacarpal fracture should prompt close evaluation of the associated CMC joint, because CMC joint dislocation often accompanies these fractures and is often missed at the initial presentation.[6]

METACARPAL HEAD FRACTURES

Fractures of the metacarpal head are usually caused by a direct blow, crush, or missile. These fractures are distal to the insertion of the collateral ligaments and are often comminuted. If a laceration is present, a human bite must be considered. Treatment consists of ice, elevation, and immobilization with referral to a hand surgeon.

METACARPAL NECK FRACTURES

Fractures of the metacarpal neck are usually caused by a direct impaction force. A fracture of the fifth metacarpal neck is often referred to as a **boxer's fracture**. These fractures are usually unstable with volar angulation. **Angulation of ≤20 degrees in the fourth and ≤40 degrees in the fifth metacarpal will not result in functional impairment. If greater angulation in these metacarpals occurs, reduction should be attempted.** To perform the reduction, flex the wrist and the MCP joint. Apply slight force to the volar aspect of the affected metacarpal while distracting the phalanx away from the palm. Following splinting, patients may have residual cosmetic deformity (not prominent metacarpal head), but in most cases regain full function. The amount of angulation at the time of injury does not correlate with resultant cosmetic defects.[7] **With second and third metacarpal fractures, angulation of <15 degrees is acceptable.** Splint metacarpal neck fractures with the wrist in 20-degree extension and the MCP joint flexed at 70 degrees. Fractures of the second or third metacarpal that are significantly displaced or angulated require anatomic reduction and surgical fixation.

METACARPAL SHAFT FRACTURES

A direct blow usually results in fractures in the metacarpal shaft region. Rotational deformity and shortening are more likely in shaft fractures than in neck fractures. If manipulative reduction is necessary, operative fixation is usually indicated.

METACARPAL BASE FRACTURES

Fractures at the base of the metacarpal are usually caused by a direct blow or axial force. They are often associated with carpal bone fractures. CMC joint subluxation or dislocation should be suspected with these injuries. Given the overlap of the bones and joints on the lateral radiograph, a CT scan may be needed to definitively rule out joint subluxation or dislocation. Fractures at the base of the fourth and fifth metacarpals can result in paralysis of the motor branch of the ulnar nerve, although this is rare.[8]

THUMB METACARPAL FRACTURES

Because of the mobility of the thumb metacarpal, shaft fractures are uncommon. Fractures usually involve the base.

Extra-Articular Fractures Extra-articular fractures are caused by a direct blow or impaction mechanism. The mobility of the CMC joint can

allow for 30-degree angular deformity. Angulation greater than this requires reduction and a thumb spica splint for 4 weeks. Spiral fractures often require fixation.

Intra-Articular Fractures: Bennett's Fracture and Rolando's Fracture

Intra-articular fractures are caused by impaction from striking a fixed object.

Bennett's fracture is an intra-articular fracture with associated subluxation or dislocation at the CMC joint. The ulnar portion of the metacarpal usually remains in place ("constant fragment"). The distal portion usually subluxes radially and dorsally from the pull of the abductor pollicis longus and the adductor pollicis. Treatment is application of a thumb spica splint and orthopedic referral.

Rolando's fracture is an intra-articular comminuted fracture at the base of the metacarpal. The mechanism of injury is similar to Bennett's fracture but less common. Treatment includes a thumb spica splint and orthopedic consultation.

COMPARTMENT SYNDROME

Crush injury of the hand, with or without associated fracture, may result in compartment syndrome. Iatrogenic causes of compartment syndrome of the hand include extravasation of IV fluids or contrast media or arterial punctures.[9,10] The involved compartments of the hand include the thenar, hypothenar, adductor pollicis, and four interossei muscles. Edema of tissues or hemorrhage within any of these compartments may lead to elevated pressures that result in tissue necrosis and subsequent loss of hand function due to contracture.[3] Classic signs and symptoms of compartment syndrome typically include pain and paresthesias early, with paralysis and pulselessness occurring later in the course of the ischemic injury. **Hand compartment syndromes, however, may not be associated with paresthesias, and the extremely subtle motor deficits and difficulty in assessing response to passive stretch make the diagnosis more elusive than at other anatomic sites.** Pain, the most consistent clinical sign, is often described as deep, constant, poorly localized, and disproportionate to clinical findings. Physical examination findings suggestive of hand compartment syndrome include extreme swelling, the intrinsic minus position at rest (MCP joint extended with PIP joint slightly flexed), pain with passive stretch of the involved compartment muscles (interosseous: performed with MCP joint extended and PIP joint fully flexed with slight radial and ulnar deviation; thenar, hypothenar: performed by extension of MCP joint), and tense swelling of the affected compartment. Compartment pressure measurement is difficult and inexact in the relatively small compartments of the hand. The diagnosis is typically made on a clinical basis, not on actual compartment pressures.[11]

In the setting of severe crush injury with signs and symptoms suggestive of compartment syndrome, immediately consult with a hand specialist to determine if emergency fasciotomy is indicated.

HIGH-PRESSURE INJECTION INJURY

The injection of certain substances under high pressures (often 2000 to 10,000 psi) into the soft tissues of the hand may initially appear benign but are actually true orthopedic emergencies. The operator of the high-pressure device typically attempts to test or clean the nozzle with the nondominant hand and inadvertently injects the substance. The initial dissipation of kinetic energy through the soft tissues of the hand and the subsequent chemical inflammation produce tissue edema and ischemia. The most commonly injected substances include grease, paint, hydraulic fluid, diesel fuel, paint thinner, and water. Paint, especially oil-based paint, triggers an intense inflammatory response that contributes to significant ischemic injury.[12] The benign appearance of the small injection site in the immediate postinjection period is misleading, and historical information must dictate treatment and disposition decisions. With time, the digit becomes edematous, pale, and severely tender to palpation, suggesting ischemic injury. Pressure to areas surrounding the wound may express the injected substance. Plain radiographs of the injected hand and forearm provide valuable information, as radiopaque substances, such as lead-based paints or grease, or subcutaneous emphysema may delineate the extent of the injection. **Definitive treatment of high-pressure injection injuries is early surgical decompression and debridement of injected areas.** Obtain immediate hand surgery consultation, immobilize and elevate the affected hand, administer tetanus prophylaxis and broad-spectrum antibiotics, and provide adequate analgesia.[13-15] Amputation rates following injection injury are as high as 30%,[16] highlighting the need for rapid identification and proper treatment of the injury.

CHAPTER 269

Wrist Injuries

Robert Escarza
Maurice F. Loeffel, III
Dennis T. Uehara

INTRODUCTION AND EPIDEMIOLOGY

The wrist is the area from the distal radius and ulna to the carpometacarpal joints. It is a complex unit with articulations among the eight carpal bones and the distal radius and ulna. Wrist injuries are common, accounting for 2.5% of ED visits annually.[1] Clinical diagnosis is often difficult, and even subtle injuries may lead to significant impairment if not properly diagnosed and treated. Management options vary from conservative to surgical, so an understanding of the functional anatomy, mechanisms of injury, and clinical evaluation is needed for proper diagnosis and treatment.

ANATOMY

DISTAL RADIUS AND ULNA

The distal radius is the only forearm bone that articulates directly with the carpal bones (scaphoid and lunate). The distal radius has three articular surfaces: radiocarpal, distal radioulnar, and the triangular fibrocartilage complex. The radiocarpal surface is concave and tilted in two planes. It has an ulnar inclination, or tilt, of 15 to 25 degrees in the frontal plane, and a volar tilt of 10 to 15 degrees in the sagittal plane[2] (**Figure 269-1**). The ulna is separated from the carpal bones by the triangular fibrocartilage complex, the main stabilizer of the distal radioulnar joint, on its distal end. The triangular fibrocartilage complex forms a smooth, continuous, ulnarly directed extension of the distal radial surface, and supports the lunate and triquetrum on the distal ulna. The distal radius has a concave sigmoid notch at its ulnar aspect that articulates with the curvature of the ulnar head, which permits wrist rotation during pronation/supination of the forearm.[3] The distal radioulnar joint is also supported by dorsal and volar radioulnar ligaments that merge with the triangular fibrocartilage complex.[4]

CARPAL BONES

Eight carpal bones are arranged in two rows. The distal carpal row (trapezium, trapezoid, capitate, and hamate) is joined tightly together and to the adjoining metacarpals. The distal row is quite stable and moves with the metacarpals as a unit in a relatively stable arch. The proximal carpal row (scaphoid, lunate, triquetrum, and pisiform) is also arranged in an arch between the distal radius and the distal carpal row. In this arrangement, the proximal row functions as a mobile link, or "intercalated segment," and is potentially unstable by virtue of this position. The scaphoid is critical to wrist stability, by acting as a stabilizing strut and linking the proximal and distal carpal rows at the radial aspect of the wrist. This position explains the scaphoid's greater propensity for injury.

Forearm muscles that insert onto the bases of the metacarpals produce wrist motion. Except for the pisiform, a sesamoid bone of the flexor

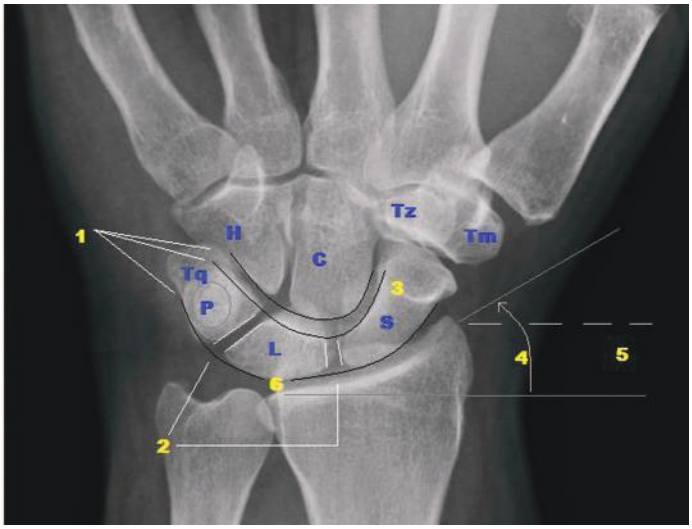

FIGURE 269-1. Wrist. Normal posteroanterior (PA) view. 1. The carpal bones are arranged in two rows forming three smooth arcs (Gilula lines). 2. The carpal bones are separated by a uniform 1- to 2-mm space. 3. The scaphoid (*S*) is elongated. 4. The radius has an ulnar inclination of 13 to 30 degrees. 5. The radial styloid projects 8 to 18 mm. 6. Half the lunate articulates with the radius, with equal length over the ulna (neutral ulnar variance). C = capitate; H = hamate; L = lunate; P = pisiform; Tm = trapezium; Tq = triquetrum; Tz = trapezoid.

carpi ulnaris, there are no direct tendon insertions on the carpal bones.[5] The carpal bones move passively in response to hand position. Often, the radiocarpal joint is referred to as the "*wrist joint*." However, wrist motion is divided almost equally between the radiocarpal and midcarpal joints.[6] This is best understood by viewing carpal movement from the sagittal view. During flexion and extension of the wrist, each row moves in the same direction with similar degrees of angulation.

The carpal bones are stabilized to one another by intrinsic ligaments and to the bones of the forearm by extrinsic ligaments. The key extrinsic ligaments are arranged in three arcades, two of which are volar and one dorsal. The two volar ligaments are arranged in two inverted V-shaped arches, and are thought to play a major role in stabilizing the wrist. The apex of one arch inserts on the lunate supporting the proximal carpal row, whereas the other arch reaches to the distal carpal row, inserting on the capitate. The area between these two palmar arches is inherently weak and is known as the *space of Poirier* (**Figure 269-2**). This space lies at the junction of the capitate and lunate and widens upon dorsiflexion

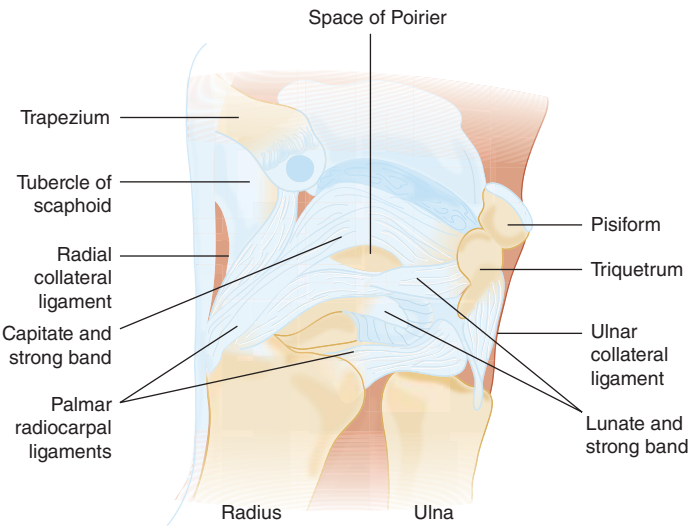

FIGURE 269-2. Ligaments of the wrist

of the wrist. Forceful dorsiflexion may tear the capsule here and produce a lunate or perilunate dislocation. The single dorsal arcade has its origins on the rim and styloid of the radius on one side and distal ulna/triangular fibrocartilage complex on the other. This ligament is less important for wrist stability, acting as a sling across the dorsum of the wrist.[6]

The space of Poirier is on the volar aspect of the wrist and is inherently weak. It is the site of disruption in perilunate and lunate dislocations. The intrinsic ligaments are largely responsible for holding the carpal bones together as a kinematic unit in their respective carpal rows. The intrinsic ligaments of the mobile proximal carpal row are particularly important because of their greater propensity for injury. The intrinsic ligaments of the proximal carpal row are named after the respective carpal bones they connect: the scapholunate and triquetrolunate. The palmar flexed posture of the scaphoid produces a flexion torque on the lunate that is counterbalanced by an extension torque from the triquetrum. This delicate balance is lost if either ligament is disrupted, producing a dorsal or volar tilt of the proximal carpal row and carpal instability.

PATHOPHYSIOLOGY

It is helpful to understand the mechanism of injury when assessing wrist injuries. Most injuries are caused by a fall creating an axial load on an outstretched arm and dorsiflexed wrist and hand. Impact on the thenar eminence is likely to injure the scaphoid and its supporting ligaments. An impact on the hypothenar eminence is likely to cause injury to the triquetrum, pisiform, and their supporting ligaments. Age affects the maturity of the bones and predisposes patients to certain types of injury.[7] **Children are likely to sustain injuries to the immature, weaker epiphyseal plate or metaphysis of the radius, sparing the still-cartilaginous carpal bones.**[8] Young adults, particularly those with active lifestyles, are likely to be injured with greater force and disrupt either the scaphoid, proximal row intrinsic ligaments, or distal radial metaphysis.[8] **In the elderly, especially with underlying osteoporosis, the weak point is the brittle distal radial metaphysis, resulting in a Colles fracture, often with intra-articular involvement.**[9]

CLINICAL FEATURES

Begin assessment by **looking at both wrists** to assess for symmetry and range of motion in dorsiflexion, palmar flexion, and radioulnar deviation, in addition to obvious deformities and soft tissue swelling. Pinpoint areas of tenderness and correlate them to anatomic landmarks of the wrist to determine which structure may be injured and the best way to evaluate it radiographically (**Figure 269-3**).

The most noteworthy landmark on the dorsum of the wrist is the anatomic snuffbox. **The anatomic snuffbox is a triangle formed by the bony radial styloid at tis proximal base, the extensor pollicis brevis tendon at its radial aspect, and the extensor pollicis longus tendon at its ulnar aspect. Palpate the scaphoid within this triangle.** Tenderness in this area may suggest a scaphoid fracture.[10] The extensor pollicis longus tendon wraps around a bony prominence of the distal radius, known as **Lister's tubercle**. The area immediately distal to this point marks the location of the scapholunate joint. Tenderness in this area suggests scapholunate ligamentous injury or lunate fracture.[11] The **scaphoid shift test** can further assess scapholunate ligament injury. To perform the scaphoid shift test, place the wrist in ulnar deviation and apply pressure with your thumb over the scaphoid tuberosity. Then move the wrist from ulnar to radial deviation; in the event of ligament injury, you will feel a palpable "clunk."

Immediately ulnar to the scapholunate joint is a palpable indentation in the center of the wrist. This is the location of the lunate and capitate, which are palpable as they rise out of this space during wrist flexion.[11] Tenderness here may indicate lunate or triquetrolunate joint injury. The ulnar styloid is the bony prominence on the ulnar aspect of the wrist. The triquetrum and triangular fibrocartilage complex are located just distal to this prominence. Tenderness over the ulnar styloid may indicate ulnar styloid or triangular fibrocartilage complex injury. The **ulnocarpal stress test** can further evaluate the triangular fibrocartilage complex; apply a compression load to the wrist in ulnar deviation.[7] Pain or clicking may indicate triangular fibrocartilage complex injury.

Pain with pronation and supination of the forearm may indicate distal radioulnar joint injury. The **piano key sign**, which is the ulnar head springing back when depressed while supporting the forearm in pronation, suggests distal radioulnar joint injury.[11]

The crease noted on the volar aspect of the wrist marks the location of the proximal carpal row (Figure 269-3). The scaphotrapezial joint is palpable at the base of the thenar eminence. The pisiform is the palpable bony prominence at the base of the hypothenar eminence. The hook of the hamate is palpable in the soft tissue distal and radial to the pisiform. Tenderness in these areas may require further evaluation than standard radiographic views.[12]

IMAGING

Clinical examination determines which radiographic views will best support a diagnosis. Standard views of the wrist include posteroanterior, lateral, and oblique views. These views are adequate in most cases, but other projections may be necessary for specific injuries.[12,13]

The key to interpreting the radiograph is to first ensure proper hand positioning, then identify specific features on each projection. On a properly positioned posteroanterior view, the distal radius and ulna should not overlap at their distal articulation, and the axis of the third metacarpal should parallel that of the radius. In addition to looking for disruption of the bony cortex, key elements on the posteroanterior view are illustrated in Figure 269-1.

On the posteroanterior view, three smooth arcs (Gilula lines) outline the articular surfaces at the radiocarpal and midcarpal joints. Two of these arcs are formed by the proximal and distal surfaces of the scaphoid, lunate, and triquetrum. The third arc is formed by the proximal articular surface of the capitate and hamate in the midcarpal joint. Any distortion of these lines implies a fracture, dislocation, or subluxation at the site.

The carpal bones fit together much like a jigsaw puzzle, with the pieces separated by a uniform 1- to 2-mm space. This space is increased or obliterated with ligament disruption, carpal instability patterns, or fracture/dislocations. This occurs most often around the lunate at the scapholunate and capitolunate joints.

The **scaphoid** has an elongated shape in its normal, palmarly flexed position. Fractures or ligament disruption may cause further palmar rotation, causing the scaphoid to appear shortened on the posteroanterior view. Injuries to the scaphoid also may obscure the **scaphoid fat stripe**, a linear or triangular radiolucent collection of fat distal to the radial styloid and parallel to the radial border of the scaphoid.

Unfortunately, incorrect positioning can produce overlap patterns that can be misinterpreted as pathologic. For example, radial deviation of the wrist causes normal physiologic rotation of the proximal carpal row, obliterating the capitolunate space. At the same time, the scaphoid that should appear elongated on the posteroanterior view appears shorter as it rotates palmarly and can be confused with a rotary subluxation of the scaphoid.

The **radial styloid** should project 8 to 18 mm beyond the distal radioulnar joint and create an ulnar inclination of 13 to 30 degrees on the PA view. Distal radius fractures can alter these measurements. At the distal radioulnar joint, the ulna and adjacent portion of the radius should be of equal length, forming a smooth articular surface, and the distal radius generally should articulate with at least half the lunate. The extrinsic ligaments along with the triangular fibrocartilage complex prevent ulnar translocation (migration of the carpal bones down the ulnar tilt of the radiocarpal surface).[14] The lunate would have less contact and support from the radius if ulnar translocation were present. A shorter ulna (negative ulnar variance) also provides less support to the lunate and increases potential shear stress to the lunate, predisposing the lunate to injury.[15]

A properly positioned lateral radiograph is important for determining carpal alignment and degree of fracture angulation.[12] The radius and ulna should completely overlap one another, and the radial styloid should be centered over the distal radial articular surface. The key elements are illustrated in Figure 269-4A.

The axis of the radius, lunate, and capitate is collinear on the lateral view. If the articular surfaces of these bones were highlighted, they

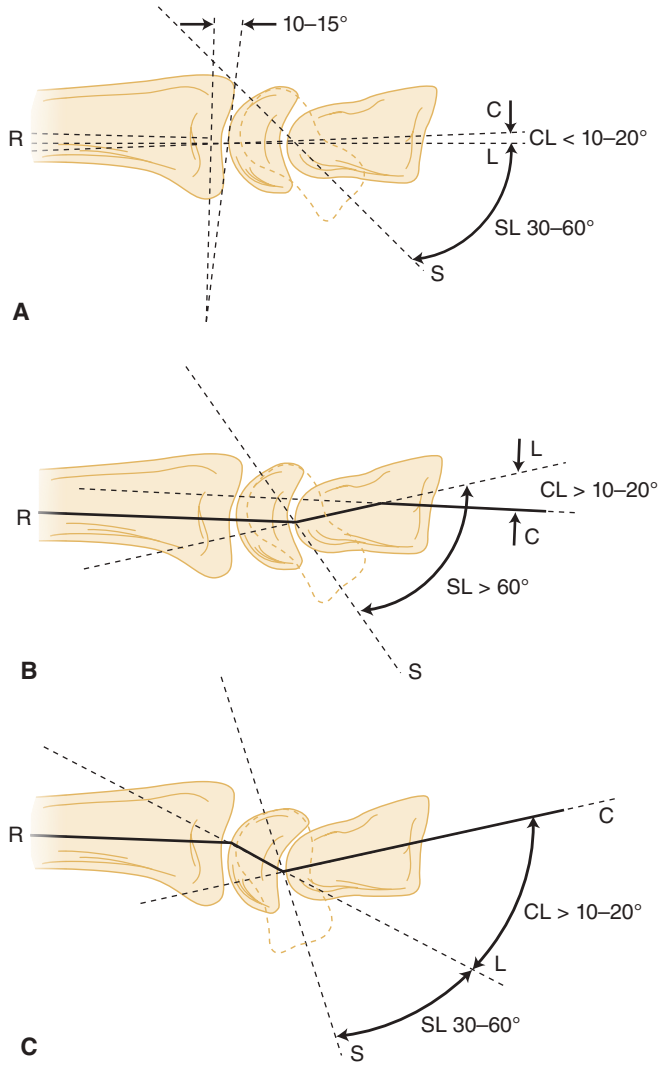

FIGURE 269-4. **A.** Normal wrist. Axis of the radius (R), lunate (L), and capitate (C) are collinear (three C's sign). The capitolunate (CL) angle is <10 to 20 degrees. The scapholunate (SL) angle is between 30 and 60 degrees. The radial volar tilt is 10 to 15 degrees. **B.** Dorsal intercalated segment instability. The lunate tilts dorsal and slides palmar, increasing the capitolunate angle. The scaphoid (S) tilts more palmar and increases the scapholunate angle. The axes of the radius, lunate, and capitate take on a zigzag pattern (yellow line). **C.** Volar intercalated segment instability. The lunate tilts palmar and the capitolunate angle increases, but the scapholunate angle is maintained. The zigzag pattern is in the opposite direction.

would appear as three consecutive C's. This provides a simple radiographic assessment of wrist dislocation. Measurement of the capitolunate and scapholunate angles is a more precise assessment of carpal alignment. The axis of the capitate, lunate, and scaphoid runs through the center of their proximal and distal articular surfaces. The axis of the lunate and capitate should nearly overlap and form an angle that is <10 to 20 degrees. **The scaphoid is normally palmar-flexed on the lateral view; its axis should form an angle between 30 and 60 degrees with the lunate.** Deviation from either of these angles suggests ligament disruption and carpal instability patterns (**Figure 269-4B** and **C**).[16]

Fracture of the distal radius is the most common fracture in the wrist.[14] Although a displaced fracture is the obvious deformity, the **alteration of the normal volar tilt of 10 to 15 degrees of the distal radial articular surface has greater long-term consequences for wrist function**, resulting in carpal misalignment and, subsequently, the instability patterns mentioned above.[15]

Other radiographic views profile specific areas of the wrist. Oblique views are performed in either partial pronation or supination, and project the scaphotrapezial joint or pisiform away from overlapping adjacent

TABLE 269-1 Wrist Radiography

View	Injuries to Identify
Posteroanterior	Distal radius/ulna fractures, carpal bone fractures, ligamentous disruptions

Grip compression	Scapholunate or triquetrolunate instability
CT	All fractures and dislocations
MRI	Occult fracture, avascular necrosis, soft tissue abnormality

carpal bones. The scaphoid view is a cone-down posteroanterior view of the scaphoid in ulnar deviation. This position extends the normal flexed posture of the scaphoid so that the bone is projected lengthwise. This view may assist in detecting subtle fractures and is used whenever scaphoid injury is suspected.[13] The carpal tunnel view is a tangential view through the carpal tunnel and is helpful in visualizing the pisiform and hook of the hamate. Motion studies are dynamic views in flexion, extension, and radial and ulnar deviation. These views examine carpal movement relative to one another, and stress the intercarpal ligaments for laxity, characterized by widening of the intercarpal space.[17] Likewise, the grip compression or fist view is a stress view in the posteroanterior projection of the tightly clenched fist. The capitate is pushed into the proximal carpal row and forces the carpal bones apart if intrinsic ligaments are disrupted. CT is useful for defining fractures and dislocations, whereas MRI is useful for evaluation for both bony and soft tissue abnormalities such as occult fractures, avascular necrosis, and triangular fibrocartilage complex abnormality.[17] **Table 269-1** presents a summary of standard and supplemental wrist radiographs and the injuries they enhance.

LIGAMENTOUS INJURIES

The lunate is located in the middle of the wrist, so it is not surprising that the majority of ligamentous injuries are centered on the **lunate**. Injuries usually result from forceful dorsiflexion of the wrist, most often from a fall on an outstretched hand. The various injuries occur sequentially depending on the degree of force and range from isolated tears to perilunate and lunate dislocations.[18,19]

SCAPHOLUNATE LIGAMENT INSTABILITY

The scapholunate ligament is the intrinsic ligament that binds the scaphoid and lunate. Because the scaphoid bridges the proximal and distal carpal rows, it is not surprising that the **scapholunate ligament has a marked propensity for injury and is the most commonly injured ligament of the wrist**. Injury most often is from a fall on an outstretched hand with impact on the thenar eminence.[18] Patients complain of pain and swelling on the radial side of the wrist and often a "clicking" sensation with wrist movement. Examination reveals localized tenderness on the dorsum of the wrist in the area immediately distal to Lister's tubercle. Ballottement of the scaphoid may also produce pain in this area.[16]

This injury is often referred to by the various radiographic appearances it may take. There are three different radiographic signs that may occur separately or in combination with one another (**Figure 269-5A**). **Scapholunate dissociation is a widening of the scapholunate joint space of >3 mm on the posteroanterior view.** If it is not apparent on routine views, a grip compression view or motion study may be necessary to demonstrate the abnormal gap (**Figure 269-5B**).[19] These maneuvers are particularly helpful in identifying an incomplete tear of the ligament. Rotary subluxation of the scaphoid is another radiographic finding that often accompanies scapholunate dissociation. A torn scapholunate liga-

FIGURE 269-5. **A.** Scapholunate dissociation and rotary subluxation of the scaphoid. The scaphoid and lunate are separated by a gap of >3 mm (*black arrow*), and the scaphoid appears shorter from rotation with a dense ring, the "cortical ring sign" (*white arrow*). **B.** Grip compression view showing enhancement of scapholunate dissociation (*arrow*). **C.** Dorsal intercalated segment instability. Lateral view exhibiting dorsal intercalated instability with scapholunate dissociation. (See fig 269-4.)

ment can cause the scaphoid to tilt more palmar and increase the scapholunate angle to >60 degrees on the lateral view. On the posteroanterior view, the scaphoid tilts toward the observer so that it appears shorter as it is viewed more on its end. This causes the circular cortex of the bone to become more prominent and appear as a ring, known as the "cortical ring sign" (Figure 269-5A). A third radiographic abnormality is a carpal instability pattern known as **dorsal intercalated segment instability** (Figure 269-4B). The normal flexed posture of the scaphoid produces a flexion torque on the lunate that is counterbalanced by an extension torque from the triquetrum. When the scapholunate ligament is torn, this balance is disrupted. The lunate tilts dorsal from the unopposed extension torque from the triquetrum, whereas the scaphoid tilts more palmar (rotary subluxation of the scaphoid) because it has lost support from the lunate. The dorsal tilt of the lunate also causes a slight flexion tilt of the capitate. In the lateral view, the normal collinear arrangement of the axes of the capitate, lunate, and radius are replaced by a characteristic zigzag pattern. Both the scapholunate and capitolunate angles are increased. The concept of the proximal carpal row being the middle link or "intercalated segment" in this system, combined with the lunate's pathologic dorsal tilt and zigzag pattern (**Figure 269-5C**), is how this abnormality came to be named dorsal intercalated segment instability.

Refer to an orthopedist or hand surgeon. **ED treatment is with a radial gutter splint or short arm volar posterior mold**. Orthopedic referral is necessary because these injuries require either closed reduction with percutaneous pinning or open reduction and internal repair of the ligament.[18] Dorsal intercalated segment instability and subsequent early, severe degenerative arthritis can occur if left untreated.[15]

TRIQUETROLUNATE LIGAMENT INSTABILITY

The triquetrolunate ligament binds the triquetrum and lunate on the ulnar aspect of the wrist. Injury to this ligament is the ulnar equivalent of the scapholunate ligament injury. Triquetrolunate ligament injury occurs much less often than scapholunate ligament injury, is more stable, and can be confused with other causes of ulnar-sided wrist pain such as triangular fibrocartilage complex injury or distal radioulnar joint abnormality.[15,16] This injury most often results from falls on the outstretched, dorsiflexed hand with impact on the hypothenar eminence. There will be localized tenderness on the ulnar aspect of the wrist just distal to the ulna. Ballottement of the triquetrum may produce a painful clicking sensation.

Subtle injuries may have a normal radiographic appearance.[15] Complete disruption of the triquetrolunate ligament removes the ability of the triquetrum to counterbalance the flexion torque from the palmar-flexed scaphoid. The lunate then tilts palmar, and the capitate extends slightly in response. A zigzag pattern in the opposite direction of the scapholunate injury is produced. The capitolunate angle is increased >10 to 20 degrees; however, the scapholunate angle is unaffected because the scapholunate ligament is still intact. The lateral radiograph may reveal the "volar intercalated segment instability" pattern (Figure 269-4C and **Figure 269-6**). The posteroanterior view may reveal a widening of the triquetrolunate joint space and obliteration of the capitolunate joint space and the normal smooth arcs typically seen because of the volar tilt of the lunate.

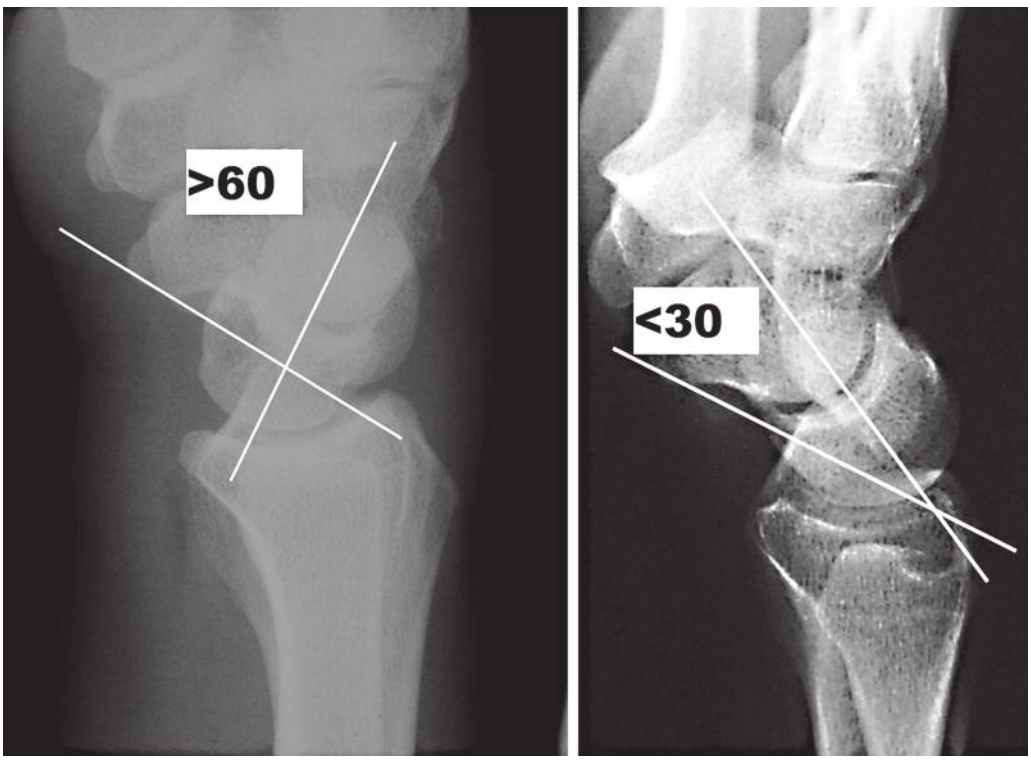
Refer to an orthopedist or hand surgeon. **ED treatment is an ulnar gutter splint or short arm posterior mold** and referral to an orthopedist. Immobilization in a cast for 6 to 8 weeks, followed by a protective splint, is sufficient in most cases. Open reduction and internal fixation are generally reserved for chronic injuries.[15] Unrecognized injuries can cause early degenerative arthritis and chronic wrist pain.

PERILUNATE AND LUNATE DISLOCATIONS

Perilunate and lunate dislocations represent the final stages of midcarpal ligament disruption and are thought to account for 10% of all carpal injuries.[20] These injuries are the result of forceful dorsiflexion and impact on the outstretched hand, but usually with great force, such as a fall from height, impact from a motor vehicle collision, or a sporting event.[21]

Perilunate dislocation is the posterior dislocation of carpal bones while the lunate maintains its position with respect to the distal radius. This is a very rare dislocation. **Lunate dislocation** produces posterior dislocation of carpal bones with the concavity of the lunate facing anteriorly.

The injury can begin on either side of the lunate, but typically begins on the radial aspect, with either a tear of the scapholunate ligament or



A B

FIGURE 269-6. **A.** Volar intercalated instability. Note widened capitolunate angle. **B.** Dorsal intercalated instability.

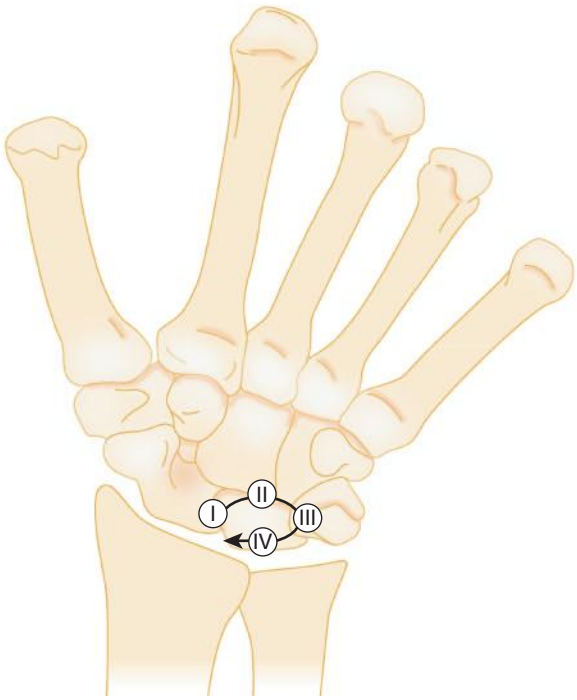


FIGURE 269-7. Four stages of perilunate instability. The first stage (I) is disruption of the scapholunate articulation (scapholunate dissociation). The second (II) and third (III) stages are separation of the capitolunate and triquetrolunate joints (perilunate dislocation). The fourth (IV) stage is a lunate dislocation.

a fracture of the scaphoid. Injury progresses around the lunate in a semicircular fashion, tearing the volar ligament arcade at the radiocapitate ligament. Remember that the extrinsic ligaments form two strong volar arcades with an inherently weak area between them that widens with dorsiflexion of the wrist (Figure 269-2). The **space of Poirier** lies at the junction of the lunate and capitate. This space opens further as heavy loading disrupts the lunatotriquetral ligament. Besides ligament disruption, any number of carpal bones may fracture along an arc around the lunate (Figure 269-7). If sufficient force is applied, the ligaments and carpal bones around the lunate are stripped away. The capitate is displaced dorsal to the lunate, producing a **perilunate dislocation**. If the capitate rebounds with sufficient force, it can push the lunate off the radius and into the palm, creating a **lunate dislocation**. These injuries are all part of a continuous spectrum of ligament disruption (**Figure 269-7**).[22]

On clinical examination, there is generalized swelling, pain, and tenderness of the wrist. However, a gross deformity, typical of many joint dislocations, is often absent. Radiographic interpretation is the key to diagnosis. **The perilunate dislocation is best appreciated on the lateral view. The linear arrangement of the three C's sign is disrupted with the capitate, represented by the third C, displaced dorsal to the lunate. The lunate retains its contact with the radius.** The scapholunate and capitolunate angles are increased. On the posteroanterior view, the three smooth arcs are disrupted, and the capitolunate joint space is obliterated as the bones overlap one another. The scapholunate and triquetrolunate joint space may either be increased because of torn ligaments or obliterated by rotation of the fractured carpal fragments. The scaphoid will appear shortened from rotary subluxation or fracture (**Figure 269-8**). A perilunate dislocation may also overshadow any associated carpal bone fracture. The scaphoid and capitate are most often involved, so carefully inspect these bones for fractures. Such fractures are designated by adding the prefix "trans-" to the carpal bone name (e.g., transscaphoid perilunate dislocation) (**Figure 269-9**).

A lunate dislocation has many similar and several distinct radiographic features when compared with a perilunate dislocation. On the posteroanterior view, the lunate has a triangular shape ("piece-of-pie" sign) that is suggestive of lunate dislocation (**Figure 269-10A**). On the lateral view, it also disrupts the three C's sign. **The lunate (represented by the middle C) is pushed off the radius into the palm. This has been called the "spilled teacup" sign because it resembles a cup spilling in the direction of the palm (Figure 269-10B).** The capitate may rebound back and even rest on the radius. The signs of ligament disruption

and the associated carpal bone fractures described with perilunate injuries may also be present.

Perilunate or lunate dislocations require emergency orthopedic/hand consultation.[22] Treatment is determined by the extent of the injury. Closed reduction and long arm splint immobilization is appropriate for reducible dislocations.[23] Open, unstable, and irreducible dislocations require open reduction and internal fixation, with repair of the ligaments and fractures. Some orthopedists operate on all perilunate and lunate dislocations.[15] **The complications include development of carpal instability patterns that lead to early degenerative arthritis, delayed union, malunion, nonunion, avascular necrosis, and, occasionally, median nerve compression from the volar dislocation of the lunate into the carpal tunnel.**[21]

CARPAL BONE FRACTURES

Carpal bone fractures are the most commonly missed wrist injuries. A careful examination is critical to recognize carpal bone fractures. The carpal fractures are in **Table 269-2** listed in descending order of occurrence.

SCAPHOID FRACTURE

The scaphoid is the most common carpal bone fractured. Injuries result from a fall on either an outstretched dorsiflexed hand or from an axial load directed along the thumb's metacarpal. There is pain along the radial aspect of the wrist and localized tenderness in the anatomic snuffbox.[24,25] Examination of the wrist in ulnar deviation exposes more of the scaphoid to direct palpation within the anatomic snuffbox. Eliciting pain in this area when the patient resists supination or pronation of the hand or pain with axial pressure directed along the thumb's metacarpal also suggests injury.

Radiographic evaluation includes both standard and scaphoid views for cortical disruption (**Figure 269-11**). The scaphoid view profiles the bone lengthwise and may assist in detecting subtle fractures. Distortion of a soft tissue fat stripe adjacent to the radial aspect of the scaphoid is suggestive of injury. Two thirds of the fractures occur at the waist or middle third of the bone, 16% to 28% in the proximal third, and 10% in the distal third. A scaphoid fracture may also have an associated injury in 12% of cases. Associated injuries may include the radius, neighboring carpal bones, a carpal instability pattern, or a dislocation. In patients with initial negative plain films, yet in whom a high index of suspicion remains for fracture, MRI is considered the gold standard for definitive diagnosis.[26]

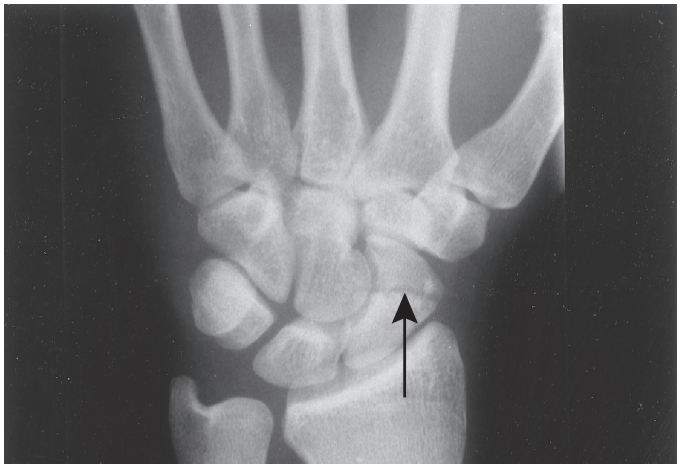

FIGURE 269-11. Scaphoid fracture in the middle third or waist (*arrow*).

A scaphoid fracture can develop avascular necrosis of the proximal fracture segment that can lead to disabling arthritis.[27] Because the vascular supply to the scaphoid enters the distal portion of the bone through small branches off the radial artery and palmar and superficial arteries, a fracture can easily disrupt the blood supply to the proximal segment. The more proximal, oblique, or displaced a fracture, the greater the risk of developing avascular necrosis. A scaphoid fracture is considered unstable if it is oblique, if there is as little as 1 mm of displacement, if there is rotation or comminution, or if a carpal instability pattern is present. Two thirds of the scaphoid's surface is articular. This only adds to the scaphoid's problems because articular fractures are more difficult to heal. Thus, the main complications of improperly healed scaphoid fractures are avascular necrosis, delayed union, nonunion, malunion, and subsequent early degenerative arthritis.

Up to 10% of initial radiographs fail to detect a fracture, so initial treatment should be directed by clinical suspicion. Nondisplaced fractures and those that are only clinically suspected can be treated in a short arm thumb spica splint. Splinting in dorsiflexion and radial deviation helps to compress the fracture fragments. Patients with unstable fractures should be placed in a long arm thumb spica splint and should be seen promptly by an orthopedic or hand surgeon for definitive treatment.

TABLE 269-2 Summary of Carpal Bone Fractures and ED Management

Carpal Bone	Mechanism of Injury	Examination	Initial ED Management
Scaphoid	Fall on outstretched hand	Snuffbox tenderness; pain with radial deviation and flexion	Short arm thumb spica splint, in dorsiflexion with radial deviation
Triquetrum	Avulsion fracture—twisting of hand against resistance or hyperextension Body fracture—direct trauma	Tenderness at the dorsum of the wrist, distal to the ulnar styloid	Short arm sugar tong splint
Lunate	Fall on outstretched hand	Tenderness at shallow indentation of the mid-dorsum of the wrist, ulnar and distal to Lister tubercle	Short arm thumb spica splint
Trapezium	Direct blow to thumb; force to wrist while dorsiflexed and radially deviated	Painful thumb movement and weak pinch strength Snuffbox tenderness	Short arm thumb spica splint
Pisiform	Fall directed on the hypothenar eminence	Tender pisiform, prominent at the base of the hypothenar eminence	Short arm volar splint in 30 degrees of flexion and ulnar deviation
Hamate	Interrupted swing of a golf club, bat, or racquet	Tenderness at the hook of the hamate, just distal and radial to the pisiform	Short arm volar wrist splint with fourth and fifth metacarpal joints in flexion
Capitate	Forceful dorsiflexion of the hand with radial impact	Tenderness over the capitate just proximal to the third metacarpal	Short arm volar wrist splint
Trapezoid	Axial load onto the index metacarpal	Tenderness over the radial aspect of the base of the index metacarpal	Short arm thumb spica splint

TRIQUETRUM FRACTURE

Triquetrum fractures are the second most common carpal bone injury, and occur as an avulsion or fracture through the body.[23] Avulsion fractures are produced when a twisting motion of the hand is suddenly resisted or a hyperextension shear stress pushes the hamate or ulnar styloid against the triquetrum. Fractures of the body occur from direct trauma and are found in association with perilunate and lunate dislocations (part of the arc fractures). Localized tenderness is found over the dorsum of the wrist in the area immediately distal to the ulnar styloid. **The dorsal avulsion fracture is best seen on the lateral radiograph or an oblique view in partial pronation.** The fracture appears as a tiny flake of bone on the dorsum of the triquetrum best seen on lateral view (**Figure 269-12**). Triquetrum body fractures are usually nondisplaced because numerous ligaments encase the bone; these are best seen on the posteroanterior view. Nonunion is possible, but avascular necrosis has not been reported.

Refer triquetrum fractures to an orthopedist or hand surgeon. Patients with a dorsal avulsion fracture have an excellent prognosis for full recovery. Symptomatic patients are treated with a wrist splint for 1 to 2 weeks. Asymptomatic or minimally symptomatic patients may be treated with early range of motion. Stable body fractures are treated in a cast for 6 weeks. Unstable body fractures (>1 mm displacement) and those associated with perilunate/lunate dislocations may require internal fixation.[28]

LUNATE FRACTURE

Lunate fractures tend to occur with other carpal injuries. Isolated lunate injuries are rare. The mechanism of injury is commonly the result of a fall on the outstretched hand. The lunate is present in the shallow indentation on the mid-dorsum of the wrist. The lunate is easily palpable as it rises out of the floor of this indentation when the wrist is in a flexed position. Examination reveals tenderness at this point. Axial compression applied along the third metacarpal ray may also elicit pain in this area and is suggestive of injury. **The lunate's blood supply enters through the distal end of the bone. A fracture subjects the lunate to risk for avascular necrosis of the proximal portion.**

The lunate is seated in the middle of the wrist, so overlap with other carpal bones may make it difficult to identify an injury on a plain radiograph. On the lateral radiograph, the lunate, capitate, and distal radius should lie in the same vertical plane.

Refer suspected or actual lunate fractures to an orthopedist or hand surgeon. Clinical suspicion dictates the acute treatment. A short arm thumb spica splint should be applied when the diagnosis is unclear. MRI and CT may be used to identify occult fractures. The major complication is avascular necrosis (Kienböck's disease), leading to lunate collapse, osteoarthritis, chronic pain, and decreased grip strength.

TRAPEZIUM FRACTURE

The trapezium is a saddle-shaped bone that articulates with the thumb metacarpal. Injuries are produced by a direct blow to the thumb or from a dorsiflexion and radial deviation force. Fractures occur either at the trapezial ridge or body and are often intra-articular. Vertical fractures occur and are analogous to a Bennett's fracture (an intra-articular proximal thumb metacarpal fracture) (**Figure 269-13**). Examination reveals painful thumb movement and a weak pinch. There is tenderness at the apex of the anatomic snuffbox and at the base of the thenar eminence. This injury is best profiled on a 20-degree pronated oblique view. The major complication is nonunion.

Refer to an orthopedist or hand surgeon. Initial ED stabilization of nondisplaced fractures is a short arm thumb spica splint. **Displaced fractures >1 mm or diastases >2 mm require surgery.**[29]

PISIFORM FRACTURE

The pisiform is a sesamoid bone within the flexor carpi ulnaris tendon. It is positioned immediately volar to the triquetrum and is the palpable bony prominence at the base of the hypothenar eminence. Injuries usually result from a fall directed on the hypothenar eminence. There will be localized tenderness on the pisiform itself. If the wrist is flexed, the pisiform can be grasped and palpated between the examiner's fingers. This should elicit pain. The pisiform and hook of the hamate form the bony walls of **Guyon's canal** that contains the ulnar nerve and artery; therefore, it is important to exclude injury to them.[30] Radiographs in partial supination, or the carpal tunnel view, are optimal because they remove the overlap with the triquetrum that is present on standard views (**Figure 269-14**).[31] The pisiform is the last carpal bone to ossify, and it is usually complete by age 12 years old. Before the age of 12, multiple ossification centers in the pisiform may be confused with a fracture. The ossification centers differ in that they will have smoother margins and lack the perfect jigsaw-puzzle fit seen with

FIGURE 269-14. Pisiform fracture. [Photo contributed by: Brooke Beckett, MD, Department of Radiology, Oregon Health & Science University, Portland, OR.]

fracture fragments. After age 12, any radiographic line is suggestive of fracture.

Refer to an orthopedist or hand surgeon. ED treatment is either a compression dressing or a splint in 30 degrees of flexion with ulnar deviation that relaxes the tension from the flexor carpi ulnaris. Pisiform fractures have an excellent prognosis.

HAMATE FRACTURE

Hamate fractures may involve the body of the hamate, the hook of the hamate, or any of its articular surfaces. Body fractures are rare and are generally associated with fracture dislocations of the fourth or fifth metacarpals (**Figure 269-15**). Most hamate fractures involve the hamate hook, which is a small bony prominence on its volar aspect. The classic mechanism is an interrupted swing with a golf club, bat, or racquet. The handle impacts against the hypothenar eminence and compresses the bone. Localized tenderness over the hook of the hamate is found by palpating the soft tissue of the hypothenar eminence, distal and radial to the pisiform. **Standard and carpal tunnel views are necessary to visualize the fracture. Occult fractures may be identified by bone scan or CT.** Physical examination should assess for injury to **Guyon's canal (Figure 269-16)**, which houses the ulnar nerve and artery.

Refer to an orthopedist or hand surgeon. In the ED, treat hamate hook fractures with a compression dressing or splint. Nonunion is common, and excision of the bone may be necessary. Nondisplaced body fractures are treated by splint immobilization. Displaced body fractures or those with injury to Guyon's canal are surgically treated.

FIGURE 269-15. Hamate fracture (*arrow*) is best seen on posteroanterior view. [Photo contributed by: Brooke Beckett, MD, Department of Radiology, Oregon Health & Science University, Portland, OR.]

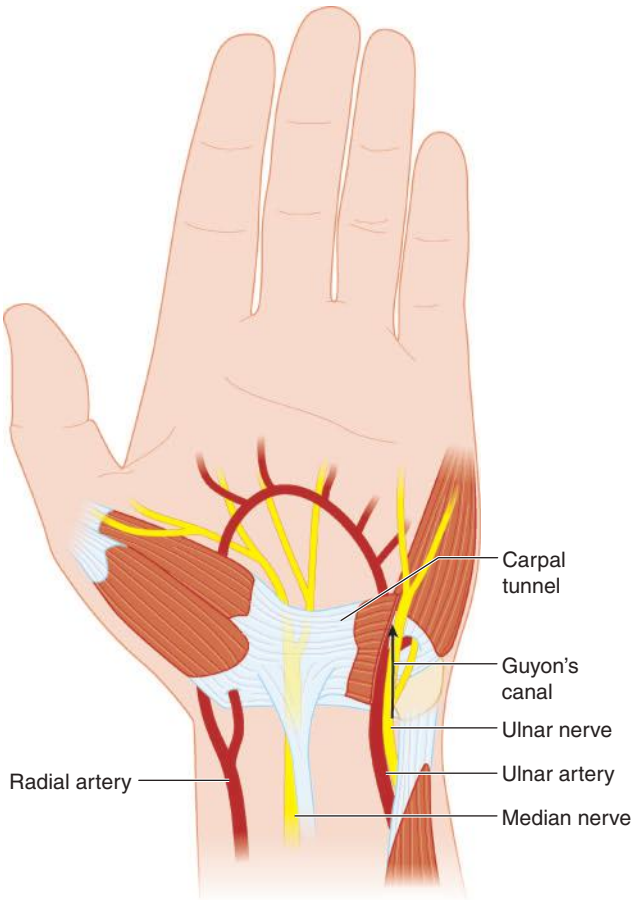

FIGURE 269-16. Guyon's canal.

CAPITATE FRACTURE

The capitate is the largest carpal bone. It is an elongated bone with a large proximal head that articulates with the lunate. The midportion of the bone is the neck, and the distal end, or body, articulates with the third metacarpal. Capitate fractures most often occur in the neck and usually occur in conjunction with a scaphoid fracture (**Figure 269-17**). The association of scaphoid and capitate fractures is called the **scaphocapitate syndrome**. Isolated capitate fractures are rare.[32] Capitate fractures result from forceful dorsiflexion of the hand with impact on the radial side. The scaphoid fractures first, and then the neck of the capitate fractures. The fracture can continue around the lunate, creating other so-called arc fractures, eventually resulting in perilunate or lunate dislocation. The capitate's blood supply enters through the distal end. Thus, capitate fractures also share the same potential avascular necrosis of the proximal fracture segment as the lunate and scaphoid.

Physical examination reveals diffuse swelling and tenderness over the capitate, just proximal to the third metacarpal. Capitate neck fractures are best seen on the lateral radiograph. The head of the capitate should be carefully identified because it can rotate as much as 180 degrees. A capitate fracture is often overlooked because of the accompanying scaphoid fracture or perilunate/lunate dislocation that overshadows it. Complications include avascular necrosis, delayed union, nonunion, and malunion.

ED treatment of undisplaced, isolated capitate fractures is splint immobilization and early orthopedic/hand surgeon referral. Most capitate fractures, however, are displaced or associated with the scaphocapitate syndrome and require surgical treatment.[33]

TRAPEZOID FRACTURE

Trapezoid fracture is extremely rare. The injury results from an axial load onto the index metacarpal. There will be tenderness on the radial aspect that is augmented by applying pressure along the index metacarpal ray. Fractures are difficult to visualize on standard radiographs, and CT or MRI may be necessary. ED treatment is with a thumb spica splint.

DISTAL RADIUS AND ULNA FRACTURES

Fractures of the distal metaphysis of the radius and ulna are among the most common injuries affecting the wrist. Among the factors that influence the type and amount of displacement of the fracture are the point and direction of impact, the degree of force, and the patient's age (**Table 269-3**).

In general, the thinner cortices of the elderly make them more likely to sustain extra-articular fractures, whereas younger adults often sustain more complicated intra-articular fractures.

FIGURE 269-17. Capitate fracture (*arrow*) is seen best on posteroanterior view. [Photos contributed by: Brooke Beckett, MD, Department of Radiology, Oregon Health & Science University, Portland, OR.]

TABLE 269-3 Radiographic Appearance of Distal Radius Fractures

Colles' fracture
Dorsal angulation of the plane of the distal radius
Distal radius fragment is displaced proximally and dorsally
Radial displacement of the carpus
Ulnar styloid may be fractured
Smith's fracture
Volar angulation of the plane of the distal radius
Distal radius fragment is displaced proximally and volarly
Radial displacement of the carpus
The fracture line extends obliquely from the dorsal surface to the volar surface 1–2 cm proximal to the articular surface
Barton's fracture
Volar and proximal displacement of a large fragment of radial articular surface
Volar displacement of the carpus
Radial styloid may be fractured

COLLES' FRACTURE

Colles' fracture results most often from a fall on the outstretched hand. This mechanism produces a distal radial metaphysis fracture that is dorsally angulated and displaced proximally and dorsally (**Figure 269-18**). Compression forces on the dorsal side often produce dorsal comminution of bone. The fracture line may also comminute and extend into the radioulnar or radiocarpal joint ("die-punch" fracture). A fracture of the ulnar styloid is often present and may be suggestive of injury to the triangular fibrocartilage complex.

A B

FIGURE 269-18. Colles' fracture. A. Anteroposterior view. B. Lateral view. [Photos contributed by: Brooke Beckett, MD, Department of Radiology, Oregon Health & Science University, Portland, OR.]

The wrist has the characteristic dorsiflexion, or "dinner-fork," deformity. Patients may complain of palmar paresthesias from pressure on the median nerve. Posteroanterior radiographs reveal a distal metaphyseal fracture of the radius that often appears shortened from the angulation or comminution. **The lateral view provides the best view of the dorsal angulation and comminution. In general, unstable fractures have >20 degrees of angulation, intra-articular involvement, marked comminution, or more than a centimeter of shortening.** These injuries are more likely to develop loss of reduction, distal radioulnar joint instability, radiocarpal instability patterns, and subsequent arthritis.

Stable fractures may be treated with a compression dressing and splint until they can be evaluated by an orthopedic surgeon; otherwise, closed reduction is performed. After adequate local anesthesia (see chapter 36, "Local and Regional Anesthesia"), provide traction with finger traps while the fracture fragment is pushed distal and palmar and the patient's forearm is held firmly (**Figure 269-19**). The goal is to restore the volar tilt, radial inclination, and proper length to the radius. This is particularly important in younger patients. The volar tilt ideally should be restored to its normal position, but a minimum of neutral or zero degrees of angulation is acceptable.

Most Colles' fractures can be treated with closed reduction and application of a sugar tong splint. If a short arm cast is applied, it should be bivalved to allow for edema. Fractures that are unstable, severely comminuted, or intra-articular may require surgery. **All open and neurovascularly compromised fractures require prompt evaluation by an orthopedic surgeon.**

Complications include malunion, median nerve injuries, triangular fibrocartilage complex injuries, radioulnar and radiocarpal instability, and arthritis. These complications may result in a weak, stiff, and painful wrist.

SMITH'S FRACTURE

Smith's fracture, or **reverse Colles' fracture**, is a volar angulated fracture of the distal radius. This may result from a fall or direct blow on the dorsum of the hand and wrist, or from a fall on the outstretched hand in supination that then shifts into a pronated position. The hand is displaced palmar and produces a "garden-spade deformity" on physical examination. The posteroanterior radiograph looks much like the Colles' fracture, with a distal metaphyseal radius fracture that may be shortened and comminuted. **The lateral radiograph shows the volar angulated and displaced fracture (Figure 269-20).**

The treatment objectives and complications are much like those seen with the Colles' fracture. In this case, however, the angulation is volar rather than dorsal, and during reduction, pressure is applied in the opposite direction.

BARTON'S FRACTURE

Barton's fractures are dorsal or volar rim fractures of the distal radius. The dorsal rim fractures result from a dorsiflexion and pronation force, whereas the less common volar rim fracture is produced by a fall on the outstretched hand in supination. These injuries are often fraction-dislocations or subluxations, because the carpus is frequently displaced in the direction of the fracture. Accompanying ligamentous injuries create radiocarpal instability. This instability is not fully appreciated in the acute setting but may lead to various secondary carpal instability patterns and premature degenerative arthritis.

The posteroanterior radiograph often shows a comminuted fracture of the distal radial metaphysis. The lateral view reveals an intra-articular fracture of the volar or dorsal rim of the radius, which may be accompanied by carpal subluxation in the same direction (**Figure 269-21**).

Minimally displaced fractures can be treated acutely in a sugar tong splint until evaluation by an orthopedist. **Unstable fractures involving >50% of the radial articular surface or those with accompanying carpal subluxation require open reduction and internal fixation.**

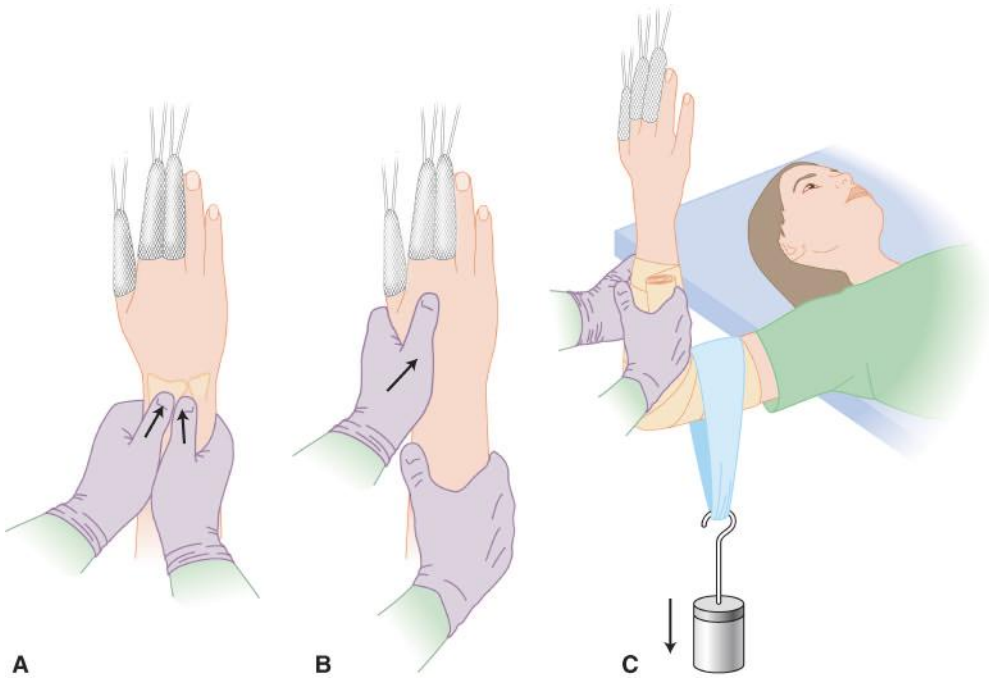

FIGURE 269-19. **A** and **B**. *Arrows* demonstrate application of force for proper reduction. **C.** Figure demonstrates proper patient position with the use of finger traps. [Reproduced with permission from Reichman EF, Simon RR: Emergency Medicine Procedures. © 2004, McGraw-Hill, New York.]

FIGURE 269-20. Smith's fracture.

RADIAL STYLOID FRACTURE

A force directed along the radial aspect of the hand can produce a transverse or oblique fracture that extends from the scaphoid fossa to the metaphysis of the radius (**Figure 269-22**). **Radial styloid fracture** is often accompanied by a dislocation of the lunate. It is best seen on the posteroanterior radiograph as a thin, lucent line beneath the radial styloid. Because the major carpal ligaments along the radial aspect of the wrist insert on the radial styloid, displacement of this fracture can produce carpal instability. This instability is aided by the extracarpal ligaments (i.e., wrist/finger flexors and extensors causing further displacement of the styloid). Displaced fractures often require open reduction and internal fixation. Displacement of as little as 3 mm is often associated with accompanying scapholunate dissociation. Failure to recognize intercarpal ligament tears adds to the potential for subsequent posttraumatic arthritis. Refer to an orthopedist. In the ED, place a short arm splint positioning the wrist in mild flexion and ulnar deviation.

ULNAR STYLOID FRACTURE

A forced radial deviation, dorsiflexion, or rotatory stress can fracture the **ulnar styloid**. The ulnar styloid fracture may be isolated or may accompany other injuries, such as a Colles' fracture. Clinically, avulsion fractures are rarely significant, with the major consideration being the associated radial soft tissue and bony injuries. Displaced ulnar base fractures can be intra-articular and be associated with tears of the triangular fibrocartilage complex, which is the main stabilizer of the distal radioulnar joint. Patients complain of a painful clicking or locking sensation in the wrist. If the distal radioulnar joint is stable, ulnar styloid fractures are treated acutely in an ulnar gutter splint in slight ulnar deviation and neutral positioning of the wrist. If there is any question about stability, these patients should be referred acutely for surgical evaluation. Arthrograms or MRI imaging may be necessary to delineate the full extent of injury.

DISTAL RADIOULNAR JOINT DISRUPTION

Distal radioulnar joint disruption is generally seen with intra-articular or distal radial shaft fractures (**Galeazzi fracture-dislocation**)[34] or with fractures of both bones of the forearm. These more apparent injuries often overshadow distal radioulnar joint disruption and, unfortunately,

FIGURE 269-21. Volar Barton's fracture. **A.** Posteroanterior view. **B.** Lateral view.

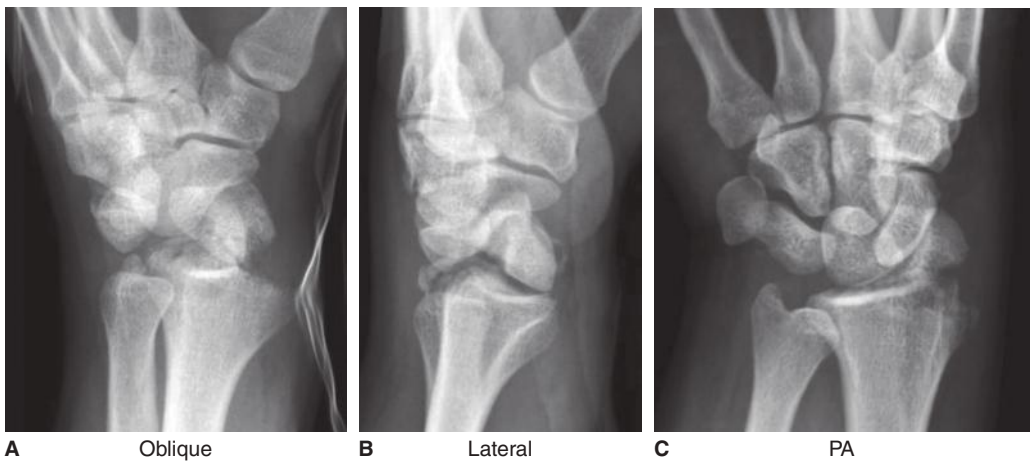

FIGURE 269-22. Radial styloid fracture (*arrow*) with lunate dislocation. [Photos contributed by: Brooke Beckett, MD, Department of Radiology, Oregon Health & Science University, Portland, OR.]

may remain unrecognized until subsequent pain and diminished wrist movement are appreciated.

Isolated radioulnar joint dislocations are uncommon and are often unrecognized acutely. Dorsal dislocation of the ulna results most often from falls on the wrist in hyperpronation. The rare volar dislocation results from forced hypersupination of the wrist. Patients with disruption of the distal radioulnar joint present with pain at the distal radioulnar joint, weak grip, and restricted range of motion, especially pronation and supination. The ulnar head is often prominent but may be subtle and easily overlooked.

The posteroanterior radiograph reveals narrowing and overlap of the distal radioulnar joint. **The lateral radiograph demonstrates either volar or dorsal displacement of the ulna, which is normally centered and overlapping the radius.** Because slight oblique positioning of the wrist can produce a misleading appearance of ulnar displacement, make sure to obtain a properly positioned lateral view. A true lateral view should have superimposition of the four ulnar metacarpals, superimposition of the proximal pole of the scaphoid with the lunate and triquetrum, and the radial styloid centered over its distal articular surface. CT scanning may be necessary to establish the diagnosis if plain films are inconclusive.

Immobilizing the wrist in supination reduces dorsal dislocations, whereas volar dislocations are placed in pronation. Patients with acute distal radioulnar joint disruption are referred acutely for orthopedic follow-up. These injuries have a high recurrence rate and may require reconstructive surgery, particularly if there is a delay in diagnosis.

CHAPTER 270

Elbow and Forearm Injuries

Yvonne C. Chow

ANATOMY

Articulations of the distal humerus and proximal ulna and radius form the elbow joint (**Figure 270-1**).

The epicondyles are nonarticulating surfaces that serve as sites of origin for forearm, wrist, and digit flexors and pronators (medial), and extensors and supinators (lateral). Medially, the trochlea articulates with the olecranon to form a uniaxial hinge joint. Laterally, the capitellum abuts the radial head to form a pivot joint. Between the condyles, the coronoid fossa is anterior, and the olecranon fossa is posterior. These allow for full flexion and extension of the ulna. The radial fossa lies proximal to the capitellum anteriorly and permits full flexion of the radius.

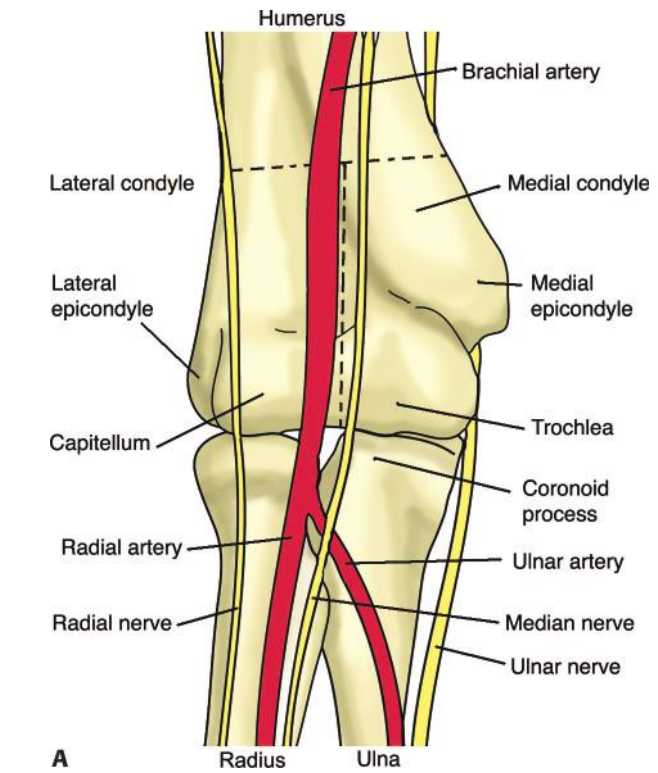
The radius and ulna are joined together along their entire length by a fibrous interosseous membrane, and articulate only at their ends to form the complex proximal and distal radioulnar joints. The ulna is a comparatively straight bone, whereas the radius has an important outward bowing. During the motions of supination and pronation, the radius rotates around the relatively fixed ulna. Because these bones have such a close relationship to one another, injury to one will have a direct impact on the other. A displaced or angulated fracture of one bone typically disrupts the other or causes a dislocation at the proximal or distal radioulnar joint.

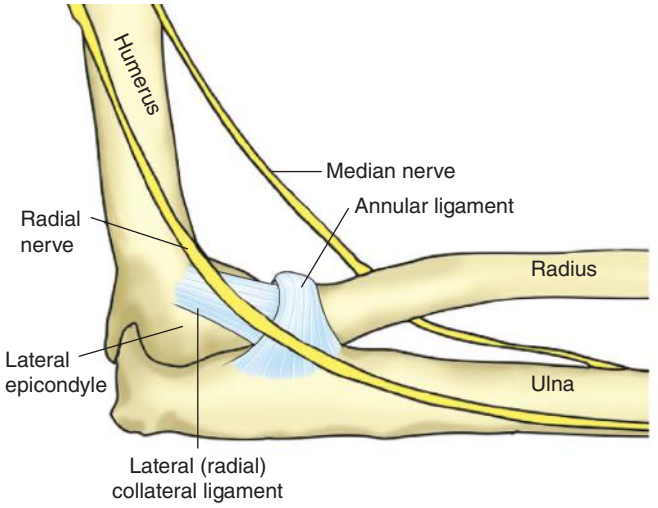
Several important neurovascular structures lie in close proximity to the distal humerus, and evaluation of their function is essential. These include the brachial artery, palpable just medial to the distal biceps tendon in the antecubital fossa, and the radial, median, and ulnar nerves (**Table 270-1**).

The neuroanatomy is best understood by appreciating the neural control of basic wrist and finger movement (**Figure 270-2**). The radial nerve travels over the lateral epicondyle and supplies the muscles of wrist extension before it branches off into the posterior interosseous nerve. This deep branch travels around the proximal radius and through the supinator muscle and controls the muscles of finger and thumb extension. The remainder of the radial nerve lies adjacent to the radial artery. This superficial branch is purely sensory and innervates the dorsal aspect of the hand from the thumb to the radial half of the ring finger. Thus, the proximal portion of the radial nerve controls the more proximal function of wrist extension, the deep branch (posterior interosseous nerve) controls the more distal function of finger extension, and the superficial branch is purely sensory. Therefore, an isolated injury to the posterior interosseous branch affects finger extension but spares wrist extension and sensation to the dorsum of the hand.

TABLE 270-1 Sensory and Motor Function Testing of the Radial, Median, and Ulnar Nerves

	Radial	Median	Ulnar
Test for sensory function	Dorsum of the thumb index web space	Two-point discrimination over the tip of the index finger	Two-point discrimination over the little finger
Test for motor function	Extend both wrist and fingers against resistance	"OK" sign with thumb and index finger; abduction of the thumb (recurrent branch)	Abduct index finger against resistance





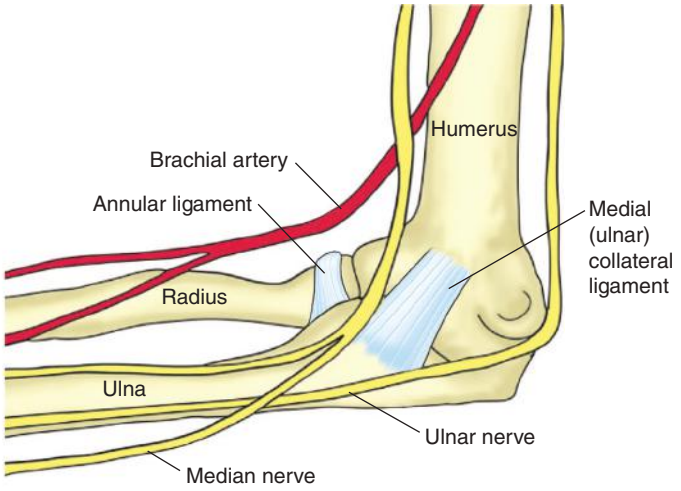


FIGURE 270-1. Elbow anatomy. **A.** Anterior view. **B.** Lateral view. **C.** Medial view.

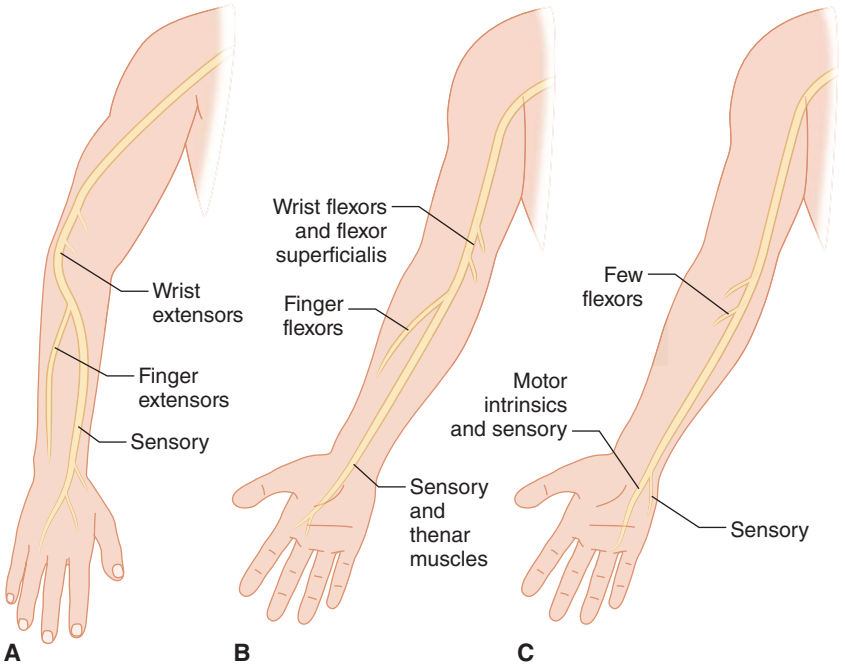

FIGURE 270-2. Neural innervation of the forearm, wrist, hand, and digits. **A.** Radial nerve innervation. **B.** Median nerve innervation. **C.** Ulnar nerve innervation.

The median nerve supplies the muscles of wrist and finger flexion and sensation over the volar surface of the hand from the thumb to the radial half of the ring finger, including the dorsal tips of the thumb and index and middle fingers. The proximal portion of the median nerve innervates the muscles that control wrist flexion and the flexor digitorum superficialis before it gives off the anterior interosseous nerve. This branch controls portions of the remaining deep finger flexors. The remaining portion of the median nerve provides sensation to most of the volar surface of the hand in addition to controlling the thenar muscles of the thumb via a separate motor branch (recurrent branch of the median nerve).

The ulnar nerve provides innervation to forearm muscles and controls the intrinsic muscles of the hand while providing sensation to the little finger and the ulnar half of the ring finger. Proximal to the elbow, the ulnar nerve courses under a ligamentous band called the arcade of Struthers prior to entering the cubital tunnel posterior to the medial epicondyle. These are two sites where the nerve can become entrapped, leading to ulnar neuropathy syndromes. The ulnar nerve is palpable as a cord in the cubital tunnel and is vulnerable to injury with trauma over this area.

The biceps muscle has two proximal heads (**Figure 270-3**). The long head originates at both the supraglenoid tubercle of the scapula and the superior labrum of the glenohumeral joint, and then travels through the capsule of the shoulder and along the intertubercular (bicipital) groove of the humerus. The short head originates at the coracoid process of the scapula. The distal attachments are to the radial tuberosity by the distal biceps tendon and the forearm by the bicipital aponeurosis. A bicipitoradial bursa lies adjacent to the radial tuberosity. The biceps muscle is innervated by the musculocutaneous nerve (C5 and C6) and functions to flex the supinated forearm and supinate the flexed forearm.

The brachialis muscle lies deep to the biceps muscle. It originates on the distal anterior humerus and inserts on the ulnar tuberosity of the proximal ulna. The brachialis muscle is innervated by both the musculocutaneous and radial nerves (C5, C6, C7, and C8) and is the primary flexor of the forearm.

The triceps muscle has three proximal heads (**Figure 270-4**): a long head originating from the infraglenoid tubercle of the scapula; a lateral head on the posterior surface of the humerus superior to the radial (spiral) groove; and a medial head inferior to the radial groove. The triceps inserts at the olecranon. A subtendinous bursa separates the triceps from the olecranon, and a subcutaneous bursa lies just distal to the tendinous insertion. The latter frequently becomes inflamed. The triceps

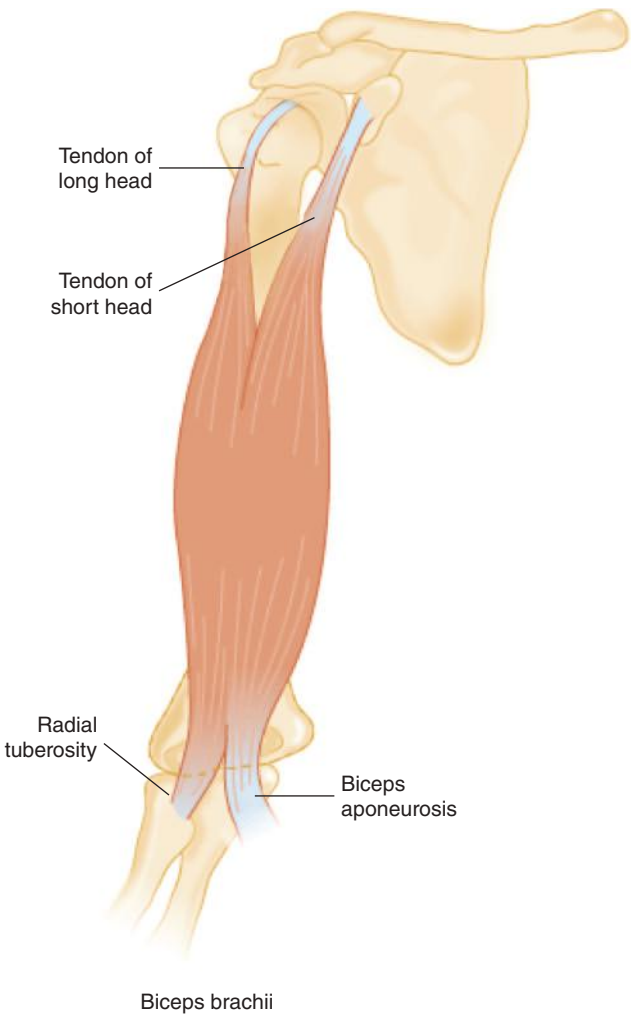

FIGURE 270-3. Biceps muscle anatomy.

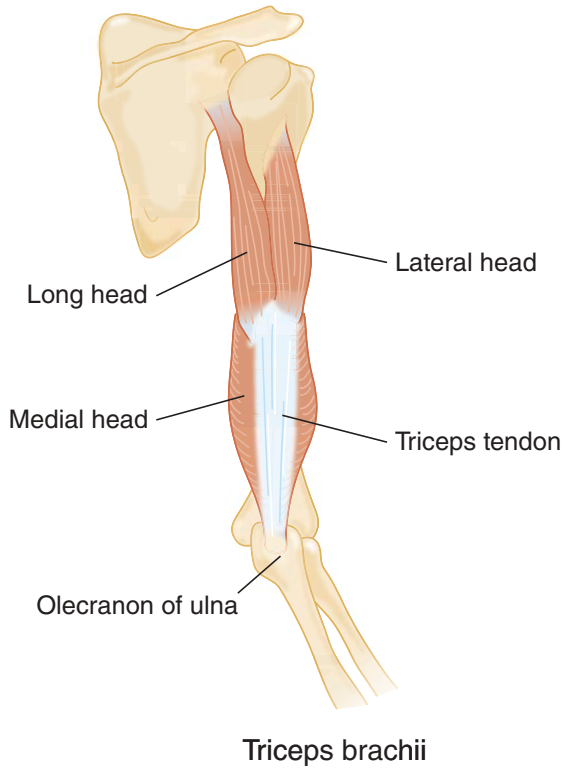

FIGURE 270-4. Triceps muscle anatomy.

muscle is innervated by the radial nerve (C6, C7, and C8) and is the sole extensor of the forearm. Additionally, the triceps aids extension and adduction of the arm, and the long head stabilizes the head of the humerus in abduction.

The intrinsic forearm muscles include the brachioradialis, pronator teres, pronator quadratus, anconeus, and supinator (**Figure 270-5**). The brachioradialis muscle originates at the lateral condyle and assists with forearm flexion. The pronator teres muscle has two proximal heads that originate from the medial epicondyle and the proximal ulna; it pronates and flexes the forearm. The pronator quadratus muscle originates from the distal ulna and is the primary pronator of the forearm. The anconeus muscle originates from the posterior lateral epicondyle and has trivial function in extending the forearm. Lastly, the supinator muscle originates from the posterior medial ulna and supinates the forearm with the biceps muscle. The deep branch of the radial nerve (posterior interosseous nerve) pierces the supinator muscle after branching off of the proximal segment of the radial nerve. Thus, a compression neuropathy to the posterior interosseous nerve can occur at this level (**Figure 270-6**).

CLINICAL FEATURES

HISTORY

A thorough history is essential for determining the correct diagnosis in a patient with elbow or forearm pain. Onset of symptoms, mechanism of injury, exact location of pain, and associated symptoms such as numbness, weakness, or distal wrist and hand complaints are important elements to obtain. Most acute traumatic injuries to the elbow and forearm occur due to a fall onto an outstretched hand or a direct blow. Chronic overuse injuries should correlate with preceding activity involving a repetitive motion. A history of arthritides may point to a systemic disorder such as lupus, rheumatoid arthritis, or gout.

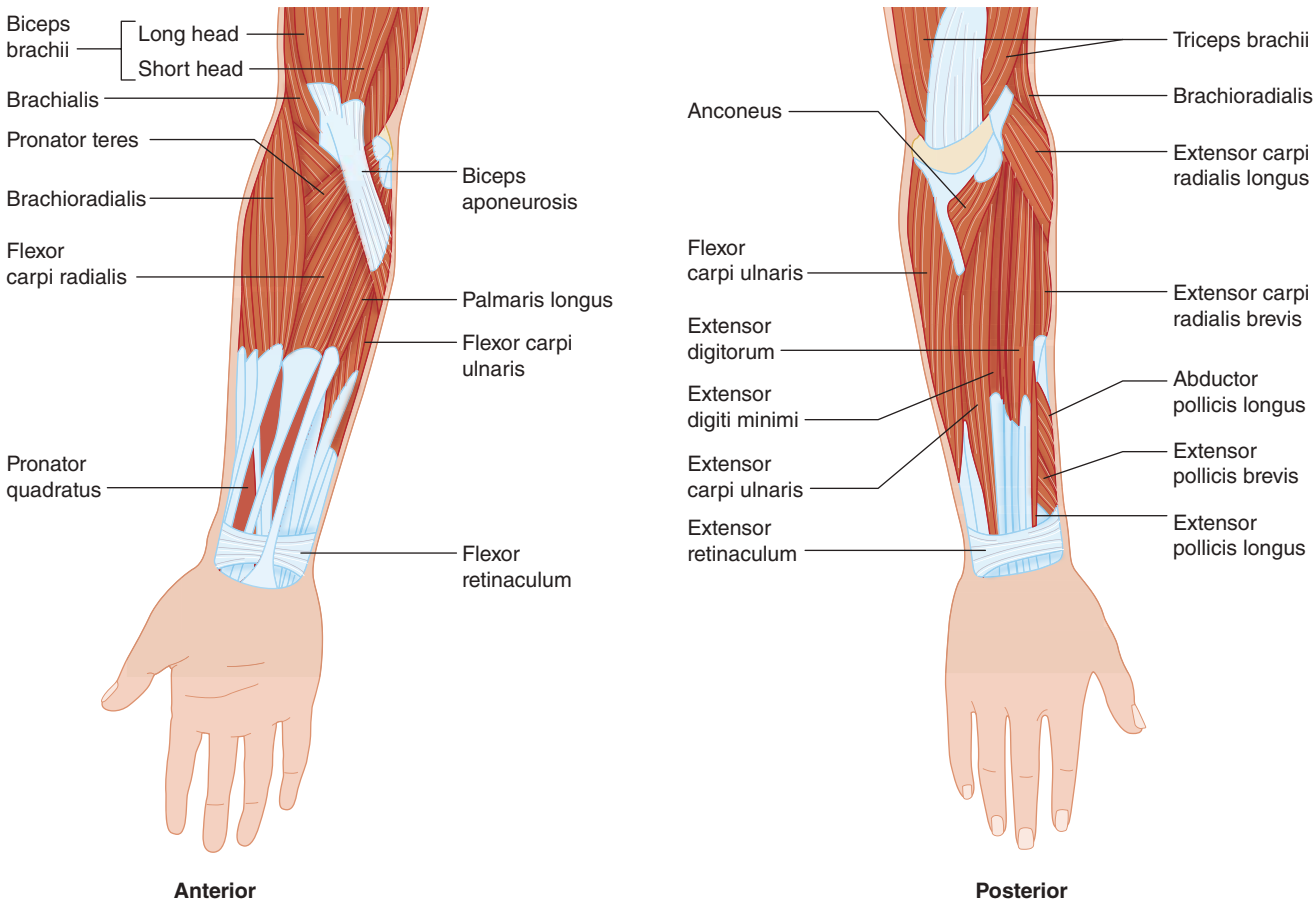

FIGURE 270-5. Intrinsic forearm muscles.

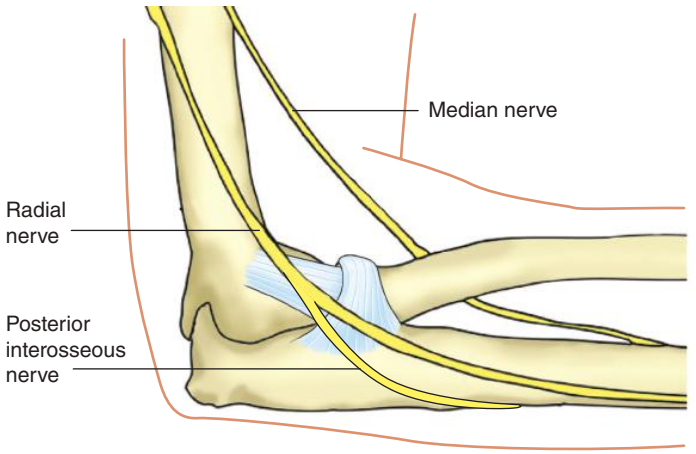

FIGURE 270-6. Posterior interosseous nerve.

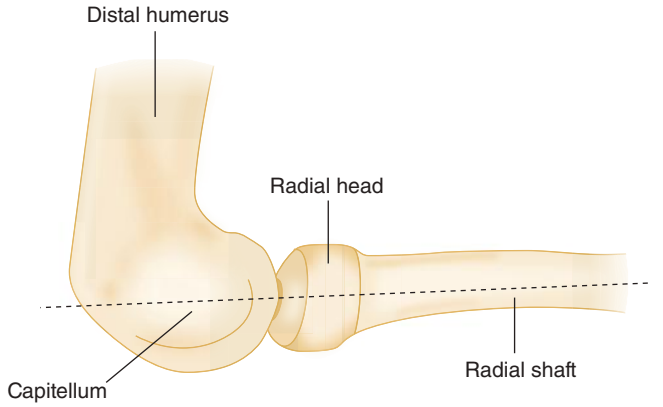

FIGURE 270-7. The radiocapitellar line. On lateral views, a line drawn through the center of the radius transects the radial head and middle third of the capitellum. This relationship is lost even in subtle fractures.

PHYSICAL EXAMINATION

General examination of the elbow and forearm should include inspection for gross deformity, soft tissue swelling such as bursitis, or open wounds. Assess range of motion of the elbow in flexion, extension, pronation, and supination. Inability to fully extend the elbow is correlated with the presence of a fracture.[1] Strength testing against resistance should also include wrist flexion and extension. Carefully assess radial, median, and ulnar nerve function. **The single best test of radial nerve motor function is to have the patient extend both the wrist and fingers against resistance** (Table 270-1). Test sensation with two-point discrimination over the dorsum of the thumb index web space. Evaluate the median nerve by assessing its distal branches. **A simple test of anterior interosseous nerve function is the ability to make a circle, or "OK" sign, with the thumb and index finger.** Abduction of the thumb against resistance (recurrent branch of the median nerve) and sensory testing over the tip of the index finger complete the evaluation of the median nerve**. The easiest way to test ulnar nerve function is to have the patient spread the fingers apart against resistance.** Sensation is tested over the tip of the fifth digit.

DIAGNOSIS

IMAGING

Initial imaging studies should include anteroposterior and lateral views of the elbow, and anteroposterior, lateral, and oblique views of the humerus and forearm. If a distal forearm injury is present, anteroposterior, lateral, and oblique views of the wrist instead of the humerus should be obtained. Attempts to derive a clinical decision rule to guide imaging decisions for the elbow, similar to published ankle and knee imaging rules, have so far produced conflicting data.[1-3]

On lateral films of the elbow, a line drawn straight through the center of the radial shaft should bisect the radial head and capitellum (radiocapitellar line) (**Figure 270-7**). Loss of this relationship should raise suspicion for an occult radius fracture or dislocation. A line drawn straight along the anterior border of the humerus should transect the posterior two thirds of the capitellum (anterior humeral line) (**Figure 270-8**). Abnormal extension of the line through the anterior one third of the capitellum suggests a distal humerus (in adults) or supracondylar fracture (in children). A small anterior fat pad may be a normal finding. Large anterior and any posterior fat pads are always abnormal and indicate the presence of a joint effusion (**Figure 270-9**).

CT imaging provides greater radiographic detail when evaluating certain elbow fractures, particularly coronoid and comminuted intra-articular fractures. MRI is useful in the evaluation of soft tissue injuries such as ligament or tendon ruptures but has limited value in the acute setting. Bedside US can demonstrate effusions and tendon injury but requires operator skill.[4,5]

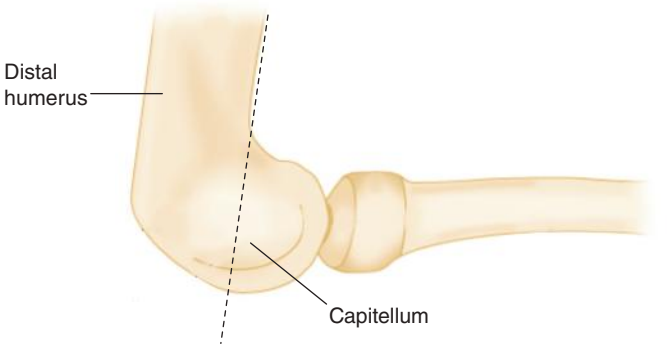

FIGURE 270-8. The anterior humeral line. On lateral views, a line drawn along the anterior cortex of the humerus transects the posterior two thirds of the capitellum. Transection of the line through the anterior one third of the capitellum suggests a fracture.

FIGURE 270-9. Anterior and posterior fat pad signs.

TABLE 270-2 Immobilization and Follow-Up Guidelines

Injury	Splint	Referral
Soft tissue injuries		
Biceps tendon rupture	Sling immobilization	1 wk
Triceps tendon rupture	Sling immobilization	1 wk
Lateral/medial epicondylitis	Forearm counterforce brace	2–4 wk PRN
Elbow dislocation		
Stable/postreduction	Long arm posterior splint, forearm in pronation	1 d
Unstable/postreduction	Long arm posterior splint (presurgical stabilization)	Immediate
Irreducible	Long arm posterior splint (presurgical stabilization)	Immediate
Elbow fractures		
Distal humerus nondisplaced	Long arm posterior splint, forearm neutral	1 wk
Supracondylar	Long arm posterior splint (presurgical stabilization)	Immediate
Intercondylar	Long arm posterior splint, forearm neutral	1–2 d
Lateral condyle/epicondyle		
Nondisplaced	Long arm posterior splint, forearm in supination, wrist extended	1–2 d
Displaced	Long arm posterior splint (presurgical stabilization)	Immediate
Medial condyle/epicondyle		
Nondisplaced	Long arm posterior splint, forearm in pronation, wrist flexed	1-2 d
Displaced	Long arm posterior splint (presurgical stabilization)	Immediate
Articular surface	Long arm posterior splint, forearm neutral	1–2 d
Coronoid		
Nondisplaced or minimally displaced	Long arm posterior splint, elbow past 90 degrees, forearm in supination	1–2 d
Markedly displaced or unstable	Long arm posterior splint (presurgical stabilization)	Immediate
Olecranon	Long arm posterior splint, forearm neutral	<24 h
Radial head		
Nondisplaced	Sling immobilization with early range of motion	1 wk
Displaced or range of motion block	Long arm posterior splint, forearm neutral	<24 h
Forearm fractures		
Both bones		
Pediatric		
Greenstick	Long arm posterior splint	1 wk
Displaced	Long arm posterior splint (prereduction stabilization)	Immediate
Adult		
Nondisplaced	Anteroposterior long arm splint	1 wk
Displaced	Long arm posterior splint (presurgical stabilization)	<24 h
Isolated ulna shaft	Long arm posterior splint, forearm neutral *or* sugar tong splint if stable and nondisplaced	1 wk
Proximal two thirds of radius	Long arm posterior splint, forearm neutral	1 wk
Monteggia's	Long arm posterior splint (presurgical stabilization)	Immediate
Galeazzi's	Long arm posterior splint (presurgical stabilization)	Immediate

TREATMENT

Consult an orthopedic surgeon immediately for open fractures, irreducible dislocations, injuries resulting in a grossly unstable elbow joint, or vascular injury with signs of ischemia or uncontrolled hemorrhage. All other injuries may be referred for follow-up within 1 to 2 days for operative planning or up to a week for nonoperative treatment. **Table 270-2** outlines guidelines for ED immobilization and appropriate orthopedic consult time frames for the conditions discussed in this chapter.

SOFT TISSUE INJURIES

BICEPS TENDON RUPTURE

Of all injuries to the biceps, the vast majority are proximal, and nearly all involve the proximal long head. Injuries are usually the result of repetitive microtrauma and overuse. Steroids, whether injected locally or used systemically, can accelerate the breakdown of tendons. Biceps tendon rupture usually occurs when there is sudden or prolonged contraction against resistance in middle-aged and older individuals with a history of chronic bicipital tenosynovitis. A snap or pop is usually described, and pain is present in the anterior shoulder. Examination of the anterior shoulder will reveal swelling, tenderness, and often crepitus over the bicipital groove. Ecchymosis may extend the entire length of the biceps. **Flexion of the elbow will elicit pain and may produce a midarm "ball," which represents the distally retracted biceps muscle.** Comparing arms for symmetry helps. Loss of strength is minimal due to the function of the brachialis and supinator. Avulsion fractures occasionally occur, so radiographs of the shoulder should be obtained.

ED treatment includes sling, ice, analgesics, and referral to an orthopedic surgeon for definitive care. Surgical repair is usually recommended for young, active patients. A conservative approach with immobilization may be adequate for elderly patients whose activities of daily living are not significantly compromised by the injury.

Distal biceps injuries are less common than proximal injuries.[6,7] Complete ruptures of the tendon are most common in middle-aged men and usually involve the dominant extremity. Partial tears are seen in men and women. Mechanism of injury is typically a sudden eccentric (extension) load applied to a flexed elbow. In ruptures of the distal biceps, pain is felt in the antecubital fossa, with swelling, ecchymosis, and tenderness to palpation noted on examination. A distal rupture is indicated by a palpable defect in the antecubital fossa and a midarm "ball." Strength loss, especially supination, is usually greater than with proximal ruptures. The **biceps squeeze test**, similar to the Thompson test for assessing Achilles tendon rupture, can detect biceps rupture.[8] With the patient seated and the forearm at 60 to 80 degrees of flexion, place one hand on the muscle belly of the biceps brachii and the other hand on the myotendinous junction, and squeeze with both hands. The squeeze should result in forearm supination, indicating an intact biceps. Lack of supination is considered a positive test, indicating rupture of the distal biceps brachii. To perform the **hook test**,[9] flex the patient's elbow to 90 degrees, and during active supination, if the biceps tendon is intact, the examiner can "hook" the index finger under the distal biceps tendon in the antecubital fossa. Obtain elbow radiographs to search for an associated avulsion fracture. Although most complete distal ruptures are diagnosed clinically, MRI and US can aid in confirming the diagnosis of partial tears.[10,11]

ED treatment includes sling, ice, analgesics, and referral to an orthopedic surgeon for definitive care. Without surgical repair of complete ruptures, supination strength is decreased by approximately 50% and flexion strength by almost 30%.[12,13]

TRICEPS TENDON RUPTURE

Injury to the triceps is rare and almost always occurs distally.[14] Ruptures result from either a fall on an outstretched hand causing a forceful flexion of an extended elbow or a direct blow to the olecranon. Spontaneous ruptures from systemic illnesses, particularly hyperparathyroidism and chronic renal failure requiring hemodialysis, have also been reported.[15,16] Triceps rupture usually causes pain in the posterior elbow. Examination of the elbow reveals swelling and tenderness posteriorly just proximal to the olecranon. A sulcus with a more proximal mass, representing the retracted triceps muscle, may be palpated. With partial tears, some degree of function remains; however, **with complete ruptures, the ability to extend the elbow is lost**. A modified Thompson test can be used to evaluate triceps function. The upper extremity is positioned such that the arm is supported and the forearm is hanging in a relaxed position with 90 degrees of flexion. Squeezing the triceps muscle should produce extension of the forearm unless a complete rupture is present. Radiographs of the elbow are needed because avulsion fractures of the olecranon are common. US and MRI may aid in diagnosis, especially of partial tears.

ED treatment includes sling, ice, analgesics, and referral to an orthopedic surgeon for definitive care. Complete ruptures require surgical repair, whereas most partial tears can be treated conservatively with immobilization.

LATERAL EPICONDYLITIS

The lateral epicondyle serves as the origin for wrist and digit extensors and forearm supinators. Lateral epicondylitis, or "tennis elbow," is an overuse syndrome affecting these soft tissues. Although the condition is often seen in tennis players, it can arise as a result of any repetitive movement involving these muscle groups. The diagnosis is made clinically by tenderness over the lateral epicondyle and pain with resisted wrist and digit extension and forearm supination. Treatment is usually conservative, with rest, ice, anti-inflammatory medications, and immobilization, often via a counterforce brace. Physical therapy consisting of forearm stretching and strengthening exercises has been proven to be a useful adjunct in addition to the above.[17,18] Corticosteroid injections can provide short-term relief of symptoms but have been shown to result in higher recurrence rates at 1 year compared to conservative measures.[17,18] Surgery may be indicated for refractory cases.

MEDIAL EPICONDYLITIS

The less common counterpart to lateral epicondylitis is medial epicondylitis ("golfer's elbow"). As with lateral epicondylitis, the diagnosis is made clinically, with tenderness over the medial epicondyle and pain with resisted wrist and digit flexion and forearm pronation, as these are the muscle groups affected. In addition, patients may develop an ulnar neuropathy, given the proximity of the ulnar nerve to the medial epicondyle. Treatment is similar to that of lateral epicondylitis, with rest, ice, anti-inflammatory medications, bracing, and physical therapy.

ELBOW DISLOCATION

The elbow is one of the more stable joints. The muscular attachments, lateral collateral ligament, and medial ulnar collateral ligament augment its inherent stability in the flexion-extension plane. Despite this, dislocations of the elbow are commonly seen and rank third in large-joint dislocations, after glenohumeral and patellofemoral dislocations. Possible fractures of the coronoid process, radial head, medial epicondyle, and olecranon complicate the treatment of elbow dislocations. **The "terrible triad" injury describes an unstable joint consisting of an elbow dislocation coupled with fractures of the radial head and coronoid.** This injury creates an unstable joint and requires surgical repair after initial reduction.

Elbow dislocations include five types: posterior, anterior, medial, lateral, and divergent (**Figure 270-10**). Some dislocations may involve a combination of the above based on the direction of force applied during the injury. **Approximately 90% of all elbow dislocations are posterolateral.**[19] The mechanism of injury is usually due to a fall on an outstretched hand.

Clinically, the patient presents with the elbow in 45 degrees of flexion. The olecranon is prominent posteriorly, and the deformity resembles a displaced supracondylar fracture. If the patient is seen immediately after the injury, the bony landmarks can be identified. Later, however, the swelling may be quite severe, with no possibility of evaluating the injury topographically. **The first priority of care is to assess the neurovascular status of structures most vulnerable to entrapment, namely the brachial artery and the ulnar, radial, and median nerves.** Perform neurovascular examination before and after manipulation, because neurovascular complications (most frequently the ulnar nerve) occur in 8% to 21% of patients. Vascular complications (most frequently the brachial artery) occur in 5% to 13% of elbow dislocations.[20] Absence of a radial pulse before reduction, an open dislocation, and systemic injuries (such as those of the head, chest, and abdomen) are associated with arterial injury.[21,22] If vascular injury is suspected, then angiography may be required to assess the extent of injury and need for repair.

On the lateral radiograph, both the ulna and radius are displaced posteriorly (**Figure 270-11**). In the anteroposterior view, there may be lateral or medial displacement, with the ulna and radius in their normal relationship to each other. Assess for associated fractures, particularly of the coronoid process and radial head. In a child, an associated fracture of the medial epicondyle is common.

Due to the amount of force that is necessary to reduce a dislocated elbow, success is often dependent on adequate analgesia and muscular relaxation. This may require the use of intravenous analgesics or procedural sedation, particularly in children. As an alternative to procedural sedation or intravenous analgesia, anecdotal success has been reported using intra-articular lidocaine to provide regional anesthesia for closed reduction of dislocated elbows, similar to the well-described use of intra-articular blocks for reduction of anterior glenohumeral shoulder dislocations.[23,24] In the elbow, intra-articular lidocaine is effective for postoperative pain control following arthroscopic procedures in adults and supracondylar fracture repairs in children.[25,26] Regardless of the type of analgesia used, ensure appropriate patient comfort prior to attempting closed reduction.

Closed reduction can be accomplished by several methods. In the first two-person reduction technique, position the patient supine and apply gentle longitudinal traction on the wrist and forearm with one hand while an assistant applies a stabilizing countertraction force on the upper

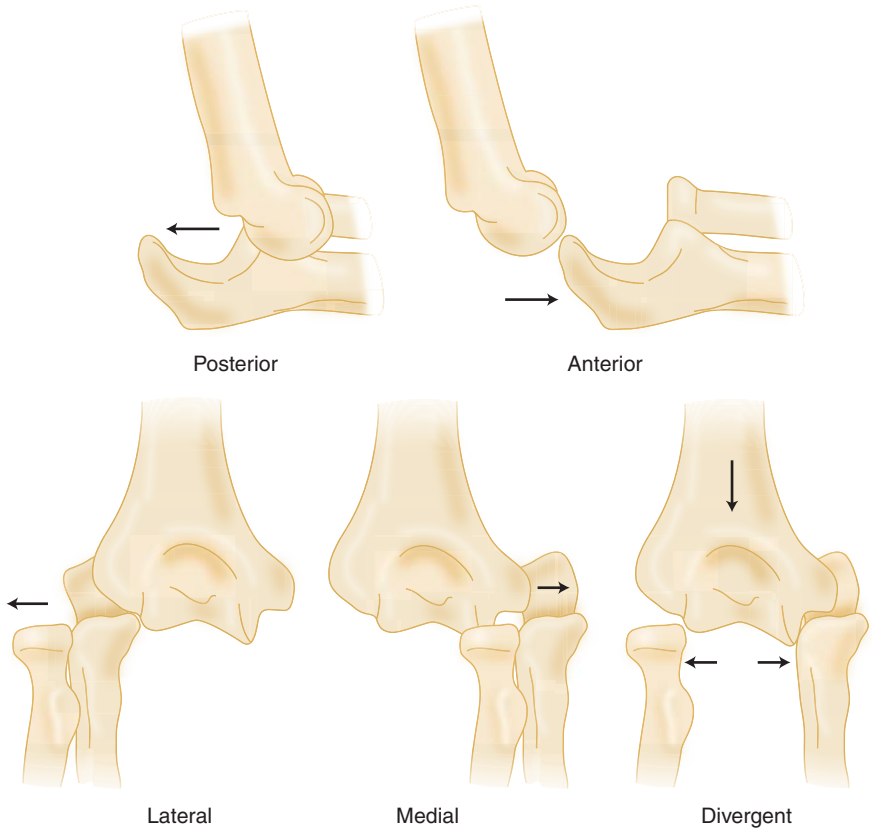

FIGURE 270-10. Elbow dislocations. [Reproduced with permission from Browner BD, Levine AM, Jupiter JB, et al: *Skeletal Trauma: Basic Science, Management, and Reconstruction*, 4th ed. Vol 1. © 2009, Saunders, an imprint of Elsevier Inc., Philadelphia, PA. Figure 42-40, p. 1533.]

arm (**Figure 270-12**). First, correct any medial or lateral displacement with the other hand. Then apply downward pressure to the proximal forearm with the other hand to help disengage the coronoid process from the olecranon fossa. Continue distal traction, and flex the elbow. In the second two-person technique, position the patient prone with the arm abducted and the elbow slightly flexed. The patient may also be positioned supine with the affected arm adducted across the torso and the elbow slightly flexed (**Figure 270-13**). Have an assistant apply longitudinal traction on the wrist and forearm. Then, grasp the elbow, positioning both thumbs on the olecranon, and apply firm pressure against the olecranon to push it up and over the trochlea and back into anatomic position. Apply countertraction with the fingers against the distal humerus. The last technique is a modification of the Stimson hanging technique used in shoulder reductions (**Figure 270-14**). One benefit of this technique is that it can be performed by a single provider. Place the patient prone with the elbow flexed over the edge of the stretcher. Support the humerus proximal to the elbow with a folded blanket or pillow. Suspend 5-lb weights from the wrist. The patient's elbow should reduce over a period of several minutes. Gentle manipulation may be applied to the olecranon to aid reduction.

FIGURE 270-11. Posterior elbow dislocation.

With reduction, a palpable "clunk" is felt as the olecranon is seated in the humeral articular surface (trochlea). Then move the elbow through its full range of motion to assess stability. Inability to maintain reduction through full range of motion necessitates orthopedic consultation for surgical repair. If full and smooth passive range of motion is not possible, examine the postreduction radiograph for entrapment of the medial epicondyle, especially common in children, or other intra-articular fragments. If the elbow remains reduced through full range-of-motion testing, assess medial and lateral stability with gentle valgus and varus stress on the elbow in full extension. Valgus (medial) laxity is more common and suggests disruption of the medial (ulnar) collateral ligament complex, which is the primary stabilizing structure of the elbow joint against valgus forces. Medial instability that stabilizes with 90 degrees of flexion and maximal pronation of the forearm should be splinted in this position and referred for follow-up.[27] Instability that cannot be stabilized with flexion and pronation suggests associated fractures or more significant disruption of the capsule and ligaments. In this case orthopedic consultation for surgical repair is necessary.

After reduction, immobilize stable dislocations in a long arm posterior splint with the elbow in slightly less than 90 degrees of flexion and the forearm in mild pronation. Obtain a neurovascular follow-up examination the following day. Treatment with an early range-of-motion program after 1 week of splinting generally leads to favorable results.

Appropriate treatment of elbow dislocations requires adequate reduction and recognition of neurovascular complications, associated fractures, and postreduction instability. If there is any question of neurovascular

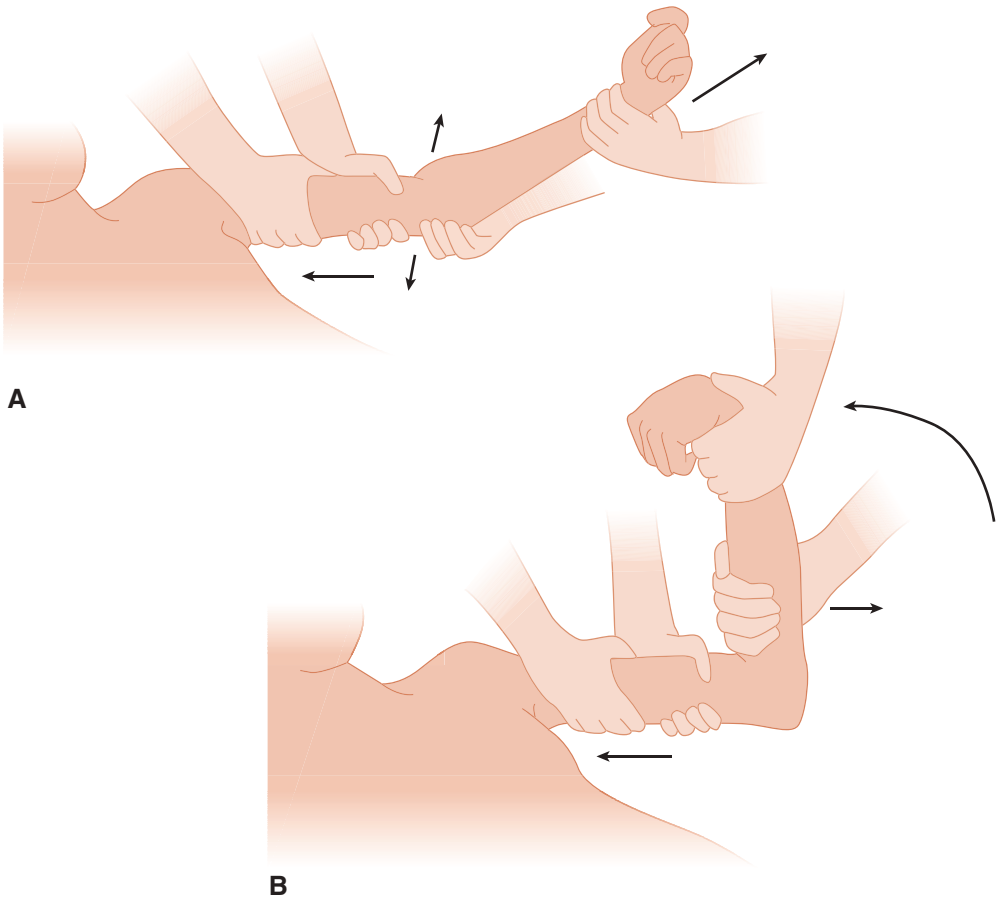

FIGURE 270-12. **A** and **B.** Traction and flexion method of reducing a posterior elbow dislocation. Side-to-side manipulation is used to correct medial or lateral displacement **(A)**. The elbow is then flexed while maintaining longitudinal traction **(B)**.

compromise, then consider admitting the patient for observation. Obtain emergency orthopedic consultation for irreducible dislocations, neurovascular compromise, postreduction instability, associated fractures, and open dislocations. Potential late complications include posttraumatic stiffness, posterolateral joint instability, ectopic ossification, and occult distal radioulnar joint disruption.

FRACTURES ABOUT THE ELBOW

Elbow fractures can be divided into those of the distal humerus, proximal ulna, and proximal radius. The distal humerus includes the condylar structures and the articular surface (trochlea and capitellum). The proximal ulna includes the coronoid process and olecranon, and the proximal radius is essentially the radial head.

Radiographs of fractures about the elbow may reveal abnormal fat pads (Figure 270-9).[28] Normally, a posterior fat pad is not visible, and an anterior fat pad may be visible as a thin lucent stripe. **With injury, fat from the olecranon fossa is displaced posteriorly (posterior fat pad), and the anterior fat pad may become quite prominent ("sail sign") due to hemarthrosis.** Abnormal fat pads may also be seen with nontraumatic joint effusions. Furthermore, they may be absent in severe trauma that disrupts the joint capsule and allows intra-articular fluid extravasation. In some nondisplaced fractures, the fracture line may not be seen, with the fat pad sign being the only evidence of injury. Treatment is initiated as though a fracture were identified, with splint immobilization and orthopedic consultation.

DISTAL HUMERUS FRACTURES

Routine ED care of nondisplaced distal humerus fractures with normal neurovascular function includes immobilization, ice, elevation, analgesics, and orthopedic referral. Displaced fractures or those with neurovascular compromise require immediate orthopedic consultation. See chapter 271, "Shoulder and Humerus Injuries," for a detailed discussion of shoulder and humerus injuries.

SUPRACONDYLAR FRACTURES

Supracondylar fractures are the most common fracture about the elbow in children between 5 and 10 years of age, but can occur in adults, especially as a result of high-velocity injuries. Fractures can be either extension type (>95%), which are displaced posteriorly, or flexion type (<5%), which are displaced anteriorly. Treatment largely depends on the degree of displacement of the distal fragment.

EXTENSION-TYPE SUPRACONDYLAR FRACTURES

Injuries most often occur with a fall on an outstretched hand with the elbow in full extension. The patient will have significant edema and tenderness at the elbow, a prominent olecranon, and a depression proximal to the elbow. The appearance may be easily mistaken for a posterior elbow dislocation. Nondisplaced fractures may be subtle and diagnosed only by the presence of a posterior fat pad, anterior "sail sign," or disruption to the normal path of the anterior humeral line. Initially treat with immobilization using a long arm posterior splint, keeping the elbow at 90 degrees of flexion and the forearm in neutral rotation, followed by outpatient referral for casting. The presence of >20 degrees of angulation necessitates orthopedic consultation for reduction under anesthesia and possible pin fixation.[29] In displaced fractures, the anteroposterior radiograph usually reveals a transverse fracture line. More severely displaced fractures may show medial or lateral displacement or rotation along the axis of the humerus (**Figure 270-15**). The lateral radiograph will reveal the fracture line extending obliquely from posterior proximal to anterior

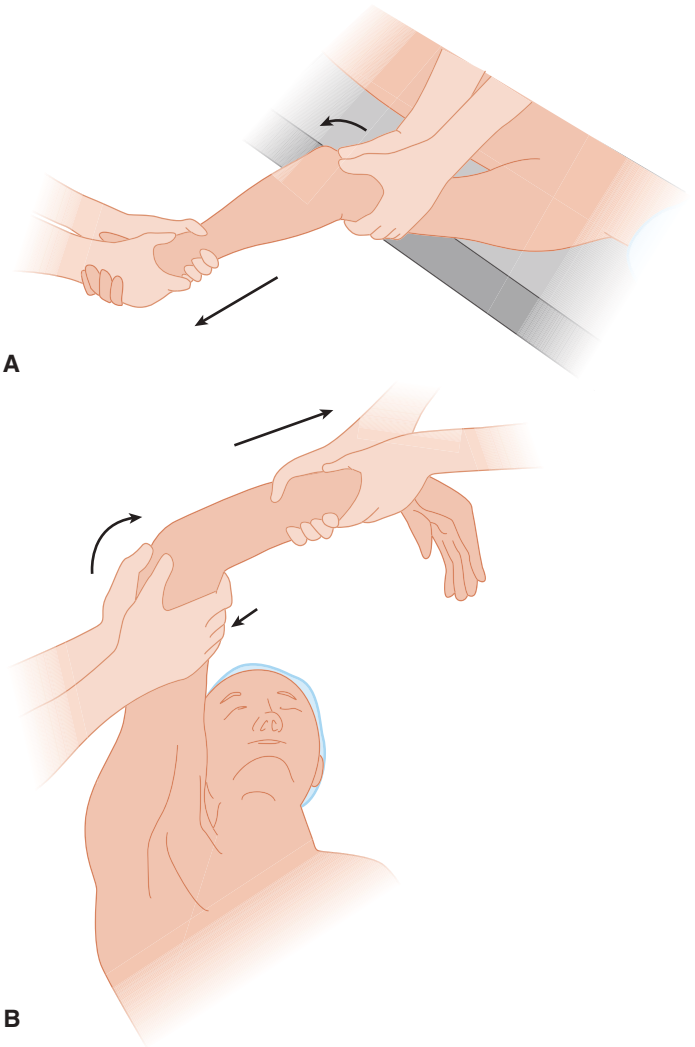

FIGURE 270-13. **A** and **B.** Olecranon manipulation method of reducing a posterior elbow dislocation with the patient positioned prone (**A**) or supine (**B**).

FIGURE 270-15. Extension-type, displaced supracondylar fracture.

distal. The distal fragment will be displaced proximally and posteriorly. **Displaced fractures must be reduced and require orthopedic consultation.** Indications for open reduction are vascular insufficiency with a probable entrapped brachial artery in the fracture site or an irreducible fracture. Admit patients with displaced fractures or significant soft tissue swelling for observation of neurovascular function.

FLEXION-TYPE SUPRACONDYLAR FRACTURES

Flexion-type fractures are rare. The mechanism of injury is a direct anterior force against a flexed elbow, resulting in anterior displacement of the distal fragment. Because the mechanism is direct force, these fractures are often open. Radiographs reveal an oblique fracture from anterior proximal to posterior distal. The distal fragment is anterior to the humerus. Displaced fractures must be reduced and require immediate orthopedic consultation. Indications for open reduction are vascular insufficiency with a probable entrapped brachial artery in the fracture site or an irreducible fracture. Admit patients with displaced fractures or significant soft tissue swelling for observation of neurovascular function.

COMPLICATIONS OF SUPRACONDYLAR FRACTURES

There are numerous potential complications of supracondylar fractures (**Table 270-3**). Neurologic complications—resulting from traction,

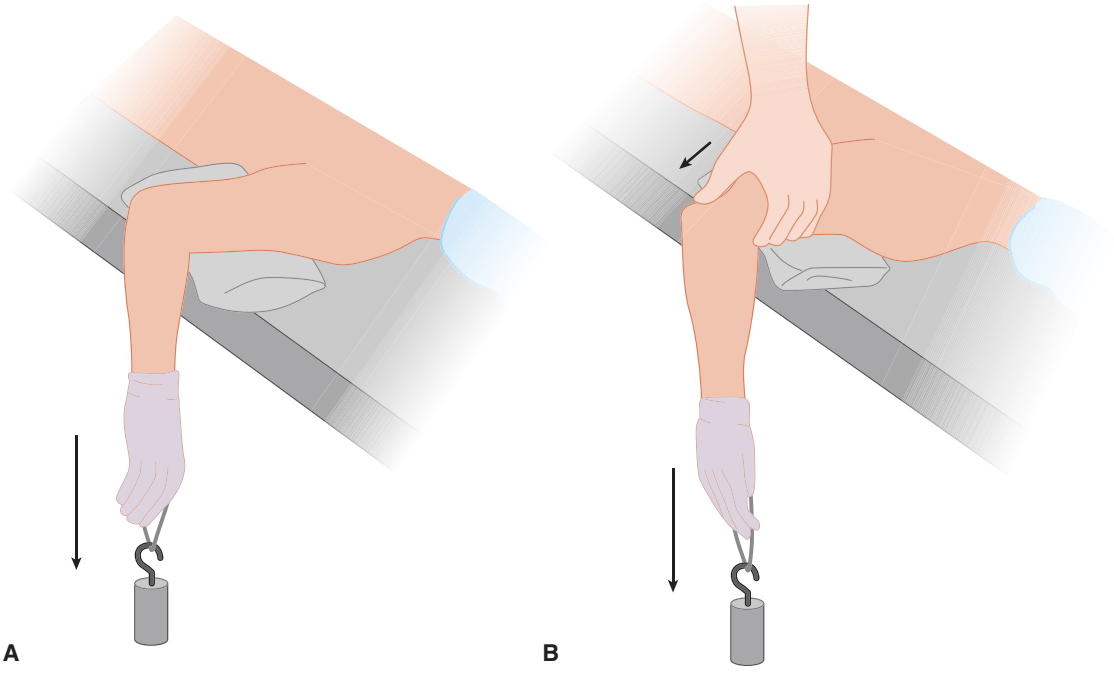

FIGURE 270-14. **A.** Hanging arm method of reducing a posterior elbow dislocation. **B.** Gentle manipulation can be applied to the olecranon if necessary.

TABLE 270-3 Complications of Supracondylar Fractures

Late complications	Nonunion Malunion Myositis ossificans Loss of motion

direct trauma, or nerve ischemia—have an incidence of 7%. **Posteromedial displacement may involve the radial nerve, and posterolateral displacement usually affects the median nerve.** Ulnar nerve injuries are uncommon, with the highest incidence reported from pin placement. However, **a high incidence has been noted of anterior interosseous nerve injuries with supracondylar fractures**. This nerve arises from the median nerve. The mechanism of injury is usually traction or contusion. Complete transection is rare, and entrapment within the fracture occurs only occasionally. **Because there is no sensory component to the anterior interosseous nerve, identification of the injury can be made only by motor testing, which consists of flexion at the index finger distal interphalangeal and thumb interphalangeal joints (making the "OK" sign).** Patients usually regain full flexion and strength after 4 to 17 weeks.[30]

Acute vascular injuries must always be suspected in patients with supracondylar fractures. Absence of a radial pulse is common in children and, in the majority of published cases, is an indicator of brachial artery injury, even if the hand appears warm, pink, and well perfused.[31] Injury can be due to a partial or complete transection, an intimal tear and thrombosis, or entrapment within the fracture fragment of the brachial artery. Treatment of supracondylar fractures with absent radial pulse begins with closed reduction and percutaneous pinning. Extremities still without a pulse despite adequate reduction warrant more aggressive vascular exploration and repair.

The most serious complication is a compartment syndrome of the forearm, also known as *Volkmann's ischemic contracture*. This classically occurs following a supracondylar fracture. Postischemic swelling, producing increased pressure within the enclosed osteofascial forearm compartment, reduces capillary blood perfusion below the level necessary for tissue viability. If unrelieved, the end result is muscle and nerve necrosis and eventual replacement by fibrotic tissue, producing a contracture. Refusal to open the hand in children, pain with passive extension of the fingers, and forearm tenderness are signs of impending Volkmann's ischemia. **It is now well understood that the mere lack of a radial pulse does not indicate ischemia unless accompanied by these signs.** Extremities with signs of ischemia are taken emergently to the operating room for fasciotomy and brachial artery exploration.

INTERCONDYLAR FRACTURES

Intercondylar fractures, in which the condylar fragments are separated, are much more common in adults than in children. Assume any distal humerus fracture in an adult to be intercondylar rather than supracondylar. The mechanism of injury is a force directed against the posterior elbow, driving the olecranon against the humeral articular surface, separating the condyles and producing the typical fracture. Carefully search for a fracture line separating the condyles from each other and from the humerus. By definition, all intercondylar fractures involve the articular surface. CT imaging is useful for identifying comminuted fractures and for planning operative therapy for displaced fractures. Treatment is dependent on the amount of displacement of the fracture fragments.

Nondisplaced intercondylar fractures are stable and can be treated initially with immobilization in a long arm posterior splint with the elbow flexed at 90 degrees and the forearm in neutral position. Treatment of displaced, rotated, or comminuted fractures is often directed at reestablishing articular surface congruity. If this cannot be achieved by closed methods, then the integrity of the articular surface is restored by an open reduction and fixation. In older patients with severely comminuted injuries, elbow replacement may be considered.[32] As in supracondylar fractures, admit patients with severe edema or displaced fractures.

EPICONDYLE FRACTURES

Lateral epicondyle fractures almost never occur, because the anatomic position of the condyle reduces its exposure to direct blows, resulting instead in fractures of the lateral condyle. When they do occur, lateral epicondyle fractures are usually avulsion fractures and may be treated by long arm posterior mold, with the elbow flexed to 90 degrees and the forearm in supination, and orthopedic referral.

Isolated medial epicondyle fractures are considered extra-articular injuries and usually occur in children and adolescents. Mechanisms include a posterior elbow dislocation, repeated valgus stress, such as throwing a baseball (Little League elbow), or a direct blow. If there is an associated tear of the medial (ulnar) collateral ligament, the epicondyle itself may become entrapped in the joint space. Patients present with pain over the medial elbow that is exacerbated by supination of the forearm and flexion of the forearm, wrist, and digits. Edema and tenderness are noted in the same area. Standard radiographs are obtained with special attention to any intra-articular fragment. Carefully test ulnar nerve function. Nondisplaced or minimally displaced medial epicondyle fractures can be treated nonoperatively, with early range of motion. There is an increasing trend toward operative treatment for these fractures due to significantly increased odds of bony union with fixation.[33] Open fractures, unstable joints, fragment displacement >5 mm, and an intra-articular fragment are well-described indications for surgical treatment with internal fixation. ED treatment consists of long arm posterior splint immobilization, with the forearm in flexion and pronation, and orthopedic referral.

Complications of lateral and medial epicondyle fractures are frequent and include nonunion, cubitus valgus or varus deformity, ulnar nerve palsy, and avascular necrosis.[34] Careful neurovascular assessment is required for these injuries. Because surgical treatment is generally preferred, orthopedic consultation is recommended for both lateral and medial epicondyle fractures.

CONDYLE FRACTURES

Lateral condyle fractures occur in children and are more common than their medial counterpart.[35] Lateral condyle fractures result from a direct blow to the lateral elbow or from varus stress with the forearm extended, as in a fall on an outstretched hand. Patients complain of pain in the lateral elbow, and swelling is noted in the same area.

Medial condyle fractures are uncommon and are mostly limited to children. Mechanism of injury is from either a transmitted force from the ulna, such as a fall on an outstretched hand, or excessive valgus stress. Pain and swelling medially are prominent findings. The injury is often confused with the more common medial epicondyle fracture for two reasons. First, the mechanism and examination findings are similar. Second, because the trochlea ossification center does not appear until age 9 to 10 years old, it is often missed on radiographs.

ED care of nondisplaced lateral and medial condyle fractures with normal neurovascular function includes long arm posterior splint immobilization, ice, elevation, analgesics, and orthopedic referral. Follow-up imaging every 2 weeks is recommended due to the risk of late displacement, which is treated with surgical fixation. Displaced fractures or those with neurovascular compromise require immediate orthopedic consultation. Complications include malunion with resultant cubital valgus or varus deformity, delayed ulnar nerve injury, and arthritis.

ARTICULAR SURFACE FRACTURES

TROCHLEA FRACTURES

Isolated trochlea fractures are rare, and they are more often associated with other elbow injuries, such as posterior elbow dislocations. Physical findings usually include swelling, tenderness, and limited movement of the elbow joint. Radiographic findings can be subtle, and CT or MRI may be required for diagnosis. ED treatment includes long arm posterior splint immobilization and orthopedic consultation because this is an articular surface injury and surgical repair is usually indicated. Complications are common and include limited flexion and extension, elbow joint instability, avascular necrosis, nonunion, and arthritis.

CAPITELLUM FRACTURES

Isolated capitellum fractures are rare. They are usually associated with radial head fractures. Pain and tenderness are present over the lateral elbow, and examination reveals swelling, lateral tenderness, and limitation of flexion and extension. If pain and tenderness are present medially, then suspect injury to the medial collateral ligament. Radiographic findings may be subtle and are best seen on a lateral view. The capitellum has no tendinous or ligamentous attachments, so many fractures are nondisplaced. A radial head–capitellum view can be helpful in addition to standard anteroposterior and lateral views. CT imaging is useful for diagnosis. ED treatment is similar to that of trochlea fractures. Definitive care is surgical, and complications are similar to those of trochlea fractures.

PROXIMAL ULNA FRACTURES

The distal humerus articulates with the proximal ulna to form a uniaxial hinge joint, which allows flexion and extension of the forearm and provides some intrinsic stability. The trochlea of the humerus rests in the greater sigmoid (semilunar) notch of the ulna. The anterior projection of the notch is the coronoid, and the posterior prominence, which is easily palpable, is the olecranon. The brachialis muscle inserts at the coronoid, and the triceps muscle inserts at the olecranon. Nearly all proximal ulna fractures are considered intra-articular, with the exception of a proximal olecranon chip fracture.

CORONOID FRACTURES

Coronoid fractures are usually associated with posterior elbow dislocations as the trochlea is driven into the coronoid. A coronoid fracture can rarely occur as an isolated injury secondary to elbow hyperextension.[36] There is pain, swelling, and tenderness over the antecubital fossa. Radiographic visualization is best with lateral and oblique films. Often CT is needed to make the diagnosis.

ED treatment should include long arm posterior splint immobilization with the elbow in flexion and the forearm in supination, ice, elevation, analgesics, and referral to an orthopedic surgeon within 24 hours. Conservative treatment of nondisplaced coronoid fractures remains controversial, and early orthopedic referral is indicated. Displaced fractures or those associated with joint instability require open reduction and internal fixation and frequently have poor outcomes.

OLECRANON FRACTURES

The olecranon is usually fractured by direct trauma or by a fall with forced hyperextension of the elbow. Olecranon fractures are quite common and represent up to 10% of upper extremity fractures.[37] Associated injuries are common, including open fractures, dislocations, other fractures (especially of the radial head), and ulnar nerve injury. Pain is present over the posterior elbow, and examination reveals swelling, tenderness, and occasionally crepitus. Because the triceps muscle inserts at the olecranon, triceps function is usually compromised. It is important to test forearm extension against resistance, as the patient may falsely appear to have intact forearm extension by using gravity to draw the forearm down. Ulnar nerve injury is common; therefore, a careful neurologic examination is required. Lateral radiographs offer the best view of the olecranon. In adolescents, the epiphysis ossifies by age 11 years old and fuses by age 16 years old, so comparison films and the appearance of an abnormal fat pad can aid in the diagnosis. ED treatment includes long arm posterior splint immobilization with the elbow in flexion and forearm neutral, ice, elevation, analgesics, and referral to an orthopedist within 24 hours. Stable, nondisplaced fractures with intact extensor function can be treated conservatively with immobilization. Nonoperative treatment may also be considered for poorly functioning elderly patients who would not tolerate surgery. All other olecranon fractures require surgical repair.[38]

RADIAL HEAD FRACTURES

The radial head is located just distal to the lateral epicondyle. Pronating and supinating the forearm with the elbow flexed allows the examiner to palpate the radial head. It articulates with the capitellum and the lesser sigmoid notch of the ulna to form a pivot joint. The radial head serves as a stabilizer of the elbow against valgus stress, along with the medial collateral ligament, and against longitudinal forces.

Radial head fractures are the most common fractures of the elbow. They result from a fall on an outstretched hand causing the radial head to be driven into the capitellum. **Associated injuries are common and may include capitellum, olecranon, and coronoid fractures, medial collateral ligament injury, medial epicondyle avulsion fracture secondary to valgus stress, and elbow dislocation.** A specific associated injury, the Essex-Lopresti lesion, occurs when there is disruption of the triangular fibrocartilage of the wrist and the interosseous membrane between the radius and ulna, causing pain in the wrist and forearm. The result is a distal radioulnar joint dissociation, which can cause migration of the radius proximally if radial head excision is performed. Open reduction and internal fixation of the proximal radius fracture is indicated for this injury.

Radial head fractures cause pain in the lateral elbow, especially with pronation and supination of the forearm. On examination, there may be swelling laterally and tenderness with palpation of the radial head. On standard elbow radiographs, radial head fractures may be subtle (**Figure 270-16**). Additional images, including obliques and a radial head–capitellum view, may be helpful. Furthermore, two radiographic clues can aid in the diagnosis. The first is abnormal displacement of the radiocapitellar line away from the center of the capitellum (Figure 270-7). This is especially helpful in children whose epiphysis has not fused. The other clue is the appearance of an abnormal fat pad (Figure 270-9).

Nondisplaced fractures with no mobility restrictions can be treated conservatively with immobilization. For these, ED treatment consists of sling immobilization with the elbow in flexion, ice, elevation, analgesics, and referral to an orthopedic surgeon within 1 week. Consider aspiration of the joint hematoma in the ED to improve pain and facilitate early mobilization.[39] Additional pain control may be obtained with intra-articular injection of lidocaine or bupivacaine following aspiration, but this does not offer any long-term benefit over aspiration alone.[40] For displaced fractures or those with restricted range of motion, surgical repair is generally indicated, and orthopedic referral within 24 hours is needed. Complications of radial head fracture include chronic pain and restricted range of motion at the elbow.

FOREARM FRACTURES

In adults, solitary fractures of the forearm are uncommon due to the close relationship of the radius and ulna. The fibrous interconnection between the radius and ulna transmits traumatic energy above and below the injury. So, fractures usually occur at two or more sites or involve a fracture of one bone with a ligamentous injury, with or without an associated joint dislocation. Because distant structures are commonly injured, examine joints above and below the involved bones both clinically and radiologically. Be especially observant for associated injuries if there is significant angulation of the fracture.

FIGURE 270-16. Subtle radial head fracture and anterior fat pad sign (*arrow*).

The radius and ulna are under the influence of numerous muscle groups, such as those that supinate and pronate (Figure 270-5). The biceps brachii and the supinator insert on the proximal radius and are the powerful supinators of the forearm. The pronator teres inserts on the radial shaft and exerts a pronating force. Radius fractures that are located between these muscle groups will result in marked displacement of the radius, with supination of the proximal segment and pronation of the distal portion. However, if the fracture is distal to the insertion of the pronator teres, these forces tend to neutralize one another and result in less rotational deformity. When considering treatment of these fractures, careful attention must be paid to the maintenance of length, alignment, and angulation. Also, the lateral bow of the radius must be preserved to allow full pronation and supination after healing.

FRACTURES OF BOTH RADIUS AND ULNA

A great amount of force is necessary to fracture both the radius and the ulna. This injury occurs most often from vehicular trauma, falls from a height, or a direct blow. Force magnitude determines injury type. Moderate forces produce transverse or mildly oblique fractures. High-impact forces produce comminuted and segmental fractures (often displaced).

Nondisplaced fractures of both bones are exceedingly rare because the force necessary to produce the injury is also sufficient to displace the bones. Examination of the forearm reveals swelling, deformity, and tenderness. Carefully assess the neurovascular status. Nerve injuries can be seen with severe open fractures but are uncommon with most closed injuries. Because of the excellent collateral circulation of the forearm, vascular compromise is generally not a major problem if either the radial or ulnar circulation is intact.

The fractures are clearly visible on the radiographs. Note the degree of angulation, displacement, and shortening. Changes in rotational alignment may be subtle. Noting the normal orientation of various bony prominences of these bones can make a rough estimate of rotational alignment. On the anteroposterior view, the radial styloid and radial (bicipital) tuberosity normally point in opposite directions, whereas the ulnar styloid and coronoid process do so on the lateral view. A change in this arrangement suggests rotation malalignment. Because these bones are also oblong rather than circular in their cross-sectional appearance, a sudden change in the bone's width at the fracture site is another clue to a rotational deformity. Obtain radiographs of the wrist and elbow because of the likelihood of an associated dislocation or articular fracture.

Treatment depends on the type of fracture. Torus or greenstick fractures with minimal angulation in children can be treated with immobilization in a long arm splint. Angulation >15 degrees warrants referral for closed reduction. In younger children, treat displaced fractures with closed reduction and cast immobilization due to the continued remodeling that occurs after fracture healing. Perform closed reduction urgently in the ED by an orthopedic consultant to ensure appropriate alignment. Surgical intervention is becoming increasingly popular, although there is a lack of evidence showing improved outcomes from surgery over conservative management.[41,42] Nondisplaced fractures in adults can be immobilized with a long arm splint and referred for urgent follow up. All other fractures in adults require operative reduction and internal or external fixation, ideally within 24 to 48 hours.

Complications include reduced ability to supinate and pronate, osteomyelitis, nonunion, malunion, neurovascular injury, and compartment syndrome. **Recognizing the development of a compartment syndrome is particularly important to prevent debilitating ischemic or Volkmann's contractures of the forearm.** The diagnostic findings are palpable induration of the area, pain with passive movement of the fingers, and pain disproportionate to the physical findings. Loss of radial pulse is often a late finding, and presence of a radial pulse does not exclude compartment syndrome. Direct measurements of elevated compartment pressures confirm the diagnosis. Urgent fasciotomy is required, ideally within 8 hours of the onset of symptoms.

ULNA FRACTURES

ISOLATED ULNA FRACTURE (NIGHTSTICK FRACTURE)

Isolated fractures of the ulna most often result from direct blows to the forearm. A fracture resulting from the natural response to raise the forearm in defense of a blow from a club is referred to as a *nightstick fracture*. Nondisplaced fractures are immobilized in a splint and closely followed for subsequent displacement. A short arm cast is preferable to a long arm cast for treatment.

Fractures with >50% displacement, with >10% angulation, or that involve the proximal third of the ulna are considered unstable.[43] Obtain orthopedic consultation for unstable fractures. Open reduction and internal fixation with a compression plate and screws are necessary to prevent angulation, loss of length, and rotational deformity. Assess injuries for any possible radius fracture or dislocation.

MONTEGGIA'S FRACTURE-DISLOCATION

Fracture of the proximal third of the ulna with a radial head dislocation is often referred to as *Monteggia's fracture-dislocation* (**Figure 270-17**). The associated radial head dislocation may be easily missed.[44] **Missing the radial head dislocation can lead to chronic pain, limited range of motion, and, possibly, radial head excision as treatment.** Monteggia's fractures can occur following a fall onto an outstretched hand or a direct blow. The most typical injury pattern seen is a diaphyseal fracture in the proximal third of the ulna with an anterior dislocation of the radial head (60% of cases). Clinically, there is considerable pain and swelling at the elbow. The radial head may be palpable in an anterolateral or posterolateral location. The forearm may appear shortened and angulated. The ulnar fracture is clearly visible and may overshadow the less obvious radial head dislocation. As a rule, the radial head normally points to the capitellum in all radiographic views of the elbow. In a Monteggia's fracture, the apex of the ulna fracture points in the direction of the radial head dislocation.

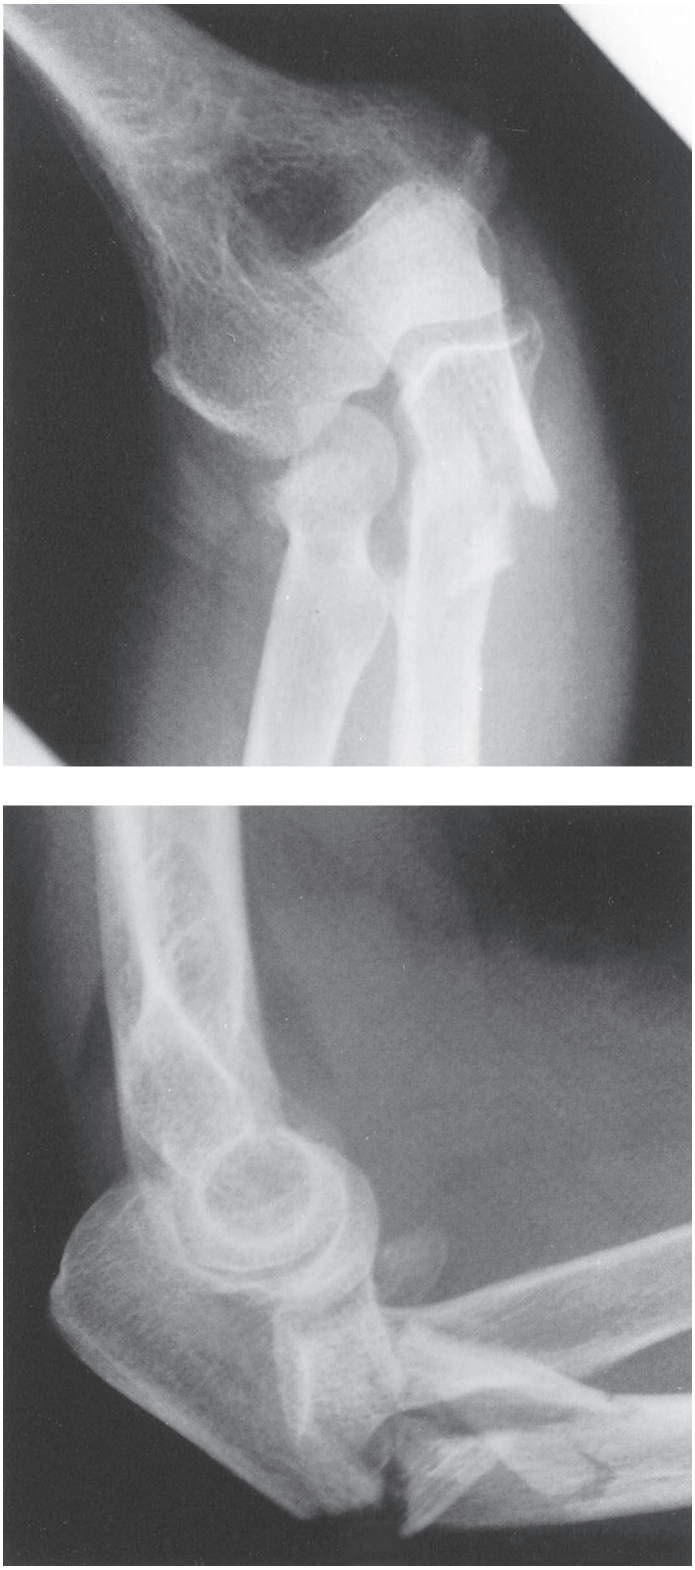

FIGURE 270-17. Monteggia's fracture-dislocation. The angulation of the comminuted fracture of the proximal ulna points in the direction of the radial head dislocation.

Obtain consultation with an orthopedic surgeon. Monteggia's fracture-dislocations are generally treated with open reduction and internal fixation of the ulna and closed reduction of the radial head dislocation. In children, the injury may be treated with closed reduction and long arm splinting. Complications include nonunion, recurrent dislocation, chronic pain, infection, and paralysis of the posterior interosseous nerve, a deep branch of the radial nerve.

RADIUS FRACTURES

FRACTURES OF THE PROXIMAL TWO THIRDS OF THE RADIUS

Radius fractures can be divided into those that are proximal and those that are distal to the junction of the middle and distal thirds of the bone. Excluding radial head fractures, isolated fractures of the proximal two thirds of the radius are uncommon because the radius is relatively well protected from direct blows by the ulna and surrounding forearm musculature. Nondisplaced fractures are rare and treated with cast immobilization. Fractures of the proximal two thirds of the radius are often displaced by both the force of the injury and the action of the supinators and pronators on the radius. They require internal fixation to prevent rotational deformity. Compartment syndrome is rare with these fractures. Most complications involve malunion or nonunion because of inadequate or lost reduction.

GALEAZZI'S FRACTURE-DISLOCATION

Fractures of the distal third of the radial shaft are produced by falls on the outstretched hand in forced pronation or by a direct blow. The radius, generally the distal third, is fractured along with a dislocation of the distal radioulnar joint. Galeazzi's fracture is often referred to as the *reverse Monteggia's fracture*. There is localized tenderness and swelling over the distal radius and wrist. The radius fracture is usually short oblique or transverse with dorsal lateral angulation. The distal radioulnar joint injury can be subtle. Radiographs may show only a slightly increased distal radioulnar joint space on the anteroposterior view. On the lateral view, the ulna is displaced dorsally. This injury is treated surgically by open reduction and internal fixation of the radius fracture. Complications include infection, nonunion, and malunion. Injuries to the ulnar nerve and anterior interosseous branch of the median nerve have been reported but usually heal spontaneously. If the radius heals with a rotational deformity, there may be pain at the distal radioulnar joint with extreme pronation and supination.

CHAPTER 271

Shoulder and Humerus Injuries

Lars Petter Bjoernsen
Alexander Ebinger

STERNOCLAVICULAR SPRAINS AND DISLOCATIONS

ANATOMY

The sternoclavicular joint contains an intra-articular fibrocartilaginous disc and has the least amount of bony stability of any major joint because less than half of the medial end of the clavicle articulates with the upper sternum. However, it is remarkably stable, due to the strong surrounding ligaments, and as a result, most injuries are simple sprains, while dislocations and fractures are uncommon.[1-3]

The medial clavicular epiphysis is the last epiphysis of the body to appear radiographically (age 18 years old) and the last to close (age 22 to 25 years old). An apparent sternoclavicular joint dislocation in children and young adults is typically a Salter-Harris type I or II fracture, with

either anterior or posterior displacement of the clavicular metaphysis that requires orthopedic consultation and follow-up for optimal healing and remodeling.[1,4]

CLINICAL FEATURES

A **posterior dislocation** results from a direct blow or from an indirect force to the shoulder, causing the shoulder to roll forward at the time of impact. An **anterior dislocation** may result from a similar indirect force if the shoulder is rolled backward at the moment of impact.

The major symptom is severe pain, exacerbated by arm motion and lying supine. The shoulder may appear shortened and rolled forward. On examination, anterior dislocations have a prominent medial clavicle end that is visible and palpable anterior to the sternum, although swelling and tenderness may impede diagnosis. In posterior dislocations, the medial clavicle end is less visible and often not palpable, and the patient may have signs and symptoms of impingement of the superior mediastinal contents, such as stridor, dysphagia, and shortness of breath (**Figure 271-1**).[3] Minor trauma, on the other hand, may result in a sprain to the sternoclavicular joint with only pain and swelling localized to the joint.

DIAGNOSIS

Routine radiographs have a low sensitivity for the detection of dislocation, but immediate chest x-ray is needed to exclude a pneumothorax, pneumomediastinum, and hemopneumothorax. Special views and comparison with the other clavicle may be helpful.[1] CT is the imaging procedure of choice (**Figure 271-2**) and is recommended in any posterior dislocation with concern for injury to the mediastinal structures. IV contrast may be administered to further delineate injury. US can identify sternoclavicular joint effusions.

STERNOCLAVICULAR SPRAIN

Sprains of the sternoclavicular joint are treated with ice, sling, and analgesics. In a nontrauma patient, pain at the sternoclavicular joint should raise suspicion for septic arthritis, especially in injection drug users. US can detect effusion and aid in joint aspiration.

ANTERIOR STERNOCLAVICULAR DISLOCATIONS

Patients with uncomplicated anterior dislocations may be discharged without an attempted reduction, because this injury has little or no impact on function. Clavicular splinting, ice, analgesics, sling, and orthopedic referral are required.

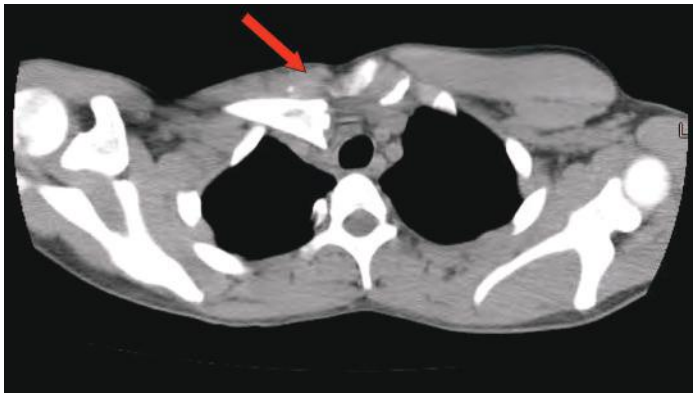

FIGURE 271-2. CT scan of right posterior sternoclavicular dislocation. Arrow indicates disrupted sternoclavicular joint with posterior displacement of clavicle and compression of adjacent lung.

For closed reduction, which can be performed within 10 days of the injury, the patient is placed supine with a towel roll or similar between the scapulae. The arm is abducted to 90 degrees, longitudinal traction is applied with slight extension by moving the arm toward the ground, and pressure is placed over the medial end of the clavicle.[5] Even with reduction, the joint is usually unstable and redislocates (50%) when pressure is released.

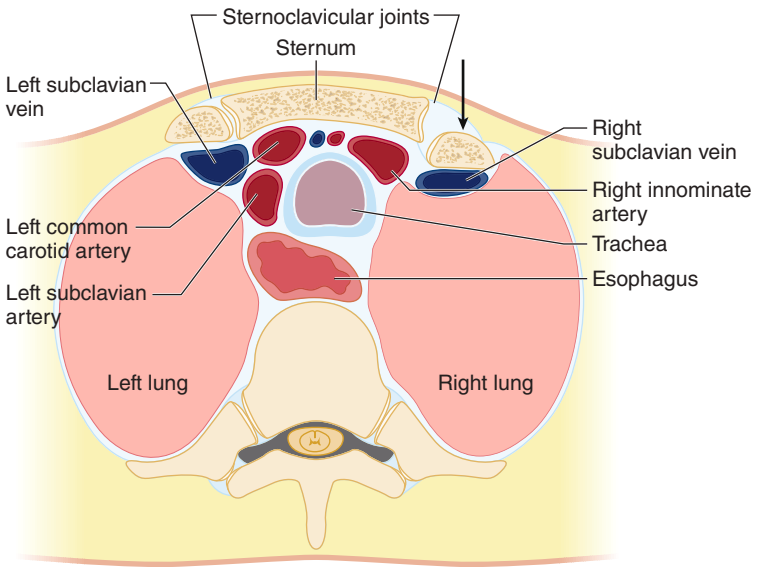
POSTERIOR STERNOCLAVICULAR DISLOCATIONS

Posterior dislocations may be associated with life-threatening injuries to adjacent structures, including pneumothorax or compression or laceration of surrounding great vessels, trachea, or esophagus.[1,2] Orthopedic consultation is necessary for closed or open reduction. Open reduction should be performed in the operating room with trauma or vascular surgery available.[1,3,5]

CLAVICLE FRACTURES

ANATOMY

The clavicle provides support and mobility for upper extremity tasks by functioning as a strut that connects the shoulder girdle to the trunk. It



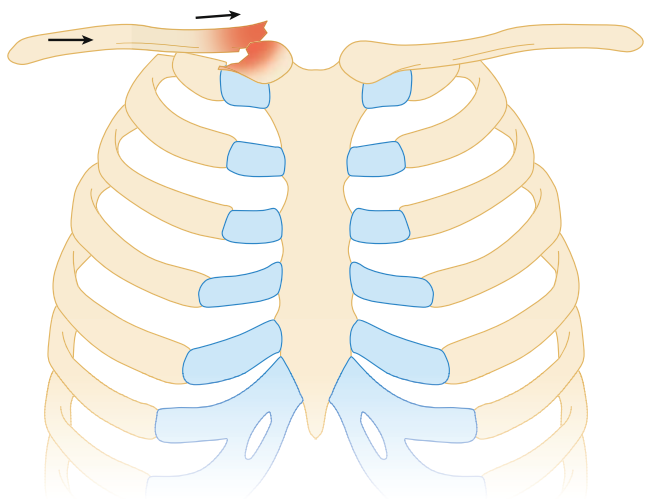


FIGURE 271-1. Posterior sternoclavicular joint dislocation impinging on the mediastinal structures.

articulates with the sternum proximally and the acromion distally. In addition, the clavicle protects the adjacent lung, brachial plexus, and subclavian and brachial blood vessels. The clavicle is S-shaped, and the mid-portion of the clavicle is the thinnest, having no accompanying ligamentous or muscular attachments. Fracture results from a direct blow to the shoulder, buckling the clavicle.

CLINICAL FEATURES

Clinical signs are swelling, deformity, and tenderness overlying the clavicle. The arm is slumped inward and downward, and range of motion is limited. The fracture can often be palpated, and crepitus may be present.

DIAGNOSIS

Most clavicle fractures can be diagnosed on standard shoulder and clavicle x-rays. Occasionally, routine clavicle radiographs may miss some fractures, particularly at either end of the bone, due to overlap of surrounding structures. If a fracture is clinically suspected but not initially diagnosed with standard radiographs, a 45-degree cephalad tilt view may be used for further assessment. Definitive diagnosis may require CT.

Obtain emergent orthopedic consultation for open fractures, fractures with neurovascular injuries, and fractures with persistent skin tenting.

MIDDLE THIRD CLAVICLE FRACTURES

Fractures of the middle third of the clavicle are most common. Although midclavicular fractures are often managed nonoperatively, operative fixation may result in improved functional outcome and a lower rate of malunion and nonunion.[6-8] Some fractures (**Table 271-1**), including severely comminuted or displaced fractures, benefit from referral and possible operative intervention.[9,10] Additional considerations for orthopedic referral include athletes, professional impact, and cosmetic concerns. Referral to an orthopedist within a few days of injury should be considered in the above instances. In cases where the patient does not want surgery or is a poor surgical candidate, conservative treatment is an appropriate strategy. Initial treatment of midclavicle fractures includes immobilization with either a sling or figure-of-eight brace. The length of immobilization is typically 4 to 8 weeks, until the fracture is no longer painful. Initial primary care or orthopedic follow-up should be in 1 to 2 weeks after injury in conservative treatment. The patient may use the arm as pain permits but should avoid repeat injury from direct contact. Encourage daily range of motion of the elbow immediately and of the shoulder as soon as pain allows (3 to 5 days).

DISTAL CLAVICLE FRACTURES

Distal clavicle fractures are divided into three subtypes. In type I fractures, the fracture is distal to the coracoclavicular ligaments, with the ligaments remaining intact. In type II fractures, the location of the fracture is the same as in type I; however, the coracoclavicular ligaments are disrupted (**Figure 271-3**). This results in an upward displacement of the proximal aspect of the clavicle. Type II distal clavicle fractures may require operative intervention to avoid nonunion.[11] Type III fractures are intra-articular fractures through the acromioclavicular (AC) joint. Type I and III fractures can be managed conservatively with sling immobilization and primary care follow-up in 1 to 2 weeks.[12]

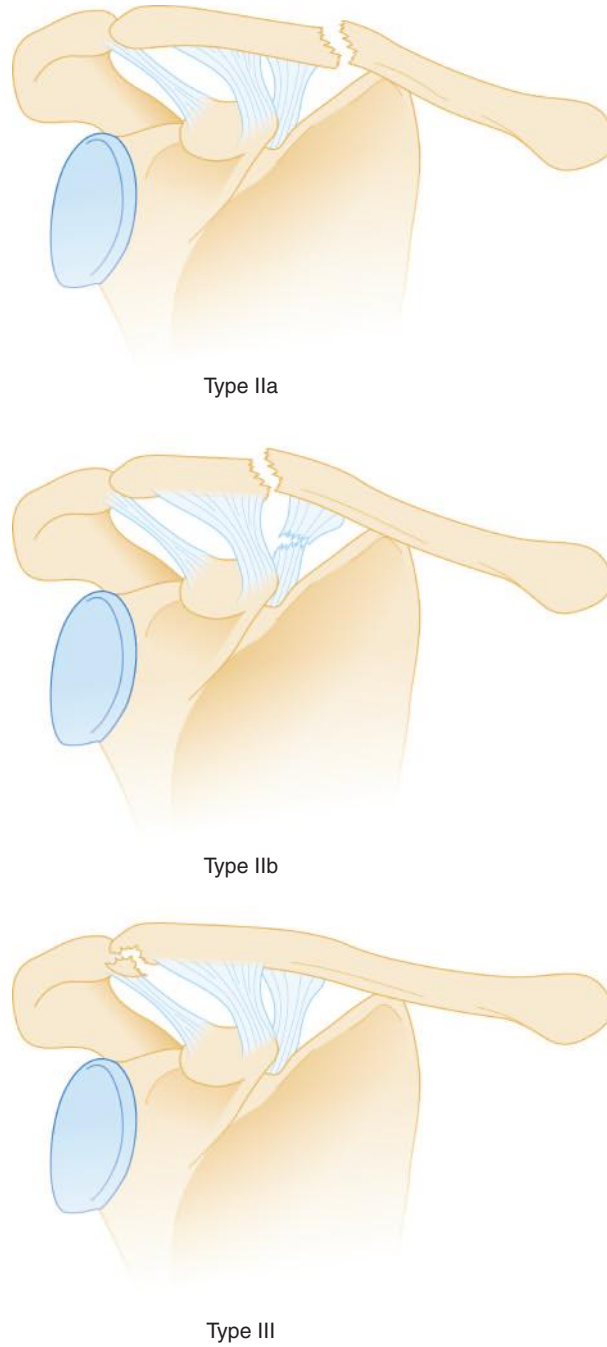

FIGURE 271-3. Classification of distal clavicular fractures. A-P = anteroposterior.

PROXIMAL THIRD CLAVICLE FRACTURES

Proximal third clavicle fractures are often high-mechanism injuries and can be associated with intrathoracic trauma. CT can diagnosis the fracture and identify additional injuries. Emergent referral is required when posteriorly displaced fragments compromise mediastinal structures. Refer all other proximal third fractures to orthopedics within 1 to 2 weeks. Initial management includes sling immobilization.

SCAPULA FRACTURES

ANATOMY

The scapula is a triangularly shaped, flat bone that links the axial skeleton to the upper extremity and stabilizes motion of the arm. It serves as the site of origin of the rotator cuff and muscles about the shoulder. The

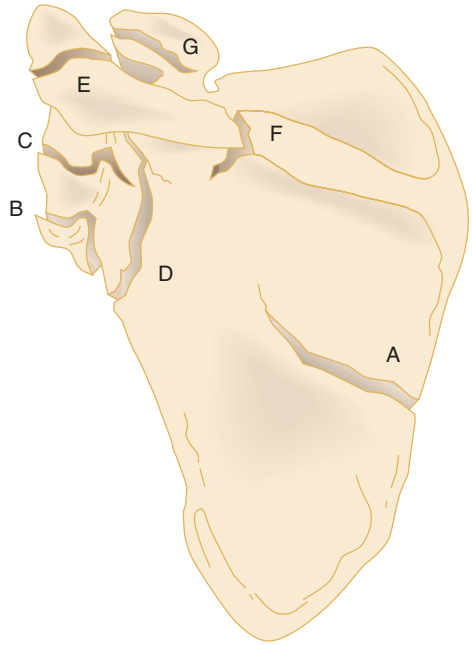

FIGURE 271-4. Sites of scapular fractures. **A.** Body. **B.** Glenoid rim. **C.** Intra-articular glenoid. **D.** Neck. **E.** Acromion. **F.** Spine. **G.** Coracoid.

mechanism of injury usually is from high-energy trauma to the shoulder area or from a fall on an outstretched hand. Scapular fractures are classified by their anatomic location (**Figure 271-4**),[13] with fractures of the body (**Figure 271-5**) and glenoid neck being most common.

CLINICAL FEATURES

Patients with isolated scapular fractures typically present with localized tenderness over the scapula and the arm held in adduction. Arm movement exacerbates pain. Due to the high energy typically required to fracture this protected bone, there is a high association of injuries to the ipsilateral lung, thoracic cage, and shoulder girdle, with fractures of the ribs being most common. Carefully determine the mechanism of injury to assist in diagnosis and raise suspicion for concurrent injuries. Assess the spine and pelvis, because scapular injuries often occur with high-impact trauma.[13,14] The indirect axial load transmitted by a fall on an outstretched arm may result in a scapular neck fracture or **glenoid fracture** through shoulder impaction or dislocation.

FIGURE 271-5. Scapular Y view demonstrating scapular body fracture. [Photo used with permission of Alexander Ebinger, MD.]

DIAGNOSIS

Overlying structures may obscure a scapular fracture on a single trauma anteroposterior chest radiograph. A dedicated scapular series, including anteroposterior, lateral, and axillary scapular views, will identify most fractures and will guide the need for a CT scan (Figure 271-4). Scapular fractures are often associated with other significant injuries, and hence, diagnosis may be delayed or initially missed entirely. CT scan of the chest can identify both scapular and associated pathology, and a dedicated CT of the scapula can also be obtained.

Most scapular fractures are treated nonsurgically, with sling, ice, analgesics, and early range-of-motion exercises. Surgery may be necessary for significant or displaced articular fractures of the glenoid, angulated glenoid neck fractures, acromial fractures associated with a rotator cuff tear, and some coracoid fractures.[13,15] Disability is more likely to be associated with fractures of the glenoid, acromion, or coracoid. Isolated scapular fractures should be referred to an orthopedic surgeon.

SCAPULOTHORACIC DISSOCIATION

Traumatic dislocation of the scapula from the thoracic wall results from severe massive traction force applied to the ipsilateral upper extremity and shoulder girdle. Associated disruption of the subclavian or axillary arteries and brachial plexus makes proper identification and treatment critical.[16,17]

Chest x-ray demonstrates significant lateral displacement of the scapula.[16,17] Associated radiographic abnormalities include distracted clavicle fracture, AC separation, and sternoclavicular dislocation. Perform a CT scan to identify intrathoracic injuries.

ACROMIOCLAVICULAR (AC) JOINT INJURIES

ANATOMY

The AC joint is a diarthrodial joint that, together with the sternoclavicular joint, connects the upper extremity to the axial skeleton (**Figure** 271-**6**).

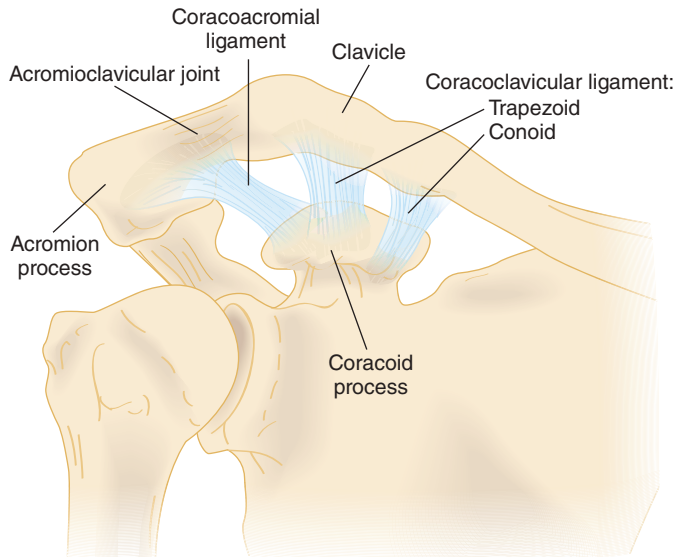

FIGURE 271-6. Anatomy of the acromioclavicular joint.

Support of the AC joint is through the AC and coracoclavicular ligaments and the attachment of the trapezius and deltoid muscles. Surrounding the AC joint is a thin capsule, which is reinforced by the AC ligaments. The AC ligaments provide horizontal stability to the joint. The strong coracoclavicular ligaments consist of two parts, the more lateral trapezoid and the medial conoid, and attach the distal inferior clavicle to the coracoid process of the scapula. The coracoclavicular ligament is the major suspensory ligament of the upper extremity and provides vertical stability to the AC joint.

AC joint injuries range from mild sprain to complete disruption of the ligaments that link the scapula and clavicle. The mechanism of injury is usually direct trauma to the joint from a fall with the arm adducted. The result is that the scapula and shoulder girdle are driven inferiorly while the clavicle remains in its normal position. An indirect mechanism is a fall on the outstretched hand with transmission of force to the AC joint.

CLINICAL FEATURES

The diagnosis of AC joint injuries is clinical. The mechanism of injury and tenderness and deformity at the AC joint, especially when compared with the contralateral AC joint, are confirmatory. Range of motion may be limited, depending on the severity of injury. Cross-arm abduction testing is often painful.

DIAGNOSIS

Radiographs are useful for identifying other fractures and determining the severity of injury. AC radiographs should specifically be ordered because they require only one-third to one-half of the penetration of standard shoulder films. Shoulder radiographs may overpenetrate the AC joint, and small fractures can be missed. Although standard AC radiographs are generally sufficient, an axillary view is required to identify posterior clavicular dislocation (type IV). Stress radiographs are no longer routinely obtained.[18]

Obtain emergency orthopedic consultation for open fractures, fractures with neurovascular injuries, and fractures with persistent skin tenting. **Table 271-2** describes specific AC joint injuries. Treatment of **type I and II injuries** consists of rest, ice, analgesics, and immobilization, followed by early range-of-motion exercises (7 to 14 days).[19]

A simple sling is the most convenient and effective initial treatment. Prognosis for type I and II injuries is excellent, with only a small percentage of patients developing late symptoms requiring excision of the distal clavicle.

Treatment of **type III injuries** varies, with most orthopedists recommending a trial of conservative treatment with sling immobilization.[20-22] Surgical strategies have yielded good results in selected patients, with the specific management being operator dependent. Treatment decisions are based on such factors as age, occupation, and activity level. **Types IV, V, and VI are severe injuries**, and most experts recommend surgical repair. Because other injuries are associated with these more severe forms of AC joint injuries (especially type VI), a careful clinical and radiographic examination must be performed.[20,21]

GLENOHUMERAL JOINT DISLOCATION

ANATOMY

The glenohumeral joint is a ball-and-socket joint, with the articulation between the glenoid fossa of the scapula and the articular surface of the humeral head. The socket of the shoulder is shallow. The glenoid labrum deepens the socket and helps provide joint stability. The capsule and tendinous attachments about the joint also provide stability. Anterior dislocations of the glenohumeral joint are the most common; posterior

TABLE 271-2 Classification and Physical Findings in Acromioclavicular Joint Injuries

Type	Injury	Mechanism	Radiograph/Exam
I	Sprained acromioclavicular ligaments		Radiograph: Normal Exam: Tenderness over acromioclavicular joint
II	Acromioclavicular ligaments ruptured; coracoclavicular ligaments sprained		Radiograph: Slight widening of acromioclavicular joint; clavicle elevated 25%–50% above acromion; may be slight widening of the coracoclavicular interspace Exam: Tenderness and mild step-off deformity of acromioclavicular joint

(*Continued*)

TABLE 271-2 Classification and Physical Findings in Acromioclavicular Joint Injuries (*Continued*)

Type	Injury	Mechanism	Radiograph/Exam
III	Acromioclavicular ligaments ruptured; coracoclavicular ligaments ruptured; deltoid and trapezius muscles detached		Clavicle elevated 100% above acromion; coracoclavicular interspace widened 25%–100% Exam: Distal end of clavicle prominent; shoulder droops
IV	Rupture of all supporting structures; clavicle displaced posteriorly in or through the trapezius		Radiograph: May appear similar to type II and III; axillary radiograph required to visualize posterior dislocation Exam: Possible posterior displacement of clavicle
V	Rupture of all supporting structures (more severe form of type III injury)		Radiograph: Acromioclavicular joint dislocated; generally 200%–300% disparity of coracoclavicular interspace compared to normal shoulder Exam: More pain; gross deformity of clavicle
VI	Acromioclavicular ligaments disrupted; coracoclavicular ligaments may be disrupted; deltoid and trapezius muscles disrupted		Radiograph: Acromioclavicular joint dislocated; clavicle displaced inferiorly Exam: Severe swelling; multiple associated injuries

dislocations account for <1%. Other dislocations include inferior (luxatio erecta) and superior (very rare).

CLINICAL FEATURES

In an anterior dislocation, the associated arm is usually in slight abduction and external rotation. The shoulder is "squared off," lacking the normal rounded contour. The patient resists adduction and internal rotation and often cannot touch the contralateral shoulder with the hand of the affected extremity. The humeral head can often be palpated anteriorly. Perform a careful neurovascular examination. The axillary nerve is most commonly injured. This nerve may be tested by pinprick sensation over the skin of the deltoid muscle.

DIAGNOSIS

Obtain anteroposterior and scapular lateral or "Y" radiographs before reduction is attempted to confirm the anatomic type of dislocation and identify any associated fractures. Although the anteroposterior radiograph will reveal the dislocation, the scapular Y radiograph will indicate whether the dislocation is anterior or posterior.[23]

ANTERIOR GLENOHUMERAL DISLOCATIONS

The combination of abduction, extension, and external rotation with sufficient force will cause an anterior dislocation. There are multiple types of anterior glenohumeral dislocations (**Figure 271-7**). These include subcoracoid, which is the most common; subglenoid; subclavicular; and the very rare intrathoracic dislocation.

Prereduction radiographs are advisable when there has been significant trauma, unless time is crucial because circulation is threatened. Radiographs are needed because dislocations and fracture-dislocations may have a similar appearance on physical examination, but the techniques used to treat them may be very different. Shoulder dislocations or subluxations combined with proximal humerus fractures generally require orthopedic consultation and may need operative repair. Shoulder dislocations with associated proximal humerus fracture increase with age. Through the third decade, fracture-dislocations occurred less than 1% of the time. This percentage rises with each decade of life.[24] Postreduction radiographs are valuable for confirming the success of joint reduction, as well as for providing documentation, in the event the joint redislocates after the patient is discharged from the ED.

There is an expenditure of time, money, and radiation associated with pre- and postreduction films; however, there is currently no validated clinician decision rule that allows safe elimination of prereduction films after injury.[25] In clinical practice, films are sometimes omitted in patients with a history of multiple recurrent dislocations of the shoulder who present with history, signs, and symptoms typical of another recurrence in the absence of significant trauma.[23,25]

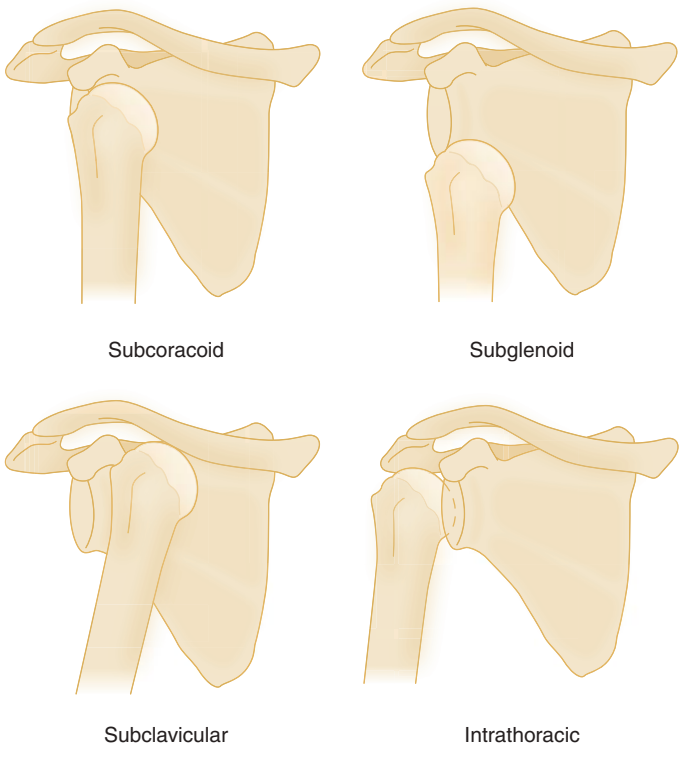

FIGURE 271-7. Types of anterior shoulder dislocations.

REDUCTION TECHNIQUES

The three main categories of reduction techniques are traction, leverage, and scapular manipulation.[26-29] Success rates are between 70% and 96% regardless of technique. It is essential to provide appropriate systemic narcotic analgesia. The use of procedural sedation is highly recommended, but any reduction technique may be attempted without medication when performed slowly and atraumatically. It is best to be comfortable with two or three techniques in case of a failed first attempt. Considerations in selection of a technique include ease of performance, effectiveness, requirement for sedation, number of assistants, and duration. The most common techniques are described below.

Intra-articular injection of 10 to 20 mL of 1% lidocaine (10 mL provides a total dose of 100 milligrams of lidocaine) reduces the pain associated with reduction and can complement procedural sedation.[30,31] After sterile skin preparation, introduce the needle at the hollow created by the displaced humeral head, just inferior to the acromion. US can facilitate intra-articular injection. Perform neurovascular examination before and after reduction.

Complications Complications associated with anterior glenohumeral dislocations include recurrence, rotator cuff tears, humeral head bony defects (Hill-Sachs deformity), glenoid labral defects (Bankart lesions), and rarely, neurovascular injuries.[32] The most common complication is recurrent dislocation, and children and young adults may have a recurrence rate of more than 90%.[32,33] Early surgical repair may decrease the recurrence rate, so patients with first-time shoulder dislocations should be referred for orthopedic evaluation.[34-36]

The rotator cuff weakens with advancing age, and in older patients, anterior dislocation is usually associated with rotator cuff tears. Rotator cuff tears can be difficult to identify on ED examination after dislocation reduction, but can be suspected with weakness upon external rotation.[32] Any patient with pain persisting for greater than 2 weeks should follow up with orthopedics. For further discussion, see chapter 280, "Shoulder Pain."

Bony injuries are common and include fractures of the humeral head (Hill-sachs lesions) and glenoid (bony Bankart lesion) (**Figures 271-8** and **271-9**) and tears of the anterior glenoid labrum (soft Bankart lesion) and greater tuberosity. Such fractures are often evident only on postreduction films,[23] and there is no specific ED treatment other than follow-up with orthopedics.

Vascular injuries are rare, but when they occur, they tend to involve the axillary artery in elderly patients. Clinical findings of vascular injury include absent radial pulse, axillary hematoma, bruising of the lateral chest wall, and an axillary bruit.

Nerve injuries, which occur in 10% to 25% of acute dislocations, are the result of traction neurapraxia. Most involve the axillary nerve, resulting in loss of sensation over the skin of the upper arm. This injury is temporary and resolves spontaneously. The motor portion of the axillary nerve supplies the teres minor and the deltoid, and injury can result in weakness of shoulder abduction and external rotation. Other nerves that may be injured are the radial, ulnar, median, musculocutaneous, and brachial plexus.[32]

Disposition After reduction, place the arm in a shoulder immobilizer or sling that maintains the shoulder in adduction and internal rotation (**Figure 271-10**). Provide instructions for orthopedic follow-up in 1 week for uncomplicated dislocations and within 1 to 2 days for dislocations complicated by bony or soft tissue injury.[37]

FIGURE 271-8. CT right shoulder showing a frontal view with fracture tear of the anterior-inferior glenoid bony cavity (Bankart lesion). [Photo used with permission of Erik Magnus Berntsen, MD, PhD, Department of Radiology, St. Olavs University Hospital, Trondheim, Norway.]

TRACTION-COUNTERTRACTION TECHNIQUE (MODIFIED HIPPOCRATIC)

A modification of the Hippocratic method uses traction-countertraction (**Figure** 271-**11**). The patient is supine with the arm abducted and elbow flexed at 90 degrees. A sheet is tied and placed across the thorax of the patient and then around the waist of the assistant. Another sheet is tied and placed around the forearm of the patient at the elbow and the waist of the physician. Gradually apply traction to the proximal forearm as the assistant provides countertraction. Gentle internal and external rotation or outward pressure on the proximal humerus may aid reduction.

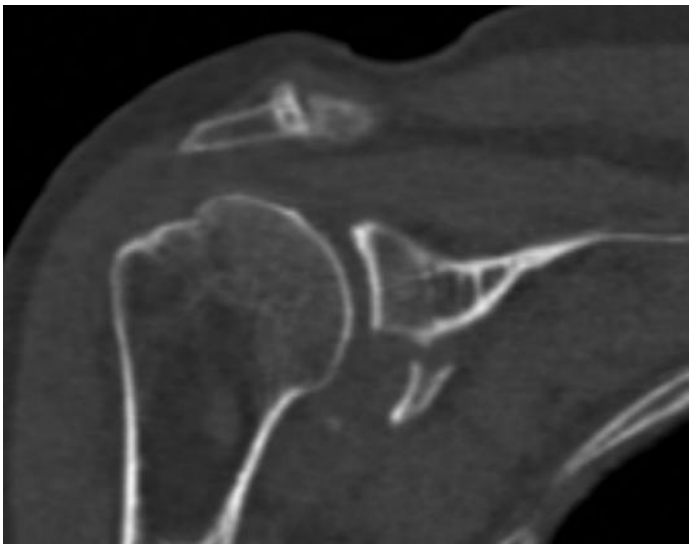

FIGURE 271-9. CT right shoulder, oblique coronal view, demonstrating both the bony Bankart lesion and the Hill-Sachs fracture of the humeral head. [Photo used with permission of Erik Magnus Berntsen, MD, PhD, Department of Radiology, St. Olavs University Hospital, Trondheim, Norway.]

FIGURE 271-10. Arm sling.

SNOWBIRD TECHNIQUE

Another version of the traction-countertraction technique is the Snowbird technique.[28] The patient should sit upright in a chair or bed with the elbow flexed to 90 degrees. Place a belt or strap across the patient's proximal forearm, so the bottom of the belt can be used to apply downward pressure with the foot. Use an assistant to place a sheet across the patient's thorax to provide countertraction. Keep the patient's elbow at 90 degrees and apply traction to the extremity by stepping on the belt with the foot (**Figure 271-12**). Gentle external rotation will facilitate reduction.

STIMSON TECHNIQUE

Place the patient prone with the dislocated extremity hanging over the side of the stretcher and a 10-lb weight attached to the wrist. Inject intra-articular lidocaine. Complete muscle relaxation is required. Reduction occurs in 20 to 30 minutes. Although the time to reduction can be a drawback, this technique is safe, effective, and easy to learn.

SCAPULAR MANIPULATION TECHNIQUE

The patient is positioned with weights in the same manner as the Stimson technique (**Figure 271-13**). After adequate sedation, the physician pushes the tip of the scapula medially using the thumbs, while stabilizing the superior aspect with the cephalad hand. This technique reports a 96% success rate.[29]

EXTERNAL ROTATION TECHNIQUE (KOCHER'S TECHNIQUE)

Place the patient supine with the affected arm adducted to the patient's side. With the elbow at 90 degrees of flexion, slowly externally rotate the arm (**Figure 271-14**). No longitudinal traction is applied. Perform the movement slowly to allow time for spasm and pain to resolve. Reduction is usually complete before reaching the coronal plane and is often not noted either by the patient or physician. If needed, the elbow may be brought anteriorly and internally rotated to the opposite shoulder.[38]

MILCH TECHNIQUE

The maneuvers for the Milch technique are external rotation, arm abduction to 180 degrees with simultaneous pressure on the humeral head, and in-line longitudinal traction with continued pressure on the humeral head (**Figure 271-15**).

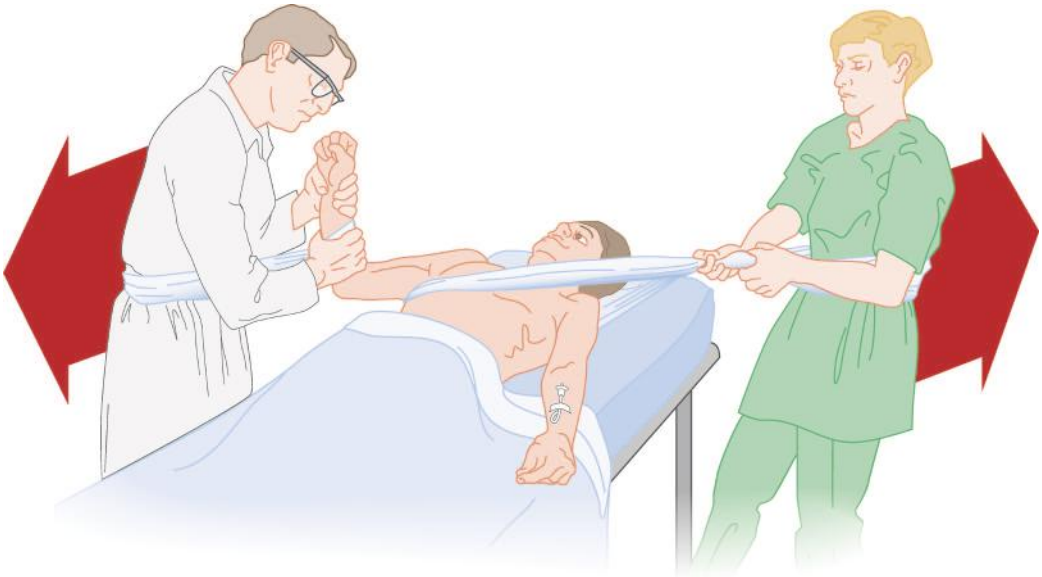

FIGURE 271-11. Modified Hippocratic technique.

CUNNINGHAM TECHNIQUE

The Cunningham technique is based on the combination of humerus and scapular positioning and specific massage of a spasming biceps muscle (**Figure 271-16**). Seat the patient comfortably, as upright as possible, with shoulders relaxed. Supporting the affected arm, slowly and gently move the humerus into full adduction with the elbow in flexion. Have the hand of the affected extremity resting against the physician's shoulder. Gently massage the trapezius and deltoids, which helps to relax the patient. Then, gently massage the biceps at the mid-humeral level. Ask the patient to elevate and shrug or retract the shoulders (attempting to touch the scapulae together) and continue the biceps massage. The goal is to wait for the patient to relax fully and have the humeral head slip back into place.[26]

POSTERIOR GLENOHUMERAL DISLOCATIONS

Posterior dislocation may occur with the humeral head in the subacromial, subglenoid, or subspinous position, but most often, it occurs with the humeral head posterior to the glenoid and inferior to the acromion (**Figure 271-17**). The subglenoid and subspinous positions are rare. The usual mechanism is an indirect force that produces forceful internal rotation and adduction or a direct blow to the anterior shoulder. On examination, there is a prominence of the posterior shoulder and anterior flattening of the normal shoulder contour on the affected side, especially when compared to the nonaffected side. The patient will be unable to externally rotate or abduct the affected arm.

The scapular Y radiograph is diagnostic (**Figure 271-18**).

FIGURE 271-12. Snowbird technique.

FIGURE 271-13. Scapular manipulation technique.

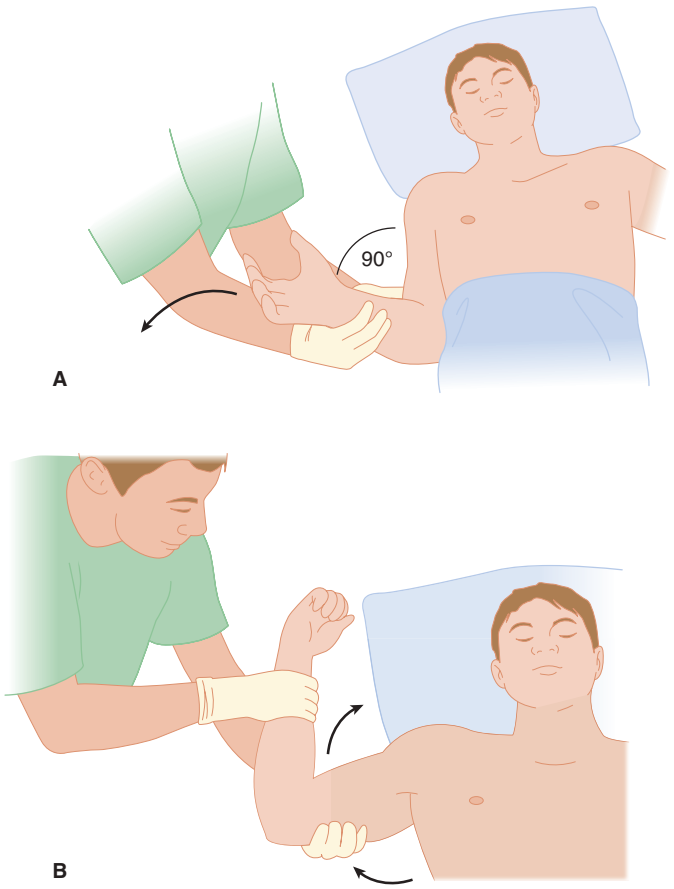

FIGURE 271-14. A and B. External rotation (Kocher's) technique. [Reproduced with permission from Simon RR, Sherman SC, Koenigsknecht SJ: *Emergency Orthopedics, The Extremities*, 5th ed. © 2007, McGraw-Hill Inc., New York.]

Reduction of a posterior dislocation is performed with the patient supine. Because severe pain and muscle spasms are common, muscle relaxation and analgesia are needed. Apply traction to the adducted arm in the long axis of the humerus. Have an assistant gently push the humeral head anteriorly into the glenoid fossa.[39] Fractures of the posterior glenoid rim, humeral head (reversed Hill-Sachs deformity), humeral shaft, or lesser tuberosity are common complications. Neurovascular and rotator cuff tears are less common than in anterior dislocations. Obtain postreduction radiographs to confirm successful reduction. Immobilize the shoulder with an arm sling, with follow-up with an orthopedist.

INFERIOR DISLOCATIONS (LUXATIO ERECTA)

Inferior dislocation is associated with significant soft tissue trauma or fracture. The mechanism of injury is a hyperabduction force, which levers the neck of the humerus against the acromion. As the force continues, the inferior capsule tears, and the humeral head is forced out inferiorly. The patient presents with the humerus fully abducted, the elbow flexed, and the patient's hand on or behind the head. The humeral head can be palpated on the lateral chest wall.

Reduction consists of traction in an upward and outward direction in line with the humerus (**Figure 271-19**). Have the assistant apply countertraction. Reduction is signaled by a "clunk." The arm is then brought to the patient's side and immobilized in a shoulder immobilizer.

Complications include severe soft tissue injuries and fractures of the proximal humerus. The rotator cuff, which usually becomes detached, requires orthopedic follow-up. Neurovascular compression injuries are usually found but almost always resolve after reduction. When the humeral head is buttonholed through the inferior capsule, the dislocation is irreducible, and operative reduction is required.

HUMERUS FRACTURES

ANATOMY

The proximal humerus is composed of the articular segment and anatomic neck, the greater and lesser tuberosities, and the proximal shaft (**Figure 271-20**). The supraspinatus, infraspinatus, and teres minor insert on the greater tuberosity, whereas the subscapularis inserts on the lesser tuberosity. The biceps tendon passes through the bicipital groove. The anterior and posterior humeral circumflex arteries branch off the axillary artery and course around the surgical neck.

CLINICAL FEATURES

Patients with fractures typically present with pain, swelling, and tenderness about the shoulder. Range of motion is often significantly limited, and the arm is held in adduction. Crepitus and ecchymosis may be present. Carefully perform the neurovascular examination. The most commonly injured nerve is the axillary nerve, and sensation overlying the deltoid muscle should be tested. The second most commonly injured nerve is the suprascapular nerve, which innervates the supraspinatus and infraspinatus.[40] Range of motion may be limited, but assessment of shoulder abduction should be performed. Vascular injuries may occur with even trivial trauma in atherosclerotic elderly patients. The most common vascular injury is to the axillary artery and may be suggested by weak distal pulses compared to the uninjured side, paresthesias, pallor, pulselessness, or an expanding hematoma. Neurovascular injuries can occur in nondisplaced and displaced fractures but are much higher (>50%) in displaced fractures.

DIAGNOSIS

Radiographs consisting of anteroposterior, lateral shoulder, and axillary views will diagnose most proximal humerus fractures and evaluate for accompanying glenohumeral dislocation.

Specific Injuries The most common fractures of the proximal humerus include the surgical neck and greater tuberosity. To guide treatment, the Neer system classifies fracture displacement into "parts." The proximal humerus is divided into four segments based on epiphyseal lines where fractures primarily occur: the articular surface of the humeral head; the greater tuberosity; the lesser tuberosity; and the shaft of the humerus (**Figure 271-21**). The displacement of a fracture fragment from the proximal humerus is called a "part." Parts are therefore not based on the number of fracture lines or segments. Rather, a "one-part" fracture is one in which the fragment is not displaced at all, is displaced <1 cm, or is not angulated >45 degrees. There can be multiple fragments, but if none of the fragments is displaced >1 cm or is angulated >45 degrees, the proximal humerus fracture is termed a "one-part" fracture. Approximately 50% of all proximal humerus fractures are one-part fractures.[41,42] Treatment of a one-part proximal humerus fracture generally consists of

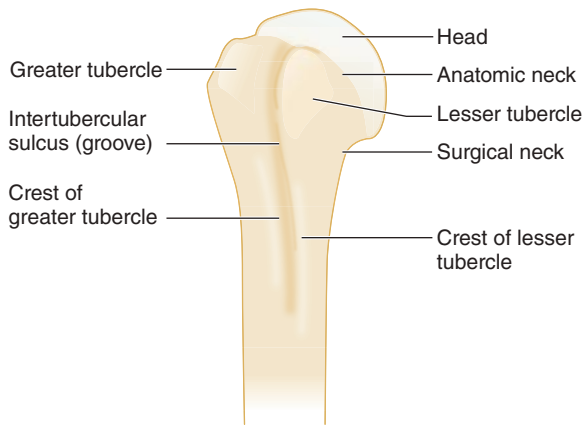

FIGURE 271-20. Proximal humerus. [Reproduced with permission from Pansky B: *Review of Gross Anatomy*, 6th ed. New York: McGraw Hill, 1995.]

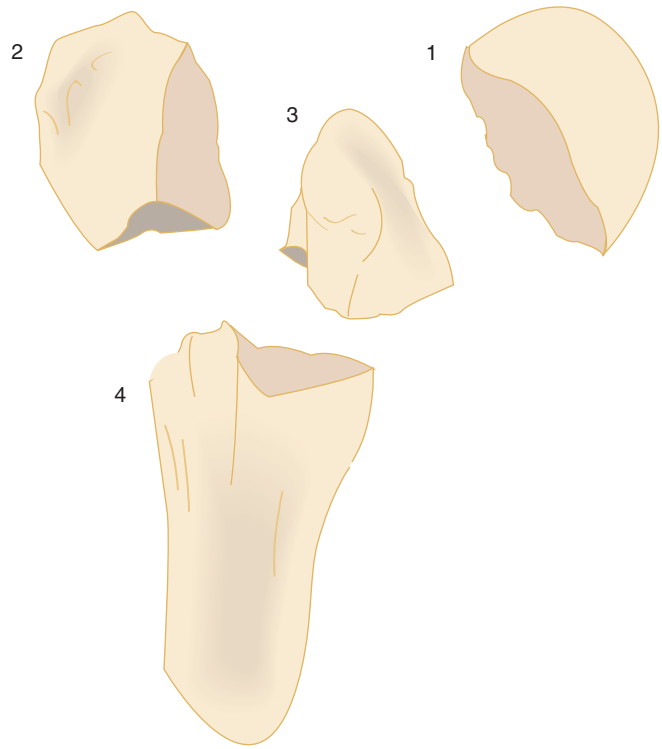

FIGURE 271-21. The four segments of the humerus according to the Neer classification: 1, articular surface of the humeral head; 2, greater tubercle; 3, lesser tubercle; 4, diaphysis or shaft of humerus. A one-part fracture is defined as a fracture fragment displaced by <1 cm or <45 degrees; two-, three-, and four-part fractures have more displacement and angulation.

immobilization (such as sling and swathe), ice, analgesics, and orthopedic referral. Early mobilization is important to avoid subsequent adhesive capsulitis and can be started when pain allows. The prognosis is generally good. All other proximal humerus fractures and fracture-dislocations require orthopedic consultation in the ED because they are more frequently associated with complications and are often difficult to manage. Closed reduction, operative treatment, or a combination of the two may be necessary.

Any fracture involving the anatomic neck or the articular surface may result in compromise of the blood supply to the articular segment of the humeral head. If ischemic necrosis of the articular segment occurs, insertion of a humeral head prosthesis may be required. Significantly angulated surgical neck fractures are a risk for neurovascular damage (axillary neurovascular structures as well as the brachial plexus) and should be immobilized and radiographed in the position of presentation.

Significant displacement of a greater tuberosity fracture implies a concomitant rotator cuff tear, with surgical repair often necessary for the active patient. Fracture of the lesser tuberosity should alert the examiner to a potential posterior shoulder dislocation.

Children may have significant displacement or separation of the proximal humeral epiphysis and need early orthopedic consultation for anatomic reduction if near skeletal maturity. Salter II injuries are most common after age 6 years old and will require closed reduction if >20 degrees of angulation is present. A shoulder spica is often used after reduction for unstable injuries, with sling and swathe immobilization for other injuries. If there is a question about the acceptability of angulation, consult the orthopedist.

HUMERAL SHAFT FRACTURES

ANATOMY

The humerus serves as the attachment site for the rotator cuff muscles, deltoid, pectoralis major, and coracobrachialis. Additionally, it is the site of origin of the biceps, triceps, and brachioradialis. The radial nerve courses along the spiral groove on the posterior aspect of the humerus.

Fractures of the humeral shaft occur in a bimodal age distribution, with peaks in the third and seventh decades of life, representing active young men and osteoporotic elderly women, respectively. Humeral shaft fractures may be caused by a direct blow that produces a bending force resulting in a transverse fracture. They may also be caused by an indirect mechanism, such as a fall on an outstretched hand that produces a torsion force, resulting in a spiral fracture. A combination of bending and torsion forces results in an oblique fracture, sometimes with comminution, producing the "butterfly" fragment. The humerus is also a common site of pathologic fractures, especially from metastatic breast cancer. Fractures in young children should raise suspicion of abuse.[43]

CLINICAL FEATURES

Clinical examination reveals localized tenderness, swelling, pain, and abnormal mobility or crepitus on palpation. Displaced fractures are associated with shortening of the upper extremity. Attention must be given to the initial neurovascular status. Complications may include injury to the brachial artery and vein, or the radial, ulnar, or median nerves. A radial nerve injury, which is the most common, may be manifested by weak wrist extension, wrist drop, or altered sensation at the dorsal thumb index web space. Fractures of the distal third are particularly prone to entrapment of the radial nerve, either as a result of the initial injury or after closed reduction. Neurovascular injuries require emergency orthopedic consultation.[44]

DIAGNOSIS

Radiographs should include two views of the humerus. Images of the shoulder and elbow should be obtained if additional injuries cannot be excluded.

FRACTURES OF THE MIDDLE THIRD OF THE HUMERUS

The most common site of fracture is the middle third of the humerus. Displacement of fracture fragments is the result of the insertions and actions of the various muscles (deltoid, biceps, triceps, supraspinatus, and pectoralis major) that act on the upper arm (**Figure 271-22**). Most closed fractures of the shaft of the humerus are managed nonoperatively, although treatment options vary. A 2012 Cochrane Review did not find any evidence to suggest outcome differences from surgery versus nonsurgical management.[45] Fractures with less than 20 degrees of angulation in the sagittal plane and less than 30 degrees of varus or valgus angulation and are shortened less than 2 to 3 cm often can be managed nonoperatively.[46] The treatment of uncomplicated fractures includes immobilization, ice, analgesia, and referral. Closed treatment options include the coaptation splint (sugar tong), hanging cast, and functional bracing. A simple sling and swathe are adequate for the emergency management of most such patients.

DISTAL HUMERUS FRACTURES

Distal humerus fractures require emergency orthopedic consultation. These fractures are complex given the anatomical relationship of the bony and neurovascular structures. Clinical examination should include evaluation of the radial, median, ulnar, and anterior and posterior interosseous nerves. See chapter 270 for a discussion of supracondylar fractures.

BRACHIAL PLEXUS INJURIES

ANATOMY

The brachial plexus (**Figure 271-23**) and its peripheral nerve branches are infraclavicular and lay anteromedial to the glenohumeral joint. Anatomically, the brachial plexus stems from the C4-T1 cervical roots and ultimately from the lateral, posterior, and medial cords. At the lateral border of the pectoralis minor, these cords ultimately form the five major peripheral nerves of the arm (musculocutaneous nerve, axillary nerve, radial nerve, median nerve, and ulnar nerve).[47] Traumatic brachial plexus lesions are the most common form of plexus injuries and can occur from

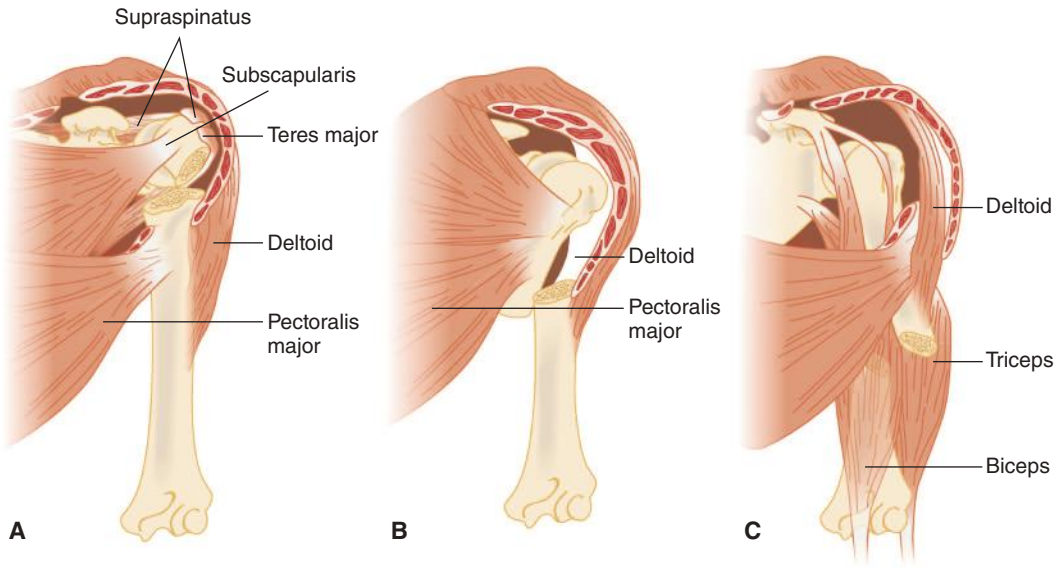

FIGURE 271-22. Humeral fractures anterior view. The actions of the muscles inserting on the humeral shaft determine fracture angulation and displacement. **A.** Angulation of fragments with fracture line distal to rotator cuff insertion. **B.** Angulation of fragments with fracture line distal to pectoralis major insertion. **C.** Angulation of fragments with fracture line distal to deltoid insertion.

penetrating, compression, or closed traction injuries. Injuries can be divided into supraclavicular (roots and trunks) or infraclavicular (cords and terminal nerves) injuries.

CLINICAL FEATURES

High-speed motor vehicle or motorcycle crashes result in traction injuries as nerves are stretched longitudinally, with simultaneous traction of the arm and opposite distraction of the head.[47,48] Penetrating trauma and surgical interventions can also lead to a disruption of the nerves. The initial identification of brachial plexus injuries is often overshadowed by the presence of other severe injuries to, for example, the head, chest, and vasculature. In addition to neurologic impairment, neuropathic pain in the arm is frequently present. Significant swelling and soft tissue injury to the neck and shoulder girdle suggest traumatic forces sufficient to injure the brachial plexus. The accumulation of cerebrospinal fluid from avulsed spinal roots may cause swelling in the posterior triangle. Horner's syndrome (ipsilateral ptosis, miosis, and anhidrosis of the face) may be present due to adjacent ganglion damage. However, brachial plexus injury may not be clinically apparent until a responsive patient can indicate the extent of motor and sensory deficits, days to weeks after initial stabilization and treatment. Arm pain that is constant and burning in character is common. The pain is usually worst in the distal parts of the arm and hand, typically in a nondermatomal distribution.

DIAGNOSIS

Upper limb and shoulder girdle motor and sensory deficits define the extent of damage to the brachial plexus. Adduction and internal rotation of the shoulder indicate weakness of the deltoid and infraspinatus

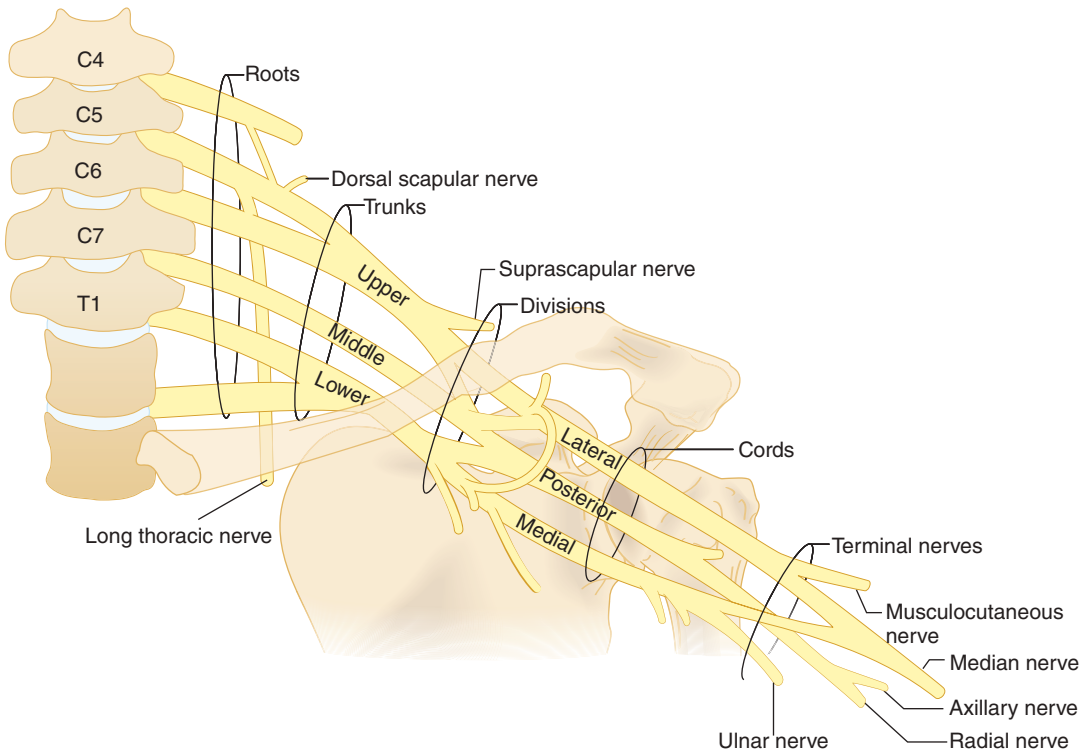

FIGURE 271-23. Brachial plexus.

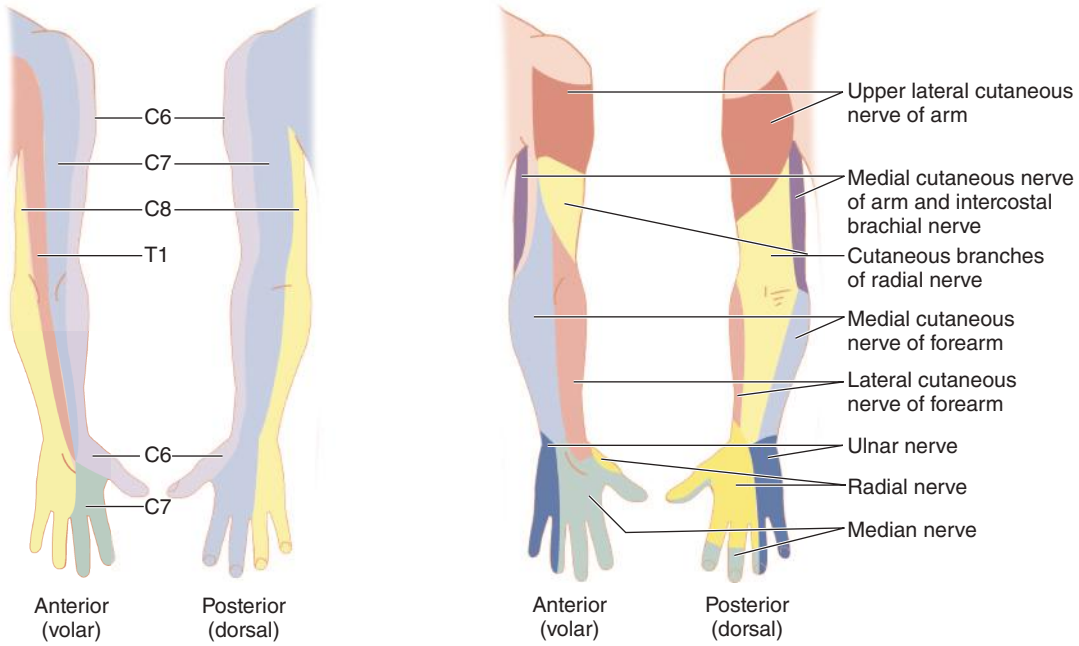

FIGURE 271-24. Sensory distribution of the brachial plexus.

muscles (C5), whereas elbow extension is due to weakness of the biceps (C6), and flexion of the digits and wrists is due to weakness of the extensors (C7). The sensory distributions of the cervical roots and the peripheral nerves are shown in **Figure 271-24**.

MRI and CT myelography are common radiographic imaging procedures. Electromyographic and nerve conduction velocity studies may aid in diagnosis, and surgical exploration of the area may be necessary. The delineation of pre- and postganglionic injury may not be possible until Wallerian degeneration is completed 2 weeks after injury. Treatment and prognosis will depend on the location and extent of nerve damage.

CHAPTER 272

Pelvis Injuries

Melissa A. Barton
H. Scott Derstine
Ciara J. Barclay-Buchanan

EPIDEMIOLOGY

Most pelvic fractures are secondary to automobile passenger or pedestrian accidents but are also the result of minor falls in older persons and from major falls or crush injuries. The mortality rate from all pelvic fractures is approximately 5%. However, with complex pelvic fractures, the mortality rate is about 20%.[1] Isolated fractures of the pubic rami are likely in the elderly who sustain a low-energy mechanism of injury, such as falling off a chair, and are due to underlying fragility and osteopenia.[2]

ANATOMY AND BIOMECHANICS

The major functions of the pelvis are protection, support, and hematopoiesis. The pelvis consists of the sacrum and coccyx as well as the bilateral "innominate bones," which are comprised of three separate bones: the ischium, ilium, and pubis. These bones provide pelvic stability that is further supported by the strong posterior sacroiliac (SI), sacrotuberous, and sacrospinous ligaments (**Figures 272-1 and 272-2**). A small amount of pelvic stability is also provided by the pubic symphysis. The bladder lies in close proximity to the symphysis, as does the rectum to the sacrum, putting each of the structures at risk for injury in a trauma patient.

Incorporated in the pelvic structure are five joints that allow some movement in the bony ring. The lumbosacral, sacroiliac, and sacrococcygeal joints, as well as the symphysis pubis, allow little movement. The acetabulum is a ball-and-socket joint that is divided into three portions: the iliac portion, or superior dome, is the chief weight-bearing surface; the inner wall consists of the pubis and is thin and easily fractured; and the posterior acetabulum is derived from the thick ischium. Any single break in the ring will yield a stable injury without significant risk of displacement, whereas the occurrence of two breaks in the ring is considered an unstable pelvis.

The pelvis is extremely vascular. The iliac artery and venous trunks pass near the sacroiliac joints bilaterally. The nerve supply through the

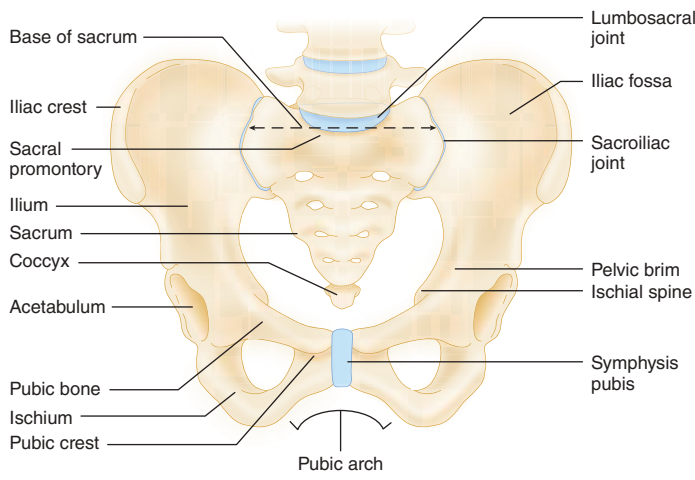

FIGURE 272-1. Bones and joints of the pelvis.

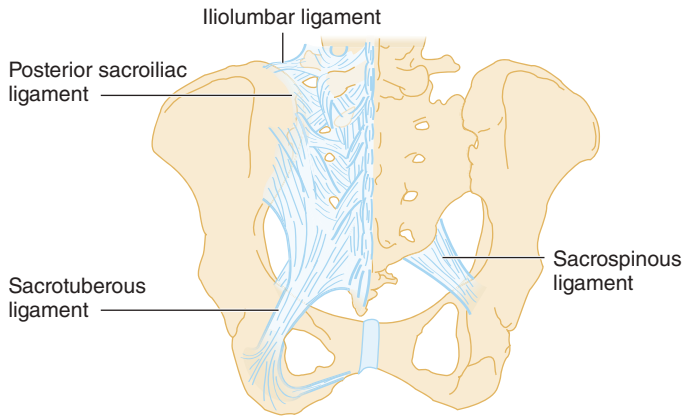

FIGURE 272-2. Pelvic ligaments.

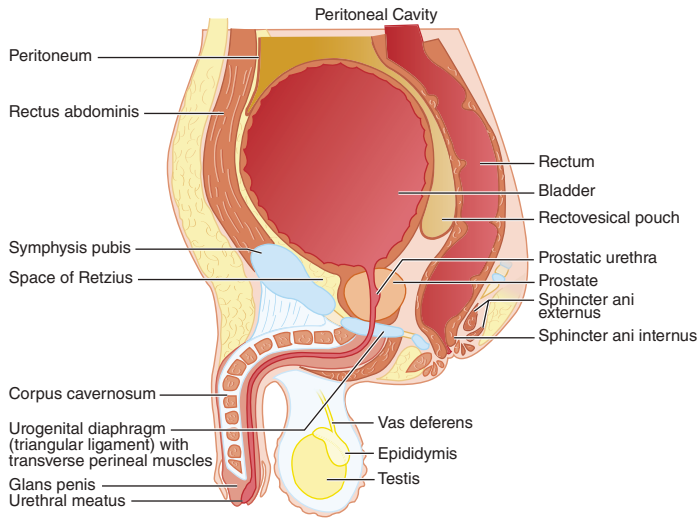

FIGURE 272-4. Sagittal section of the male pelvis showing the relation of the full bladder.

pelvis is derived from the lumbar and sacral plexuses. Injury to the pelvis may produce deficits at any level from the nerve root to small peripheral branches (**Figure 272-3**). The lower urinary tract is contained in the pelvis (**Figure 272-4**). In the adult, the bladder lies behind the symphysis and pubic bones, and the peritoneum covers the dome and base posteriorly. The location of the bladder and the degree of peritoneal reflection are determined by urine content. The lower GI tract housed in the pelvis includes a small portion of the descending colon, the sigmoid colon, the rectum, and the anus. In women, the uterus and vagina are also housed in the bony pelvis.

CLINICAL FEATURES

HISTORY

Consider the possibility of pelvic fracture in every patient with serious blunt trauma (e.g., falls from a height, pedestrian hit by a motor vehicle, crush injury, individuals ejected from a vehicle). Determine the mechanism of injury and the prehospital evaluation and treatment. Ask the patient about areas of pain, last urination or defecation, present bladder sensation, and last solid and fluid intake. In addition, determine the time of the last menses or the presence of pregnancy, brief past medical history, current medications, and allergies.

PHYSICAL EXAMINATION

In patients who are awake and alert, a careful physical examination is likely very sensitive (93% in one study) for the diagnosis of a pelvic fracture.[3] Symptoms and signs of pelvic injuries vary from local pain and tenderness, or inability to bear weight, to pelvic instability and severe shock. Unexplained hypotension may be the only sign of a major pelvic disruption.

Serious Injury For a patient with a serious or high-energy mechanism of injury, examine for abdominal tenderness, perineal and pelvic ecchymoses, lacerations, and deformities. Scrotal hematoma (Destot's sign) indicates a pelvic fracture. Leg length discrepancy or rotational deformity of the lower extremity without an obvious fracture suggests a pelvic fracture. Evidence of blood at the urethral meatus suggests a urethral injury.

Perform **focused abdominal sonogram for trauma** (FAST) examination as an adjunct to the physical examination during the primary trauma survey in any unstable patient or when the mechanism of injury could suggest a pelvic fracture. Fluid in the peritoneum can suggest solid organ injury, but fluid in the pelvis can also lead the clinician to suspect a pelvic fracture prior to radiologic confirmation.

Do not perform compressive pelvic maneuvers in a patient with shock or an obvious pelvis fracture because movement of unstable fractures could produce further injury and blood loss.

However, some type of assessment for pelvic instability should be done on every trauma patient, which could include only visual inspection in patients with obvious pelvic fractures, physical examination by pelvic rim compression, or radiologic survey. Gentle downward and medial manual compression of the pelvis over the iliac wings should be performed only **once** during the trauma survey. Repeated manipulation of the pelvic ring on any patient with a suspected pelvic fracture can increase the severity of injury, resulting in greater blood loss. Rectal examination may detect superior or posterior displacement of the prostate, rectal injury, or an abnormal bony prominence or large hematoma or tenderness along the suspected fracture line. Proctoscopic and/or bimanual pelvic examination may be required to fully assess mucosal tears in order to properly diagnosis open fractures. Such injuries increase the risk of infection at the fracture site and sepsis.[4] Decrease in anal sphincter tone may suggest neurologic injury. Carefully evaluate lower extremity pulses and sensation. If a pelvic fracture is found, assume intra-abdominal, retroperitoneal, gynecologic, and urologic injuries until proven otherwise.

Stable Patient and Low Mechanism of Injury In stable patients and those with a low-energy mechanism of injury, such as in the elderly patient who falls from a seated position, examine the entire spine and the abdomen. Palpate for tenderness along the pelvic bony structures—the iliac crests, pubic rami, sacrum, and coccyx. Compress

the pelvis, lateral to medial, through the iliac crests as well as through the greater trochanters. Additionally, compress the pelvic ring from anterior to posterior through the symphysis pubis and iliac crests. Evaluate lower extremity pulses, motor function, and sensation.

IMAGING

The initial stabilization of the patient takes priority over obtaining radiographs. If not already done, perform a FAST scan to identify intraperitoneal bleeding.

In patients with suspected hip fracture, a standard anteroposterior pelvis radiograph is often used to evaluate for bony injury. If there is no tenderness to palpation in an otherwise stable, alert patient, then a plain pelvic radiograph is not indicated.[5,6] Indications for a pelvis radiograph include a hemodynamically unstable blunt trauma patient, pelvic tenderness, or other finding on physical examination concerning for pelvic fracture. With an ***unstable*** blunt trauma patient, a pelvic radiograph can be used to identify a pelvic fracture quickly, allow early stabilization maneuvers, and mobilize resources for emergent angiography. Routine pelvic radiographs are not needed in ***stable*** patients who will undergo an emergency CT scan of the abdomen and pelvis anyway.[7-10]

CT is the gold standard for evaluating pelvic injuries. **CT is more sensitive than plain radiographs for the detection of pelvic fractures; plain radiographs rarely change the management plan in stable patients. Compared with CT, pelvic radiographs have a sensitivity of ≤85% for identifying pelvic fractures in blunt trauma patients.**[2] CT is also superior to radiography in evaluating pelvic ring instability.[7-9,11] Therefore, indications for CT include a high clinical suspicion for pelvic fracture but negative pelvic radiographs, or pelvic fractures on plain films with need to evaluate for additional pelvic fractures and instability. Contrast-enhanced CT provides useful information about posterior pelvic ring ligamentous injuries, contrast extravasation, pelvic hematoma, and retroperitoneal bleeding. Contrast extravasation on CT scan is 80% to 90% sensitive for the identification of arterial bleeding.[12,13]

If additional radiograph views are needed for stable patients, obtain lateral views, anteroposterior views of either hemipelvis, internal and external oblique views of the hemipelvis, or inlet and outlet views of the pelvis. An inlet view shows anterior-posterior displacement of ring fractures. An outlet view shows superior-inferior displacement. Oblique views of the hemipelvis are true anteroposterior and lateral views of the acetabulum. Sacral fractures may be difficult to visualize on plain films, so obtain CT or three-dimensional reconstruction of CT images when there is concern.[14]

Extremes of age require different approaches for pelvic imaging. Up to half of elderly patients with a low-energy mechanism and pubic ramus fracture may have an associated posterior pelvic ring disruption demonstrated on CT scan.[15] Pain on sacral palpation may suggest posterior ring disruption and indicate the need for pelvic CT scan. This often overlooked finding may contribute to the fact that one third of the elderly with isolated rami fractures do not return to their previous living independence or may fail conservative treatment for pain management.[15]

Most children with a low-energy mechanism and normal examination do not usually require even plain radiographs, because pelvic fractures are rare in young children. Avulsion/iliac wing fractures from sports injuries are reportedly the most common pelvic injuries in children.[16] Clinical scenarios that have been associated with a pelvic fracture in children include a high-risk mechanism (e.g., motor vehicle collision with/without ejection or rollover; automobile versus pedestrian or bicycle) combined with either a Glasgow coma scale score <14 or pelvic tenderness.[17] Other associations with serious pelvic fractures in children include medically complex children, preexisting bone disease, or developmental delay.[16]

PELVIC FRACTURE PATTERNS

Pelvic fractures include those that involve a break in the pelvic ring, fractures of a single bone without a break in the pelvic ring, and acetabular fractures. Pelvic fractures involving a break in the pelvic ring can be complex and difficult to classify.

The most clinically useful classification, the Young-Burgess Pelvis Fracture Classification System, is presented in a simplified version in **Table 272-1**. This system differentiates fracture patterns based on mechanism of injury and direction of causative force. Incidence of complications (i.e., urogenital and vascular) is correlated with the fracture pattern, making identification of the type more clinically significant and useful.

There are three main types of pelvic fracture patterns: lateral compression, anterior-posterior compression (open-book), and vertical shear. The different injury types may be suggested by history but may often be differentiated radiographically. The alignment of pubic rami fractures is a clue to the mechanism and direction of force. In general, horizontal fractures suggest lateral compression injury, whereas vertical fractures point to vertical shear force. Open-book fractures point to an anteroposterior injury. Based on the recognition of the fracture pattern, one can then predict the likelihood of severe hemorrhage or urogenital injury (Table 272-1).

LATERAL COMPRESSION FRACTURE

Lateral compression fractures are the most common mechanism, accounting for 60% to 70% of pelvic fractures with an overall mortality rate of 8%.[18] Motor vehicle crashes in which a car is broadsided or a pedestrian is struck from the side are examples. At a minimum, a pubic ramus will be fractured. As the pelvis is further compressed and the degree of injury progresses, the sacroiliac joint is crushed, leading to disruption of the posterior ligaments, fracture of the sacrum, and rotation of the contralateral hemipelvis. (**Figure 272-5**).

ANTERIOR-POSTERIOR COMPRESSION OR OPEN-BOOK FRACTURE

Anterior-posterior compression, or open-book fracture, accounts for about 25% of severe injuries. A head-on motor vehicle crash is the classic example. The force is delivered in an anteroposterior direction (arrow in

TABLE 272-1 Abbreviated Young-Burgess Classification System and Potential Incidence of Complications

Category	Characteristics	Severe Hemorrhage (%)	Bladder Rupture (%)	Urethral Injury (%)
Lateral compression fractures	Transverse fracture of pubic rami, ipsilateral or contralateral to posterior injury	60	20	20
Anterior-posterior fractures (open-book)	Symphyseal diastasis and/or longitudinal rami fractures *Secondarily injured structures vary based on severity of AP pelvic fracture*			
	Minimal widening of SI joint with intact posterior ligaments	1	8	12
	Complete SI joint widening with disruption of posterior ligaments	53	14	36
Vertical shear fractures	Separation of symphysis and/or SI joint with vertical displacement anteriorly or posteriorly, occasionally through iliac wing and/or sacrum	75	15	25
Mixed patterns	Combination of other injury patterns, LC/VS being the most common	58	16	21

Abbreviations: AP = anteroposterior; LC = lateral compression; SI = sacroiliac; VS = vertical shear.

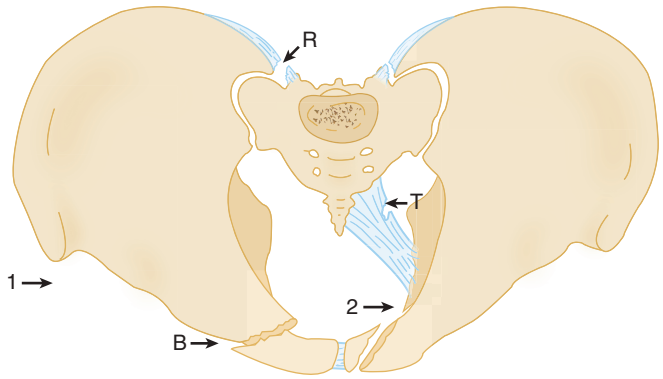

FIGURE 272-5. Lateral compression fracture (*arrows 1 and 2*) with rupture of posterior sacroiliac ligaments (R), sacrospinous/sacrotuberous complex (T), and rupture of pubic ramus (B).

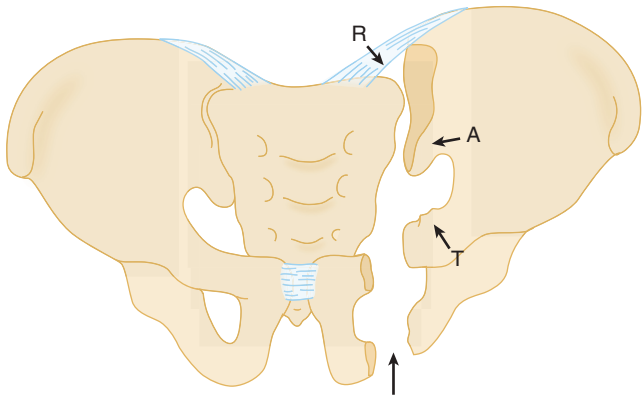

FIGURE 272-7. Vertical shear fracture. Injury vector is delivered in a vertical plane (*arrow*). There is injury to the posterior (R) and anterior (A) sacroiliac ligaments and sacrospinous/sacrotuberous (T) ligaments.

Figure 272-6), tending to "open" the pelvis. This splays the pubic symphysis and ruptures the sacral ligaments (**Figure 272-6**). Finally, total disruption of the sacroiliac joint will occur because of the wide "opening" of the pelvis. All supporting ligament groups, including the posterior sacroiliac ligaments, can be disrupted.

VERTICAL SHEAR FRACTURE

The least common mechanism is **vertical shear fractures**, which are typified by a fall or jump from a height, accounting for approximately 5% of fractures. Combinations of injury patterns can make up the other 20% to 25% of injuries. In vertical shear injury, the injury force vector is delivered in a vertical plane (**Figure 272-7**). Fractures of the pubic rami are usually seen anteriorly, whereas fractures of the sacrum, sacroiliac joint, or iliac wing are usually seen posteriorly. Any of the pelvic ligaments may be disrupted.

AVULSION AND SINGLE-BONE PELVIC FRACTURES

Isolated, closed avulsion fractures of the pelvis or single-bone, closed pelvic fractures are more commonly encountered in the ED than pelvic ring disruptions. It is important to know which of these subsets of fractures require further diagnostic testing, orthopedic consultation, or admission.

Isolated fractures of the anterior superior iliac spine, anterior inferior iliac spine, ischial tuberosity, pubic ramus, body of the ischium, iliac wing, sacrum, or coccyx typically do not disrupt the pelvic ring and, as a result, typically do not require surgical repair (**Figure 272-8** and **Table 272-2**). Most of these fractures require only appropriate analgesia, crutches, either bed rest or non–weight-bearing status, and orthopedic follow-up on an outpatient basis.

Simple fractures in the elderly may not be as benign as at first glance. If indicated by physical exam or mechanism of injury, obtain a CT scan of the pelvis with bone windows to detect occult posterior pelvic ring disruption that will alter management (**Figures 272-9** and **272-10**).[15] Although isolated pelvic ramus fractures are frequently due to low-impact trauma (e.g., fall from standing) in the elderly, isolated pelvic fractures still result in an increased rates of hospital admission, morbidity, need for living assistance after hospital discharge, and overall mortality at 1 year.[19]

Pay special attention to isolated fractures of either the sacrum or iliac wing due to the tremendous amount of force that has occurred. If there is concern for associated injuries, then a more extensive evaluation is mandated with admission for observation.

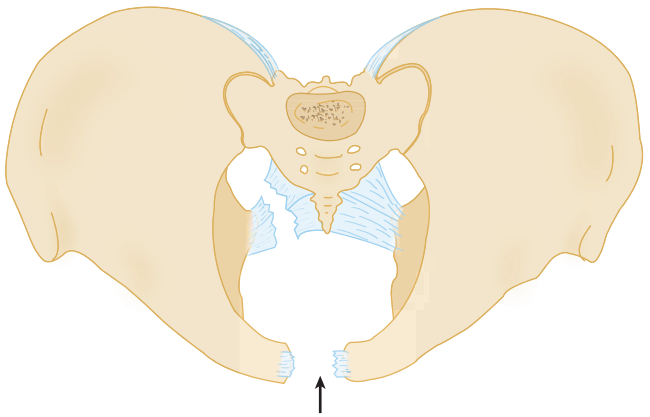

FIGURE 272-6. Open-book fracture, with opening of the anterior pelvis (*arrow*) and rupture of the sacral ligaments.

ACETABULAR FRACTURES

Acetabular fractures are usually secondary to motor vehicle crashes. The fracture force is either transmitted laterally through the hip or posteriorly through the femur as with a knee-versus-dashboard mechanism. Acetabular fractures are seen commonly with other injuries, including pelvic, femur, and hip fractures and dislocations (**Figure 272-11A**), and

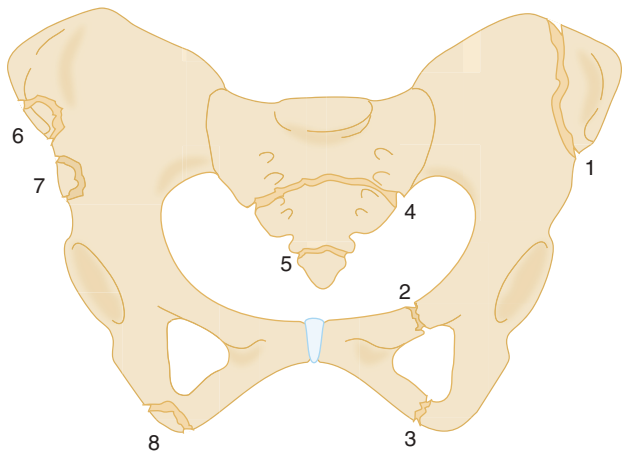

FIGURE 272-8. Avulsion fractures of the pelvis. (1) Iliac wing fracture (Duverney fracture). (2) Superior pubic ramus fracture. (3) Inferior pubic ramus fracture. (4) Transverse sacral fracture. (5) Coccyx fracture. (6) Anterior superior iliac spine avulsion. (7) Anterior inferior iliac spine avulsion. (8) Ischial tuberosity avulsion.

TABLE 272-2 Avulsion and Single Bone Fractures

Fracture	Description/Mechanism of Injury	Clinical Findings/Associated Injuries	Treatment	Disposition and Follow-Up
Iliac wing (Duverney) fracture	Direct trauma, usually lateral to medial	Swelling, tenderness over iliac wing; abdominal pain; ileus; acetabular fractures; serious injury infrequent	Analgesics, non–weight-bearing until hip abductors pain-free, usually nonoperative	Discharge with orthopedic follow-up in 1–2 wk; admit for open fracture or concerning abdominal examination
Single ramus of pubis or ischium	Fall or direct trauma in elderly; exercise-induced stress fracture in young or in pregnant women	Local pain and tenderness; may have inability to ambulate	Analgesics, crutches	Discharge with PCP or orthopedic follow-up in 1–2 wk
Ischium body	External trauma or from fall in sitting position; least common pelvic fracture	Local pain and tenderness; pain with hamstring movement	Analgesics, bed rest, donut-ring cushion, crutches	Discharge with orthopedic follow-up in 1–2 wk
Sacral fracture	Transverse fractures from direct anteroposterior trauma; upper transverse fractures from fall in flexed position	Pain on rectal examination; sacral root injury with upper transverse fractures; vertical fractures may transect the pelvic ring	Analgesics, bed rest, surgery may be needed for displaced fractures or neurologic injury	Discharge with orthopedic follow-up in 1–2 wk; orthopedic consultation for displaced fractures or neurologic deficits
Coccyx fracture	Fall in sitting position; more common in women	Pain, tenderness over sacral region; pain on compression during rectal examination	Analgesics, bed rest, stool softeners, sitz baths, donut-ring cushion	PCP or orthopedic follow-up in 2–3 wk; surgical excision of fracture fragment if chronic pain
Anterior-superior iliac spine	Forceful sartorius muscle contraction (e.g., adolescent sprinters)	Pain with hip flexion and abduction	Analgesics, bed rest for 3–4 wk with hip flexed and abducted, crutches	Discharge with orthopedic follow-up in 1–2 wk
Anterior-inferior iliac spine	Forceful rectus femoris muscle contraction (e.g., adolescent soccer players)	Pain in groin; pain with hip flexion	Analgesics, bed rest for 3–4 wk with hip flexed, crutches	Discharge with orthopedic follow-up in 1–2 wk
Ischial tuberosity	Forceful contraction of hamstrings	Pain with sitting or flexing the thigh	Analgesics, bed rest for 3–4 wk in extension, external rotation, crutches	Discharge with orthopedic follow-up in 1–2 wk

Abbreviation: PCP = primary care physician.

FIGURE 272-11. A. Left posterior hip dislocation with avulsed fracture fragments of the posterior acetabular rim. B. Multiple curvilinear lucencies demonstrating nondisplaced fractures (*arrows*) of the right acetabulum and right ischium. Pubic symphysis is also slightly widened.

knee injuries. However, these fractures may be subtle and, as a result, necessitate careful inspection on x-ray (**Figure 272-11B**). If an acetabular fracture is suspected, it can be evaluated with an anteroposterior film, a 45-degree iliac oblique, and a 45-degree obturator oblique view—together known as *Judet views*. **CT is more sensitive than radiography in detecting acetabular injury.**[20] Also, CT is able to give more detailed information about the displacement of fracture fragments, degree of comminution, and other information that is useful in preoperative planning.

Patients with acetabular fractures require hospital admission and orthopedic consultation. Look for associated visceral, neurovascular, and orthopedic injuries. Sciatic nerve injury is a common complication.

TREATMENT

Prevent movement of fracture segments, particularly in the hemodynamically unstable patient. The pelvis can be temporarily yet quickly stabilized with a bed sheet or other pelvic binding device to reduce pelvic volume and stabilize fracture ends.[21-23] The simplest technique is the application of either a folded bed sheet secured with towel clips or a commercially manufactured binder that is tightly wrapped around the pelvis at the level of the greater trochanters. A pelvic binder can decrease the volume of the pelvis and, in turn, help diminish blood loss for both open-book and vertical shear fractures. Lateral compression pelvic fractures would not benefit from the application of a pelvic binder because they are already rotated internally; in fact, these patients may be harmed from further lateral compression.[24]

Provide resuscitation as needed with crystalloid, blood, and blood products. **Retroperitoneal bleeding may complicate pelvic fractures. Up to 4 L of blood can be accommodated in the pelvis, until vascular pressure is overcome and tamponade occurs.** Most bleeding is due to low-pressure venous bleeding and bleeding from mobile bone edges. Predictors for the need for either a transfusion or a therapeutic intervention due to hemorrhage include: (1) initial hematocrit less than 30%, (2) presence of pelvic hematoma on CT scan, or (3) a systolic blood pressure of less than 90 mm Hg upon arrival.[25] Presence of any of these factors mandates close observation of the patient in an intensive care setting.[25] Moreover, a recent prospective study showed that base deficit <6 mmol/L or worsening base deficit >2 mmol/L while in the ED also significantly correlated with the need for either angiography or laparotomy.[26]

FAST, CT, AND PELVIC FRACTURE

In hemodynamically unstable trauma patients with pelvic fractures, carefully evaluate for other sources of blood loss. Patients who have sustained a pelvic fracture from a significant mechanism of injury should undergo a thoraco-abdomino-pelvic CT scan even if the FAST is negative. In the presence of pelvic fracture and serious mechanism blunt trauma, FAST-negative patients are still very likely to have concomitant visceral injury.[27]

If the FAST examination reveals free intraperitoneal fluid (**Figure 272-12**), then CT scan is also needed to determine the next treatment step. The FAST false-positive rate for intraperitoneal hemorrhage in patients with pelvic ring disruption can be up to 30%.[28,29] Distortion of the anatomy from fractures, retroperitoneal bleeding, urine from ruptured bladder, or pelvic hematomas may result in fluid collections that mimic free intraperitoneal fluid. The sensitivity and specificity of FAST for free peritoneal blood in major pelvic injury appear to be related to the severity of the pelvic fracture.[28,29]

One study reported the overall sensitivity and specificity of FAST to detect free peritoneal fluid in major pelvic injury to be 81% and 87%, respectively.[29] The fluid was blood in 76% and urine in 19%.[29] Moderate to large free fluid as evidenced by fluid noted in two or more regions of

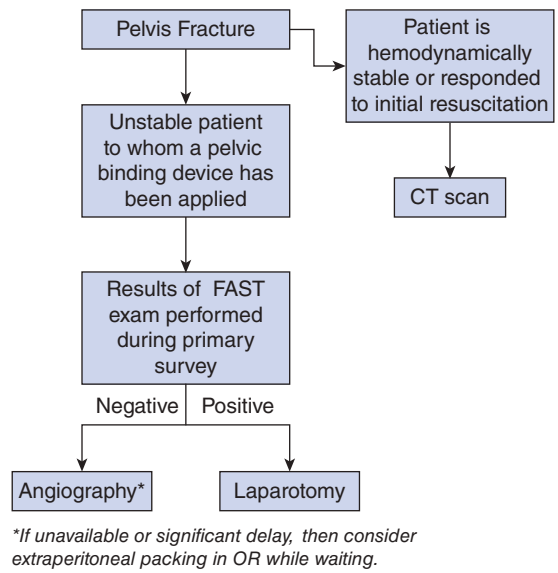

FIGURE 272-12. Suggested algorithm for pelvic fracture treatment. FAST = focused abdominal sonogram for trauma; OR = operating room.

the FAST exam is reported to be associated with the need for hemorrhage control, either by laparotomy or angiography.[30]

ANGIOGRAPHY, EMBOLIZATION, AND EXTERNAL FIXATION

If a patient with a pelvic fracture is hemodynamically unstable and other sources of bleeding (e.g., splenic or liver laceration) have been excluded through CT scan or laparotomy, treatment options include angiography with embolization, with or without external fixation of the pelvic fracture. Angiographic embolization is effective at controlling arterial bleeding, and external fixation is thought to be effective at controlling venous bleeding.[31,32] Both may be needed to control hemorrhage.

Shock and death are generally due to arterial rather than venous bleeding.[12,13,33,34] Arterial bleeding can occur in all types of pelvic fractures yet does so in only 10% to 15% of cases.[31] The arteries involved are typically branches of the internal iliac system, with the superior gluteal artery and the obturator artery being the most common (Figure 272-2). Hemorrhage from pelvic fractures refractory to resuscitation is more likely arterial than venous in origin; angiography and embolization can control arterial hemorrhage in most patients.[31-33] **Consider angiography early in a hemodynamically unstable patient with a pelvic fracture, after other sources of bleeding have been excluded.**

Contrast extravasation on CT is considered by many to be an indication for angiography to evaluate for an arterial source of bleeding that may be amenable to embolization.[12,13,32,35] Some protocols advocate angiography based on hemodynamic status, the need for ongoing blood transfusion, or in patients who meet certain blood transfusion amounts.[13,31] No intervention is needed for nearly half of all patients who demonstrate a pelvic blush on CT scan without clinical signs of ongoing bleeding.[36] The need for arterial embolization has a positive predictive value of 39% for death in open pelvis fractures, as noted in one recent study.[4]

Another hemorrhage control method used in the treatment of pelvic fractures is extraperitoneal packing. This technique involves surgically placing packing in the pelvis to reduce the potential space needed to tamponade bleeding. Consider this treatment option for an unstable patient who is bleeding secondary to a significant pelvis fracture in a hospital where angiography is not readily available, when a laparotomy is needed prior to angiography, or the patient is in extremis and needs quick stabilization prior to angiography.[25]

The definitive treatment of pelvic fractures occurs once the patient has been stabilized and after other associated injuries have been addressed. All pelvic fractures require orthopedic consultation and admission, even in the most stable of patients. Elderly patients with simple pubic ramus fractures typically require admission for pain control, observation for complications, and physical therapy for ambulation. The exact treatment of pelvic fractures is guided by fracture location and pelvic stability. Fractures that disrupt the pelvic ring need open reduction and internal fixation within 5 to 14 days of injury.[37] The decision as to which service to which to admit the patient will vary between hospitals and depend on multiple factors including the presence of a trauma surgery service, volume of orthopedic cases, comorbidities of the patient, and absence of other significant injuries.[38]

COMPLICATIONS OF PELVIC FRACTURES

Acute complications and associated injuries of pelvic fractures include urogynecologic injury, rectal injury, ruptured diaphragm, and nerve root injury. Pelvic fractures can also have long-term effects, including chronic pain, sexual dysfunction, and persistent functional disability.

UROGYNECOLOGIC INJURY

If a urethral injury is suspected clinically, perform retrograde urethrography before placing a Foley catheter. Urinary tract injuries are discussed in greater detail in chapter 265, "Genitourinary Trauma." Gynecologic injuries are uncommon with pelvic trauma. Vaginal laceration can occur with anterior pelvic fractures. Perform a bimanual pelvic examination on women with pelvic fractures. If blood is detected, a speculum examination is needed to identify vaginal hematoma, laceration, or urethral bleeding.

RECTAL INJURY

Rectal injuries are uncommon and are usually associated with urinary injuries and ischial fractures. Diagnosis is by careful rectal examination or by proctoscopy, during which gross blood is found in the rectum. Treatment includes early diverting colostomy with washout of the distal colon and presacral space drainage. Antibiotics that cover gram-negative organisms should be administered as soon as the injury is discovered.

NERVE ROOT INJURY

Nerve root or peripheral nerve injuries can occur because of traction, pressure from hemorrhage, callus or fibrous tissue, and impingement laceration by bone fragments. The onset of symptoms and signs may be delayed, but deficits usually follow a nerve root pattern. Lumbar nerve root injuries are associated with sacroiliac joint dislocation or fracture and longitudinal displacement of the fracture.[14] Sacral root injuries are associated with transverse fractures of S1 and S2 as can be seen secondary to trauma from a suicidal jump (Figure 272-4).[14]

CHAPTER 273

Hip and Femur Injuries

Mark Steele
Amy M. Stubbs

INTRODUCTION AND EPIDEMIOLOGY

Injuries to the hip and femur are common, occurring most often in the elderly population secondary to falls. Hip fractures are a significant and costly public health concern. Age, race, and gender are important risk factors for hip injuries; the incidence is more than two times greater in women than in men.[1]

Morbidity and mortality from hip and femur fractures are due to complications from prolonged immobilization, with venous thromboembolism being the most common complication. Patients with hip fracture have a five- to almost eightfold increased risk of all-cause mortality in the first 3 months after the injury, and increased mortality persists for years afterward. Another significant portion of patients will have markedly decreased functional capacity. Advanced age, male gender, and comorbidities all increase mortality risk following hip fracture.[2]

This chapter discusses the diagnosis and ED management of fractures of the hip and proximal femur, fractures of the femoral shaft, and anterior and posterior hip dislocations. Fractures involving the femoral condyles are discussed in chapter 274, Knee Injuries.

ANATOMY AND PATHOPHYSIOLOGY

For purposes of this chapter, we define the hip as the anatomic region including the head and neck of the femur to 5 cm distal to the lesser trochanter. The femoral shaft is the portion of the femur distal to the lesser trochanter, down to but not including the femoral condyles.

The hip is a ball-and-socket joint formed by the femoral head and the acetabulum. The fibrous capsule that surrounds the joint on all sides is quite strong, attaching proximally at the acetabulum and distally on the intertrochanteric line on the anterior surface. The joint capsule is weakest posteriorly where it attaches to the femoral neck. The femoral head and shaft are connected at the obliquely angled femoral neck. Blood is supplied to the femoral head mainly from the medial and lateral femoral circumflex arteries that form an extracapsular ring with branching retinacular arteries in the joint capsule. Therefore, intracapsular fractures can compromise blood supply to the femoral head. Less important blood

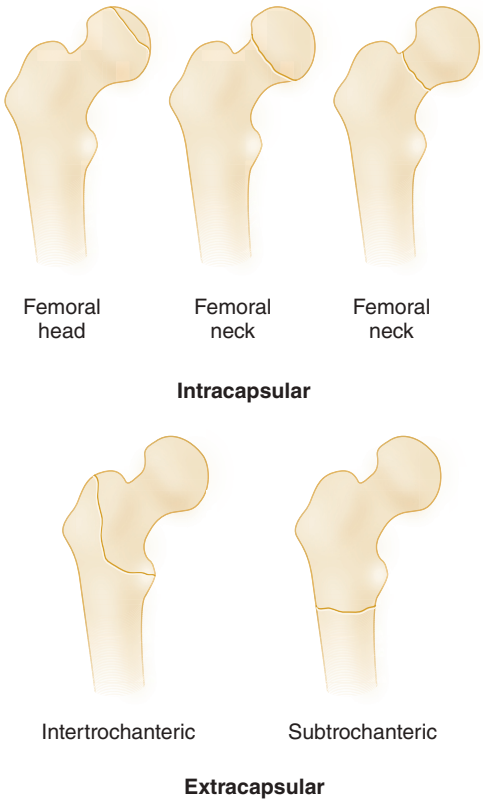

FIGURE 273-1. Fractures of the proximal femur are traditionally classified as intracapsular and extracapsular.

supply includes branches of the obturator and gluteal arteries, with a small contribution from the foveal artery at the ligamentum teres.

Hip fractures are classified as **intracapsular** (femoral head and neck) or **extracapsular** (trochanteric, intertrochanteric, and subtrochanteric). See **Figures 273-1** and **273-2** and **Table 273-1**. The prognosis for successful union and restoration of normal function varies considerably with the fracture type. Most fractures occur in older patients with osteoporosis or other bony pathology secondary to systemic disease. Younger patients are more likely to have femoral shaft fractures or hip dislocation secondary to high-energy trauma.

In intracapsular fractures with displacement, blood supply to the femoral head may be compromised due to direct injury to the blood vessels, tension from the fracture, or compression secondary to a hemarthrosis. Urgent reduction of the fracture may restore blood flow, although avascular necrosis occurs in 15% to 35% of patients unless some of the capsular vessels remain intact.[3] Extracapsular fractures less commonly cause vascular compromise.

CLINICAL FEATURES

HISTORY

History of a recent fall or motor vehicle crash suggests the possibility of hip fracture and other injuries. Falls should also prompt questioning about possible syncope, especially in the ill or elderly. Understanding the mechanism of injury can identify associated fractures, such as fractures of the pelvis or about the knee. Important historical factors, such as cancer, chronic kidney disease, or prolonged steroid use, increase the risk of osteoporosis, avascular necrosis, and pathologic fractures.

Patients with hip fracture or dislocation will typically have pain at the site of the injury, but may also report knee pain, groin pain, or pain at sites of other injuries. Determine the duration of immobilization to assess for dehydration, venous thrombosis, or rhabdomyolysis.

PHYSICAL EXAMINATION

After the primary survey and stabilization, carefully examine the patient for deformities, shortening, rotation, lacerations, bruising, or instability of the limbs or tenderness of the pelvis or sacrum. Note any focal tenderness or crepitance. If no significant abnormalities are found, evaluate range of motion of the hips. If rotation of the hip with the leg in extension is painful, avoid other hip maneuvers. Identification of a hip or pelvic injury in a trauma victim should raise suspicion for concomitant intra-abdominal, retroperitoneal, femoral shaft, knee, or urologic

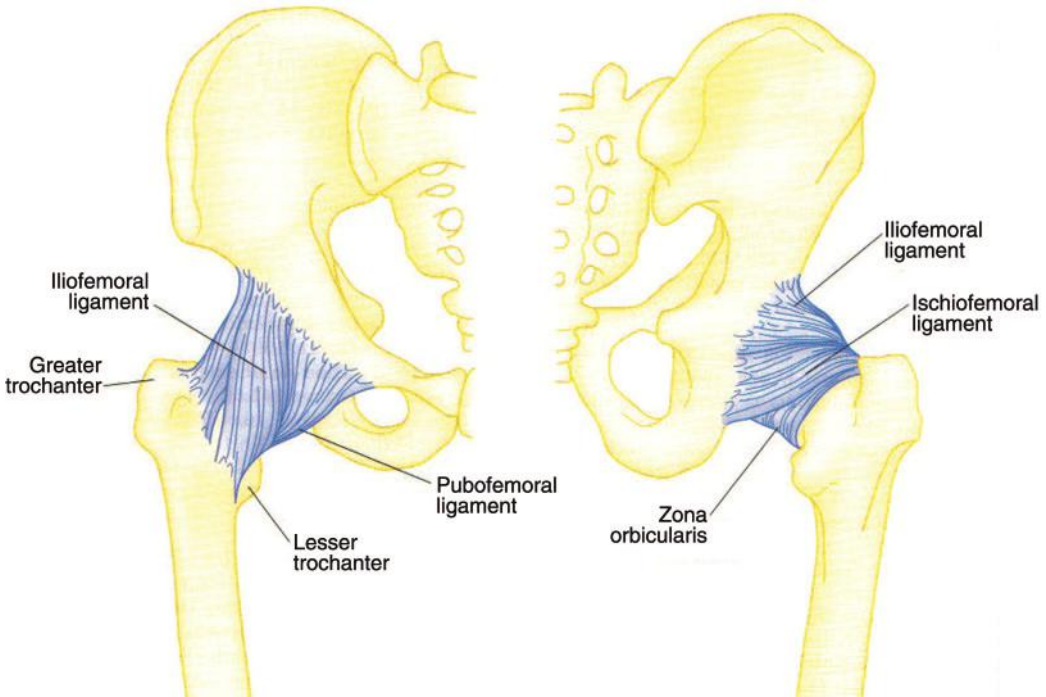

FIGURE 273-2. Hip and joint capsule.

TABLE 273-1 Proximal Femur Fractures: Demographics and Clinical Features

Fracture	Incidence/Demographics	Mechanism	Clinical Findings	Concomitant Injuries
Femoral head	Isolated fracture rare; seen in 6%–16% of hip dislocations	Usually result of high-energy trauma; dashboard to flexed knee most common	Limb shortened and externally rotated (anterior dislocation); shortened, flexed, and internally rotated (posterior dislocation)	Closed head injury; intrathoracic and/or intra-abdominal injuries; pelvic fracture, knee injuries
Femoral neck	Common in older patients with osteoporosis; rarely seen in younger patients	Low-impact falls or torsion in elderly; high-energy trauma or stress fractures in young	Ranges from pain with weight bearing to inability to ambulate; limb may be shortened and externally rotated	Ipsilateral femoral shaft fracture
Greater trochanteric	Uncommon; older patients or adolescents	Direct trauma (older patients); avulsion due to contraction of gluteus medius (young patients)	Ambulatory; pain with palpation or abduction	—
Lesser trochanteric	Uncommon; adolescents (85%) > adults	Avulsion due to forceful contraction of iliopsoas (adolescents); avulsion of pathologic bone (older adults)	Usually ambulatory; pain with flexion or rotation	—
Intertrochanteric	Common in older patients with osteoporosis; rare in younger patients	Falls; high-energy trauma	Severe pain; swelling; limb shortened and externally rotated	Anemia from blood loss into thigh; concomitant traumatic injuries
Subtrochanteric	Similar to intertrochanteric; 15% of hip fractures	Falls; high-energy trauma; may also be pathologic	Severe pain; ecchymosis; limb shortened, abducted, and externally rotated	Vascular injuries, anemia/hypovolemic shock from fracture itself or other traumatic injuries

injuries. Perform a rectal exam if concern exists for concurrent spinal or pelvic injuries, including evaluation of the prostate in males.

Injuries to the hip and femur should also raise concern for damage to adjacent nerves and vasculature, especially the femoral and sciatic nerves and femoral blood vessels. **Assess motor and sensory function of these nerves and their major branches (Table 273-2).** Evaluate pulses distal to the site of injury, including popliteal, dorsalis pedis, and posterior tibialis pulses. If concern exists for vascular injury, further testing should be performed and may include ankle-brachial indices, angiography, or duplex US.

DIAGNOSIS

IMAGING

Consider radiographic evaluation of the pelvis and hips in all unconscious patients who have sustained multiple injuries or have a concerning mechanism for pelvic, hip, or lower extremity injury.

Include anteroposterior and lateral views of the hip in the initial radiographic evaluation. An anteroposterior pelvis view is also useful as it allows comparison of both sides. Conventional radiographs are estimated to be 90% to 98% sensitive for hip fractures.[4] Other views may be requested by consulting orthopedists; in certain instances, additional views (e.g., Judet view) may allow better identification and detail of the acetabulum or femoral head and neck. Imaging of the femoral shaft or knee may also be necessary, following the adage to **assess the joint above and the joint below the injury**.

Pain with weight bearing in the face of normal radiographs should raise suspicion for occult fracture, especially at the femoral neck or acetabulum.[5] MRI is highly sensitive (nearly 100%) for occult fractures and is also useful in identifying other injuries that may explain the patient's symptoms. CT may be useful in identifying nondisplaced fractures not easily seen on conventional radiographs but is not as sensitive or accurate as MRI for occult fracture. Although bone scanning is sensitive for detecting occult fracture, neoplasm, and avascular necrosis, MRI has largely replaced it.[4-7]

TABLE 273-2 Motor and Sensory Evaluation of Sciatic and Femoral Nerves

Nerve	Motor	Sensory
Sciatic	Knee flexion	
Common peroneal	Dorsiflexion of foot and toes	Lateral lower leg, first web space of foot
Tibial	Plantarflexion of foot and toes	Posterior lower leg
Femoral		
Anterior branch	Hip flexion	Anterior and medial thigh
Posterior branch	Knee extension	Medial lower leg

HIP FRACTURES

FEMORAL HEAD FRACTURES

Isolated femoral head fractures are uncommon and are typically associated with dislocations of the hip (Table 273-1). The signs and symptoms are often from the dislocation rather than from the fracture itself. They are usually best seen on radiographs obtained after reduction of a hip dislocation.

The standard anteroposterior and lateral views usually demonstrate the fragment adequately. Judet views or thin-cut CT scans are often recommended for further evaluation of the acetabulum and fracture fragmentation.

Treatment is to reduce the associated dislocation and then attain anatomic reduction of the fracture fragment (**Table 273-3**). See subsequent section on dislocations for further discussion. Management of concomitant life-threatening injuries due to high-energy trauma must take priority.

Prognosis is related to the severity of the initial trauma resulting in the dislocation and associated injuries, delay to reduction, and repetitive unsuccessful reduction attempts.[8]

FEMORAL NECK FRACTURES

Femoral neck fractures are most commonly seen among older adults with osteoporosis and occur more frequently in women than in men. Falls are the most common cause (90%), but stress or traumatic femoral neck fractures may be seen in younger patients (Table 273-1).[9] There are multiple classification systems for femoral neck fractures, but it is most useful to describe them as displaced or nondisplaced. **Femoral neck fractures are intracapsular, and blood supply to the femoral head may be disrupted.**

The symptoms seen with femoral neck fractures range from complaints of mild pain in the groin or inner thigh in patients with an incomplete fracture, to moderate to severe pain in patients with displaced fractures. Patients with nondisplaced fractures may be somewhat ambulatory, whereas those with displaced fractures are typically unable

TABLE 273-3 Proximal Femur Fractures: Treatment Issues

Fracture	ED Management	Disposition and Follow-Up	Complications
Femoral head	Immediate orthopedic consultation; emergent closed reduction of dislocation; ORIF if closed reduction is unsuccessful	Admission to orthopedic or trauma service	AVN; posttraumatic arthritis; sciatic nerve injury; heterotopic ossification
Femoral neck	Orthopedic consultation; ranges from nonoperative to total hip arthroplasty	Admission to orthopedic service	AVN; infection; DVT and/or pulmonary embolus
Greater trochanteric	Analgesics; protected weight bearing	Orthopedic follow-up 1–2 wk; possible ORIF if displacement >1 cm	Nonunion rare
Lesser trochanteric	Analgesics; weight bearing as tolerated; evaluate for possible pathologic fracture	Orthopedic or PCP follow-up in 1–2 wk; admit or urgent follow-up for pathologic fracture	Nonunion rare
Intertrochanteric	Orthopedic consultation	Admit for eventual ORIF; may need preoperative testing and clearance by PCP or hospitalist	DVT and/or pulmonary embolism; infection
Subtrochanteric	Orthopedic consultation; consider Hare® or Sager® splint	Admit for ORIF	DVT and/or pulmonary embolism; infection; malunion (shortened limb); nonunion

Abbreviations: AVN = avascular necrosis; DVT = deep venous thrombosis; ORIF = open reduction and internal fixation; PCP = primary care physician.

to bear weight at all. Examination findings can be subtle in nondisplaced fractures, while displaced fractures are quite evident with the leg held in external rotation, abduction, and shortened (**Figure 273-3**).

Radiographic evaluation is essential in any patient suspected of having a femoral neck fracture. Ideally, the standard anteroposterior view should have the patient internally rotated as much as patient condition allows to best demonstrate the femoral neck. Nondisplaced fractures may be subtle. The anteroposterior view should be inspected for a fracture line starting on the superior surface of the neck (**Figure 273-4**). Disruption of **Shenton's line**, a smooth curvilinear line along the superior border of the obturator foramen and the medial aspect of the femoral metaphysis, may be appreciated on the anteroposterior view in some instances (**Figure 273-5**). Evaluate the **neck-shaft angle** in suspected fractures; normal is 120 to 130 degrees (**Figure 273-6**). The neck-shaft angle is measured at the intersection of lines drawn down the axis of the femoral shaft and the femoral neck.[10] Displaced fractures are obvious on the anteroposterior view, but a lateral view should also be obtained to ascertain the exact fracture position. Approximately 6% to 9% of patients with a femoral neck fracture will have an ipsilateral femoral shaft fracture.[11]

Treat pain, immobilize the extremity in a position of comfort, and obtain orthopedic consultation in the ED. **Skeletal traction is contraindicated for femoral neck fractures because it may further compromise femoral head blood flow.**

FIGURE 273-4. Radiograph of femoral neck fracture. The disruption of the bone is most visible when following the superior surface of the femoral neck. Also notice the shortening and impaction of the femoral neck.

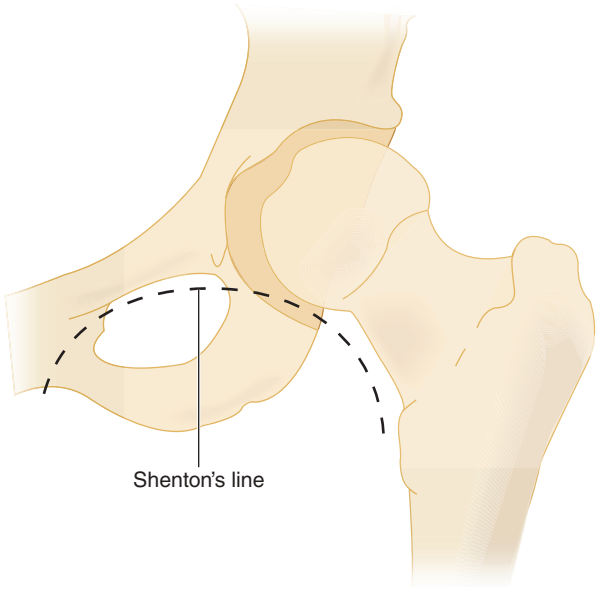

FIGURE 273-5. Shenton's line.

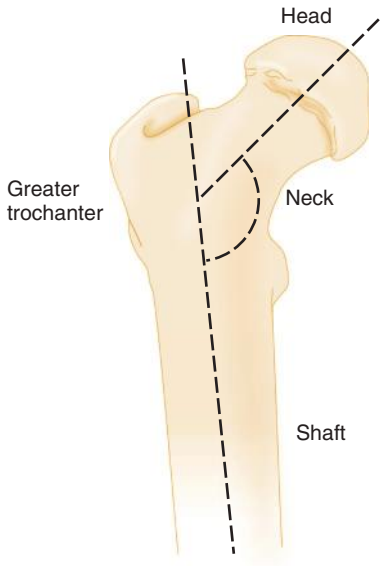

FIGURE 273-6. Neck-shaft angle.

For both displaced and nondisplaced fractures, outcomes are generally best with surgical fixation because this leads to earlier mobilization and less morbidity and mortality than with conservative management.[12,13] Decisions regarding the timing and type of operative intervention depend on the patient's physiologic age, activity level, and fracture severity.[14] Conservative treatment may be considered in those whose operative risk outweighs potential benefit or in patients who are not ambulatory.

The complications of femoral neck fractures are significant (Table 273-3). Prognosis is related to the number and severity of complications. A higher grade of fracture displacement also implies a worse prognosis for healing and repair.

ISOLATED TROCHANTERIC FRACTURES

Greater trochanteric fractures are usually caused by avulsions at the insertion of the gluteus medius. In the younger population (7 to 17 years of age), this is a true epiphyseal separation, in contrast to the adult population, in whom the cause is direct trauma (Table 273-1).

Lesser trochanteric fractures caused by an avulsion secondary to forceful contraction of the iliopsoas are commonly seen in children and young athletic adults, particularly gymnasts and dancers. Lesser trochanter fractures in older patients with minimal trauma should be considered pathologic until proven otherwise.[15]

Standard anteroposterior and lateral views reveal the displacement. CT of the pelvis may be helpful if a fracture is strongly suspected but difficult to visualize.

In most instances, the treatment is crutches with weight bearing as tolerated until orthopedic follow-up is obtained within 3 to 5 days, and then gradually increasing to full activity. Full recovery generally occurs in patients with healthy bone. Operative fixation may be indicated in cases where there is significant displacement of the fracture fragment (Table 273-3).

INTERTROCHANTERIC FRACTURES

Intertrochanteric fractures are defined as extracapsular fractures occurring in a line between the greater and lesser trochanters. They generally occur in the elderly and are more common in women, again due to the high incidence of osteoporosis. The mechanism of injury is usually a fall (**Table 273-1**).

Patients typically have marked pain and deformity on examination, and fractures are usually easily visualized on standard anteroposterior and lateral views. Intertrochanteric fractures should be classified as stable or unstable based on the number of fracture lines and the amount of displacement.[16]

After life-threatening injuries have been excluded, the consulting orthopedic physician can then admit the patient to the hospital and perform surgical fixation as soon as possible (Table 273-3). Skin traction is not recommended for either stabilization or pain control.[17,18]

The complications and prognosis are related to associated injuries and prior disease. **Blood loss into the leg can be significant, and some patients will require crystalloid or blood transfusion.**[19] Infection and pulmonary embolism are the main complications. Avascular necrosis and nonunion are uncommon complications.

SUBTROCHANTERIC FRACTURES

Subtrochanteric fractures may be seen in three different populations: older patients with osteoporosis who fall (Table 273-1), younger patients as a result of major trauma, or patients with bony metastases.

The symptoms and signs are similar to those of intertrochanteric or femoral shaft fractures: localized pain, deformity, swelling, and crepitance. Significant blood loss may develop. Evaluate for concomitant life-threatening injuries.

Standard anteroposterior and lateral views of the hip are typically sufficient to evaluate these fractures. Consider radiographic studies of the pelvis, femur, and knee to exclude associated fractures.

ED treatment consists of pain control, immobilization, and orthopedic consultation. Hare® (Dynamed, Westbury, Tasmania) or Sager® (Minto Research and Development, Inc., Redding, CA) splints (**Figures 2-7** and **2-8,** respectively) are commonly employed in the prehospital setting and infrequently in the ED (also see chapter 2, Prehospital Equipment and Adjuncts). Traction splinting may ease pain and provide some fracture reduction.[18] Do not apply a traction splint if there is open fracture, suspected pelvic fracture, hip dislocation, suspicion for neurovascular injury to the extremity, or injury about the knee, as a traction splint may exacerbate neurovascular or knee injury. Operative reduction/internal fixation is generally indicated for complicated fracture management.

OCCULT HIP FRACTURES

Symptoms suggestive of fracture, but with negative plain radiographs, are called occult hip fractures.[4] Anywhere from 3% to 38% of hip fractures are initially "occult."[6] Stress, incomplete, or nondisplaced fractures may not become evident on plain radiographs for days or weeks after injury. **Pain with axial loading, restricted mobility prior to the injury, and risks for osteoporosis should all raise suspicion for occult fracture.**[20] MRI is the imaging of choice because it is both sensitive and specific.[4] If clinical suspicion is high, obtain an MRI in the ED, or if that is not possible, obtain an MRI within the next 24 to 48 hours—with the patient non–weight bearing until diagnosis is confirmed and orthopedic follow-up is obtained.

FEMORAL SHAFT FRACTURES

Fractures of the shaft of the femur most often occur in younger patients secondary to high-energy trauma; associated traumatic injuries are common. Severe, direct trauma may result in transverse fractures (most common) with displacement, oblique or spiral oblique fractures, or comminuted segments. Pathologic fractures are uncommon but can occur secondary to metastases or to primary bone tumors. Femoral shaft fractures are generally evident in the prehospital setting because of the shortening, deformity, and associated swelling. Initial stabilization of the patient should take place in the field along with spinal immobilization. It is generally advised to splint the affected extremity with a traction splint at the time of injury, to minimize pain, prevent further fracture comminution, and minimize blood loss. Hare® or Sager® traction splints can be placed over the trousers, applying traction to a sling around the ankle and forefoot. Traction splints are contraindicated in cases of open fracture or in suspected sciatic nerve, knee, or vascular injury. For the latter, splint placement without application of traction is indicated.

Neurovascular examination of the affected extremity is important since sciatic nerve injury, though uncommon, can occur (Table 273-2). The fracture is typically evident on standard anteroposterior and lateral views of the femur. Evaluation, including a thorough exam and imaging, of the joints above and below (pelvis, hips, knees) is generally needed to assess for other orthopedic injuries. Open femur fractures require broad-spectrum antibiotics and copious irrigation. Further irrigation and debridement are accomplished in the operating room. Obtain early orthopedic consultation; most patients require surgical intervention. Blood loss can be significant from the fracture itself or from other injuries.

Intermedullary nailing is the preferred treatment for most femoral shaft fractures. In severely contaminated open fractures, external fixation may be the preferred method of treatment. Patients with severe concomitant injuries may benefit from early external fixation and delayed operative reduction and internal fixation.[21]

A

B

FIGURE 273-7. Posterior dislocation of the hip. **A.** Posterior dislocation of the hip. **B.** The clinical appearance of a posterior dislocation of the right hip.

HIP DISLOCATION

Dislocations of native hips typically result from high-energy trauma, and up to 95% of patients have other associated injuries.[22] Motor vehicle crash is the most common cause. **Posterior dislocations of native hips account for >90% of dislocations**; the remaining 10% are anterior and can be classified as superior or inferior.[23] Dislocations of prosthetic hips can occur with minimal trauma. This section discusses the diagnosis and management of posterior and anterior native hip dislocation and the ED management of prosthetic hip dislocation.

Hip dislocations (dislocations of native hips) are orthopedic emergencies and should be reduced as quickly as possible, preferably within 6 hours of the event, in order to reduce the risk of avascular necrosis to the femoral head. Dislocations with neurovascular compromise need reduction as soon as possible. Treatment options include closed reduction of posterior hip dislocations or prosthetic hip dislocations in the ED under procedural sedation, or in the operating room with general anesthesia. Anterior hip dislocations require reduction in the operating room. Open reduction by an orthopedic surgeon is indicated for irreducible fractures, unsatisfactory reductions, and complex fracture dislocations.[23]

POSTERIOR HIP DISLOCATION AND REDUCTION MANEUVERS

Posterior hip dislocations (**Figure 273-7**) are caused by posterior force applied to a flexed knee, most commonly a dashboard injury from high-speed motor vehicle crashes. Acetabular fractures often result; femoral neck, femoral shaft, and knee injuries are often seen as well. On examination, the extremity is shortened, internally rotated, and adducted. Perform a careful neurovascular examination to identify associated sciatic nerve injury or vascular injury (Table 273-2).

Anteroposterior and lateral radiographs of the pelvis and hip identify the posterior dislocation (**Figure 273-8**), but further assessment of the acetabulum and femur must be performed, either with Judet views or CT, to evaluate for associated fractures. Hip dislocations are difficult to recognize if there is an associated femoral shaft fracture, so routinely obtain radiographs of the pelvis and hips in such cases. **Complications of posterior dislocation include sciatic nerve injury in approximately 10% of patients and avascular necrosis of the femoral head that increases in direct proportion to the delay in anatomic reduction.**

Multiple techniques exist for closed reduction of posterior hip dislocations (Figures 273-9 to 273-12); it is advisable for the ED physician to be proficient with more than one technique. Nearly all of the techniques involve providing in-line traction while flexing the hip to 90 degrees, and then performing gentle internal-to-external hip rotation.

The **Allis maneuver** is the most commonly performed technique. In-line traction is performed with simultaneous hip flexion and internal

FIGURE 273-8. Radiograph of posterior hip dislocation. There is also a concomitant acetabular fracture visible.

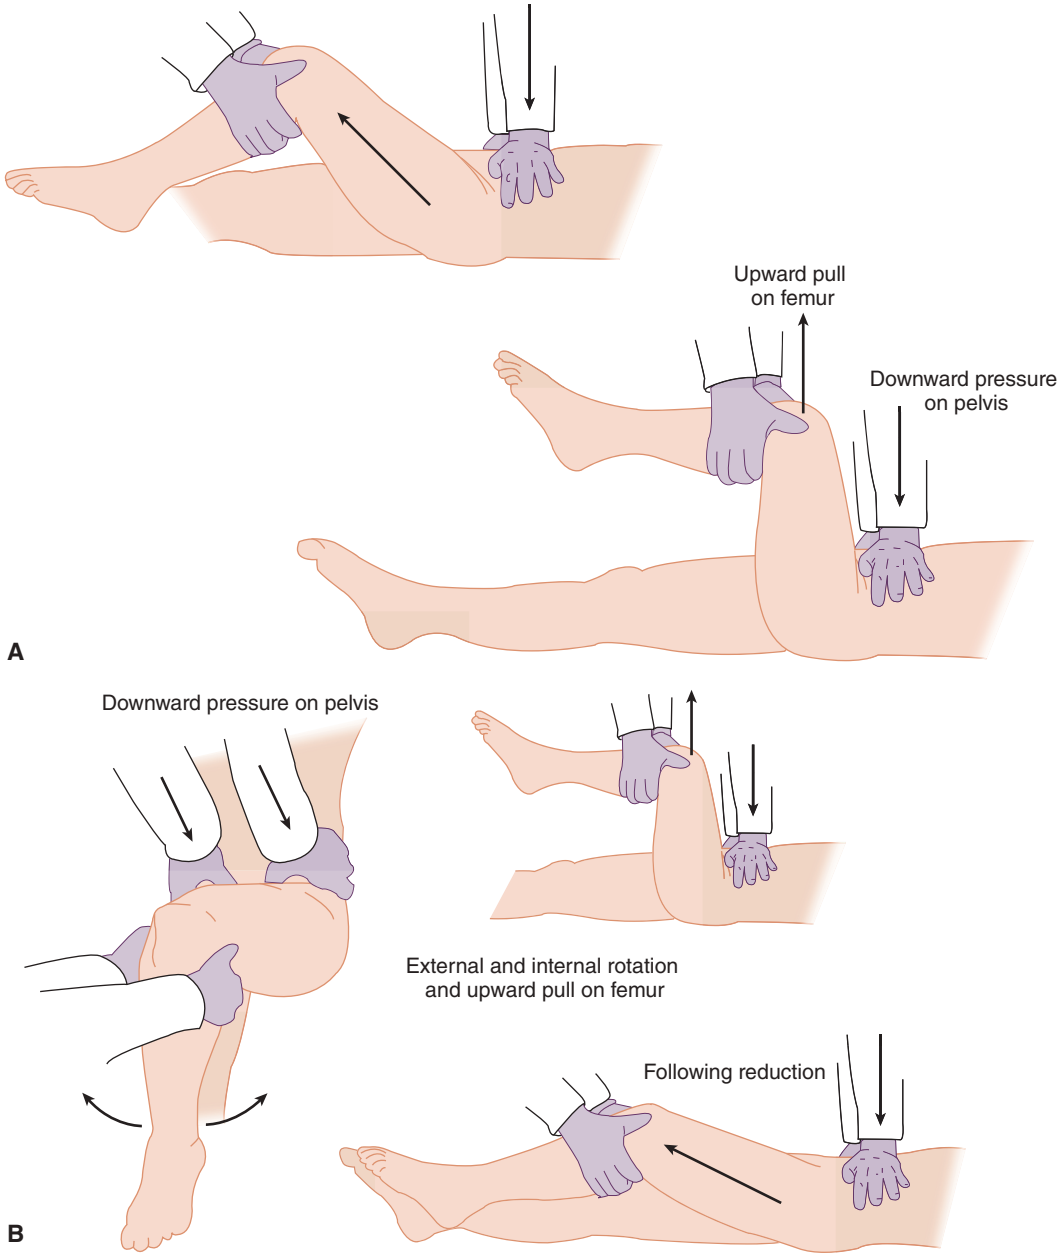

FIGURE 273-9. **A** and **B.** Allis maneuver for reduction of posterior hip dislocation.

rotation (**Figure 273-9**). Flex the patient's knee and hip to 90 degrees. An assistant should apply downward pressure to the anterior superior iliac spines. Grasp the knee with both hands. Pull and simultaneously rotate the femur laterally and medially.

With the **Bigelow maneuver**, the patient should lie supine with the affected hip and knee flexed 90 degrees (**Figure 273-10**). Secure the patient's knee with your flexed elbow, and grasp the patient's foot with the opposite hand. Have an assistant apply downward pressure to the anterior superior iliac spines. Now, using your flexed elbow, lift upward at the patient's knee to apply traction to the femur. Externally rotate and extend the hip while applying traction to the femur at the patient's knee. Another variation is represented in **Figure 273-11**.

Another method is the **Captain Morgan technique**, in which the physician's knee is used as a fulcrum (**Figure 273-12**).[24]

After reduction, gently take the hip through range of motion to ensure stability, repeat the neurovascular examination, and obtain postreduction imaging to ensure reduction is satisfactory. The patient may then be placed in an abduction pillow or brace, a hip binder, or a knee immobilizer based on the consulting orthopedist's preference. Most patients will require admission, because this injury is most often due to significant trauma.

If several attempts at reduction are unsuccessful, emergency orthopedic consultation is needed to provide reduction either in the ED or the operating room. Difficulties with reduction may be due to occult fracture or incarcerated tendon or capsule. A postreduction CT is generally recommended to specifically identify associated acetabular or femoral head fractures that were not evident on plain radiographs.[23]

ANTERIOR HIP DISLOCATION

In anterior hip dislocations (**Figure 273-13 A,B**), the femoral head rests anteriorly to the coronal plane of the acetabulum. Anterior dislocations can be superior (pelvic) or inferior (obturator) depending on the degree of hip flexion present at the time of injury. The mechanism of injury is forced abduction that causes the femoral head to be levered out through an anterior capsular tear. The affected extremity is in abduction and external

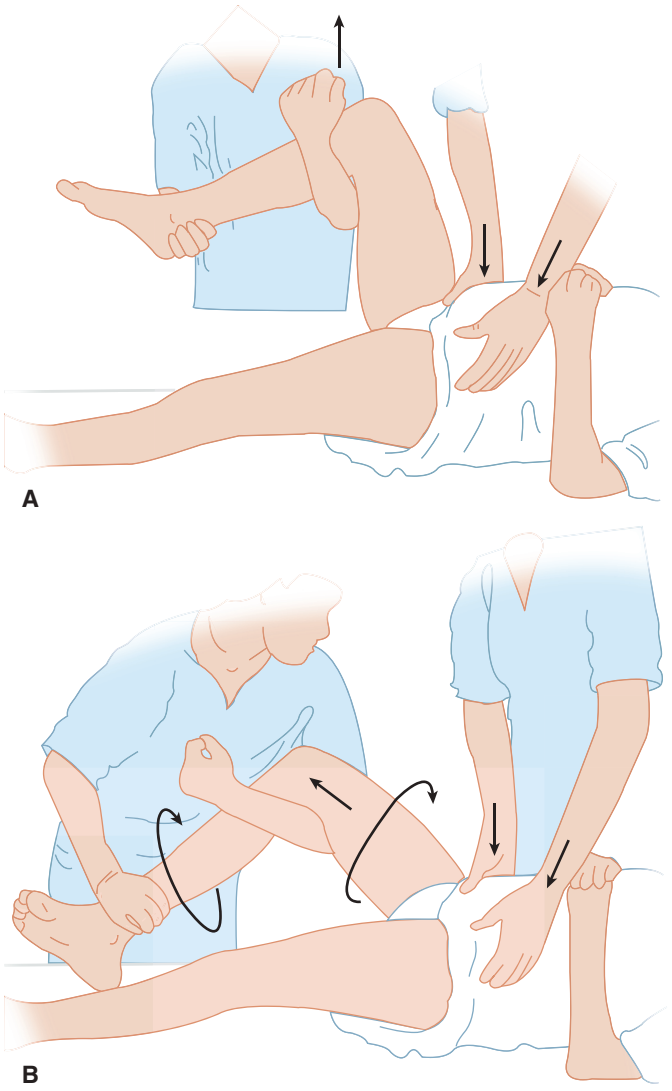

FIGURE 273-10. The Bigelow maneuver for reduction of posterior hip dislocation. **A.** The physician applies upward traction on the femur while an assistant stabilizes the pelvis. **B.** The hip is externally rotated and extended while the femur is distracted. rotation. The clinical appearance of superior versus inferior dislocations is dramatically different (**Figure 273-13 C,D**). Neurovascular compromise is an unusual complication. However, a thorough exam is warranted to detect injury to the femoral artery or nerve (Table 273-2).

An anteroposterior view of the pelvis can easily demonstrate the femoral head to be anterior to the acetabulum. A lateral view illustrates the anterior dislocation more clearly, although it may be difficult to obtain secondary to patient discomfort. Anterior hip dislocations usually require reduction in the operating room.

DISLOCATIONS OF PROSTHETIC HIPS

Prosthetic hips may dislocate relatively easily from minor trauma or movements that place the hip past 90 degrees of flexion while adducted. Approximately 1% to 10% of prosthetic hips dislocate, the majority in the first few months after surgery.[25] Avascular necrosis of the femoral head is not a complication since there is no blood flow to the prosthetic joint capsule. However, sciatic nerve injury or damage to the prosthesis may occur.

Most dislocations of prosthetic hips are posterior and can be reduced using procedural sedation in the ED with the techniques described previously. A review of 410 prosthetic hip dislocations reported that

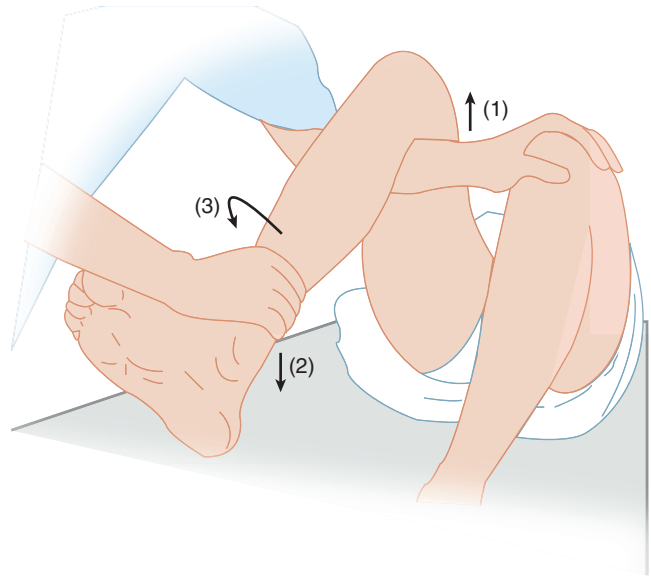

FIGURE 273-11. (*1*) Flex the patient's knee 90 degrees and place your flexed elbow under the patient's knee while placing your hand on the other knee to stabilize the pelvis. emergency physicians were successful at 79% of reductions in the ED, and orthopedists were successful at 71% of reductions in the ED—with no difference between emergency physicians and orthopedists in the proportion of successfully relocated hips in the ED and no difference in complications. The ED length of stay for ED-reduced prosthetic hip dislocations was about one third shorter than that for orthopedist-reduced dislocations. This study did not describe the types of prostheses reduced.[26] There are multiple types of implants, such as modular or constrained implants, which may not be amenable to closed reduction. **It is advisable to discuss the treatment plan with the consulting orthopedist prior to attempting any reduction maneuvers.**

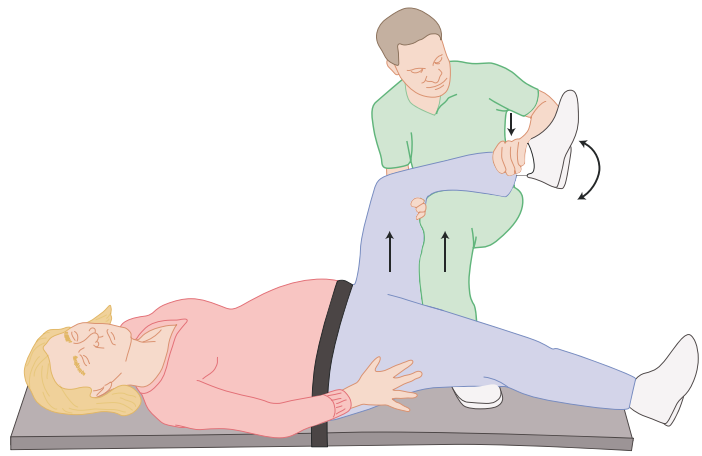

FIGURE 273-12. The Captain Morgan technique for reduction of posterior hip dislocation. (*1*) Stabilize the patient's pelvis by placing the patient on a backboard in the supine position and strapping the pelvis to the board, or have an assistant stabilize the pelvis on the stretcher by placing both hands on the patient's iliac crests and using pressure to keep the pelvis stable. (*2*) To reduce the dislocation, place your foot on the stretcher or board with your knee posterior to the patient's knee. (*3*) With the patient's knee in flexion, gently pull downward at the patient's ankle while applying an upward force to the patient's hip by lifting your heel by stepping on your toes and contracting your calf. Gently rotate the patient's hip while applying the upward traction behind the patient's knee.

SPECIAL POPULATIONS

ATHLETES

Stress fractures of the femoral neck are a recognized cause of hip pain in athletes, especially runners and football players. The onset of pain is often insidious and may mimic other common conditions such as bursitis or muscle strain. Patients often report pain in the groin, medial thigh, or knee. Consider MRI if clinical suspicion is present for stress fracture in a high-risk patient.[27] If imaging is not readily available, then the patient should be made non–weight bearing and told to avoid all athletic activities until orthopedic evaluation can be obtained (optimally in the next 48 hours).[28]

ELDERLY PATIENTS

The majority of hip and femur injuries occur in the elderly. Most will have underlying comorbidities that also require evaluation. For this reason, it is often useful to employ a multidisciplinary approach, which may involve social services to follow up for home safety evaluation as well as early involvement of the patient's primary care physician or a hospitalist.[12] Admit patients with suspected fractures who have poor follow-up, no social support, or suboptimal living conditions. Consider the possibility of elder abuse in elderly patients with falls and fractures. See chapter 295, Abuse of the Elderly and Impaired, for a detailed discussion of elder abuse.

SPECIAL CONSIDERATIONS

PAIN CONTROL

Nearly all patients with hip or femur injuries will require analgesia. Patients with orthopedic injuries sometimes receive inadequate analgesia in the ED.[29] Use parenteral narcotics for pain control unless there is a contraindication. Femoral nerve block should be considered (see chapter 36, Local and Regional Anesthesia, for technique).

INJURY PREVENTION

The use of hip protection pads for the prevention of hip fractures in the elderly have yielded conflicting results, with no definitive reduction in fracture rates demonstrated.[30] The increasing use of bisphosphonates for osteoporosis prevention has coincided with the modest reduction in hip fracture incidence in the U.S.; however, there is no evidence for a directly causal relationship as of now. Calcium and vitamin D supplementation may also play a role.[1] The best current recommendations are finding strategies to reduce falls and preventing osteoporosis.

CHAPTER 274

Knee Injuries

Rachel R. Bengtzen
Jeffrey N. Glaspy
Mark T. Steele

ANATOMY

The knee consists of two joints, the tibiofemoral joint and the patellofemoral joint. Within the tibiofemoral joint, the distal femur (comprised of the medial and lateral femoral condyles) articulates with the proximal tibia (comprised of the medial and lateral tibial condyles) (**Figure 274-1**). The medial and lateral menisci are situated between the articular surfaces, and the menisci provide cushion, lubrication, and resistance to articular wear (**Figure 274-2**). In the patellofemoral joint, the patella articulates with the distal femur along the anterior depression called the patellofemoral groove during flexion and extension of the knee. The patella is stabilized by the patellar tendon and medial retinaculum.

There are four ligaments in the knee: the anterior cruciate ligament, the posterior cruciate ligament, and the medial and lateral collateral ligaments (Figure 274-2). These ligaments provide strength and stability to the knee. The posterior aspect of the knee, the popliteal fossa, contains the popliteal artery and vein, the common peroneal nerve, and the tibial nerve (**Figure 274-3**).

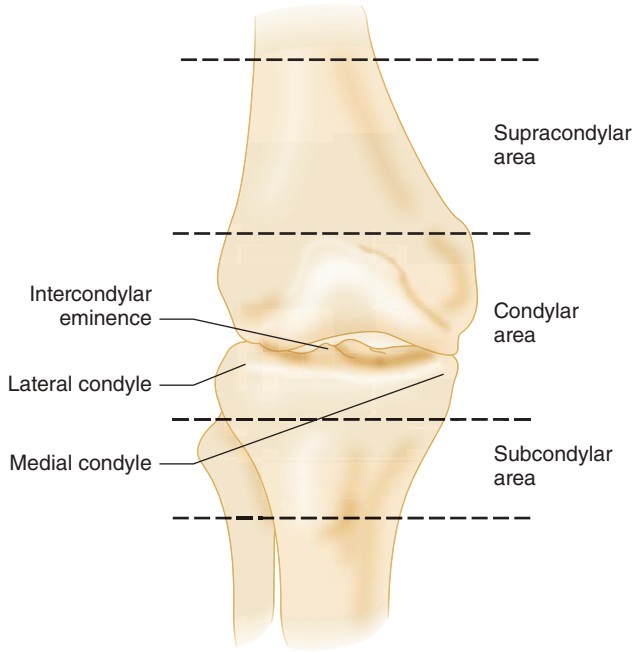

FIGURE 274-1. The supracondylar and condylar areas of the femur, and the medial and subcondylar areas of the tibia.

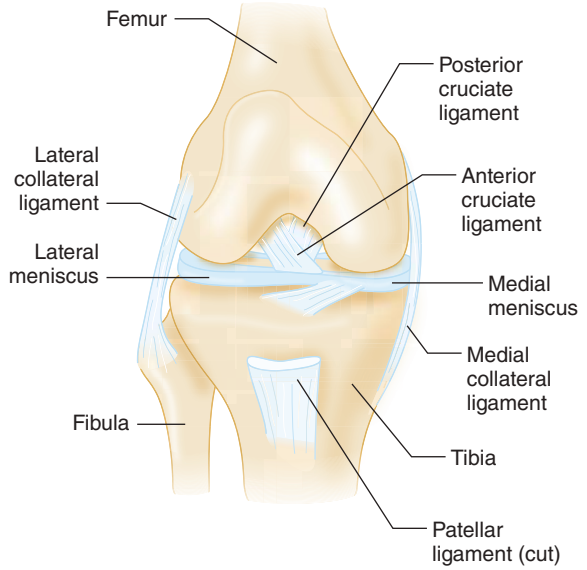

FIGURE 274-2. Ligaments of the right knee joint. The articular capsule and the patella have been removed.

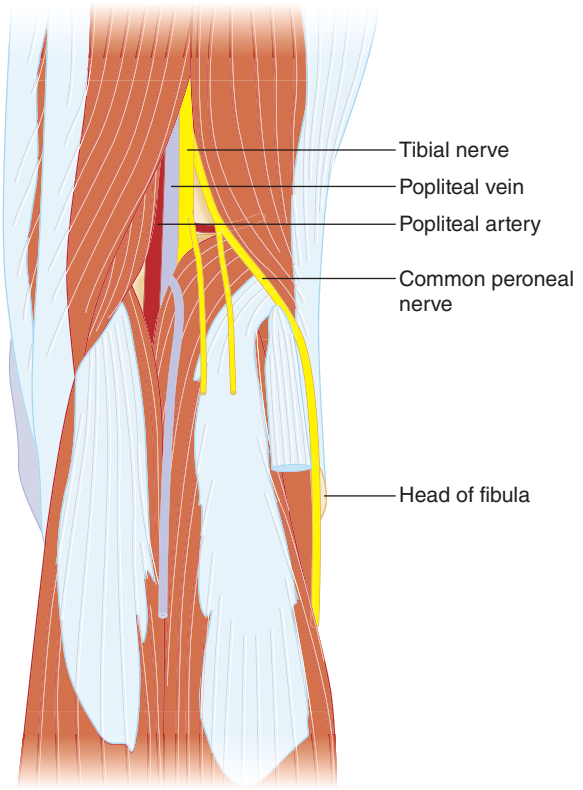

FIGURE 274-3. Posterior knee: popliteal fossa anatomy.

CLINICAL FEATURES

Determine the mechanism of knee injury and review all prior orthopedic injuries or surgical procedures. As with all orthopedic examinations, compare the noninjured or normal joint with the injured joint during all aspects of the examination, but especially during palpation and stress testing.

The first examination is usually the easiest to perform and may be the most valid, because the patient does not anticipate pain and may not guard against the examination, and because inflammation and effusion limiting the examination may have not yet developed.

Assess gait (if possible), functional range of motion, and the ability to perform a straight leg raise (evaluates the extensor complex). Evaluate the knee for ecchymoses, swelling, effusion, masses, patella location and size, muscle mass, erythema, and evidence of local trauma. With the patient supine, determine whether leg lengths are equal or unequal. Ask the patient to demonstrate the best possible active range of motion. Assess distal neurovascular function. Palpate the nontender areas first and work toward the tender area to minimize patient apprehension. Palpate the patella, patellar facets, proximal fibula, and femoral and tibial condyles for pain and crepitus. Make note of joint effusion, tenderness, increased temperature, strength, sensation, and location of pulses.

Examine the patella for size, shape, and location with the knee in flexion. Check patellar mobility with the knee in extension, making sure it can move laterally and medially without apprehension. Palpate the popliteal space for masses, swelling, and pulses. With the knee in flexion, palpate both the medial and lateral joint lines and the medial and lateral collateral ligaments, because tenderness at those locations suggests the possibility of a meniscal or ligamentous injury, respectively. The final phase of the examination of the knee is stress testing (see "Ligamentous and Meniscal Injuries" below). This is the most difficult aspect of the examination, although potentially the most informative. The patient must be relaxed and made as comfortable as possible. Testing is often easier if the patient sits up with the leg hanging over the side of the bed and with the bed supporting the posterior thigh. Examine the uninjured, presumably normal, opposite knee first to determine the patient's normal laxity.

NEUROVASCULAR INJURIES

Popliteal artery injury can occur from fractures about the knee, especially femoral condyle fractures or displaced tibial plateau fractures, and from ligamentous injuries such as isolated posterior cruciate ligament injuries, multiple ligamentous injuries, or knee dislocation.[1,2] Popliteal artery circulation must be restored within 8 hours to avoid amputation, because collateral circulation is insufficient to maintain blood flow to the leg. Measure distal pulses on ED admission and after any manipulation, and compare pulses to those in the noninjured leg. A diminished pulse raises concern for vascular injury and should not be interpreted as vascular spasm. An abnormal finding on pulse examination is reported to have a sensitivity of only 79% and a specificity of 91% for arterial injuries that require surgical intervention,[2] so it is important to remember that vascular injury can be present even in the presence of normal pulses. Ancillary studies include measurement of ankle-brachial index (<0.9 in a patient with peripheral vascular disease or vascular injury) and duplex US (reported to be 95% sensitive and 99% specific for arterial injury).[1] Vascular surgery consultation is required for any potential popliteal arterial injury to determine the need for angiography, as well to monitor for the development of compartment syndrome, venous injury, and arterial thrombosis.

Peroneal nerve injuries can result from severe ligamentous knee injuries and knee dislocations. Nearly half of fibular head fractures or avulsions are associated with peroneal nerve injury. The deep peroneal nerve provides sensation to the first dorsal web space of the toes and allows dorsiflexion of the foot and extension of the toes. Injury results in foot drop and gait difficulty. Prognosis is variable, depending on the severity of injury.

DIAGNOSIS

IMAGING

The **Ottawa Knee Rules** (**Table 274-1**) are sensitive in identifying fracture, and their use reduces ED waiting times and costs. The **Pittsburgh Knee Rules** (**Figure 274-4**) are similar and may have greater specificity.[3,4]

Both rules are applicable to children >2 years old and adults.[4] It would be reasonable to order radiographs on a higher number of patients with knee pain who are multisystem trauma patients, and thus immobilized and unable to undergo gait testing.

Anteroposterior and lateral radiographs are typically obtained if radiographs are needed.[5] Fat-fluid levels (lipohemarthrosis) suggest intra-articular fracture and may be identified on a lateral view of the knee.[6] Consider weight-bearing radiographs when tolerated, which allows for a functional assessment. Additional radiograph views can be very useful. Oblique views are particularly helpful for detecting subtle tibial plateau fractures (internal oblique view is best for visualizing the lateral plateau, and external oblique view is best for visualizing the medial plateau).[5,7] A tunnel or intercondylar view provides a clear image of the intercondylar region and is particularly useful in identifying tibial spine fractures. A sunrise (skyline, axial, or tangential) view is most useful in detecting nondisplaced vertical or marginal fractures of the patella, which may be missed with the conventional views. The sunrise view is indicated if patellar subluxation or fracture is suspected. CT may be necessary to fully delineate the extent of tibial plateau fractures. MRI is also helpful in this regard and has the added benefit of being able to assess soft tissue (i.e., ligamentous and meniscal) injury.[5]

TABLE 274-1 Ottawa Knee Rules: X-Ray if One Criterion Is Met

Patient age >55 y (rules have been validated for children 2–16 y of age)
Tenderness at the head of the fibula
Isolated tenderness of the patella
Inability to flex knee to 90 degrees
Inability to transfer weight for four steps both immediately after the injury and in the ED

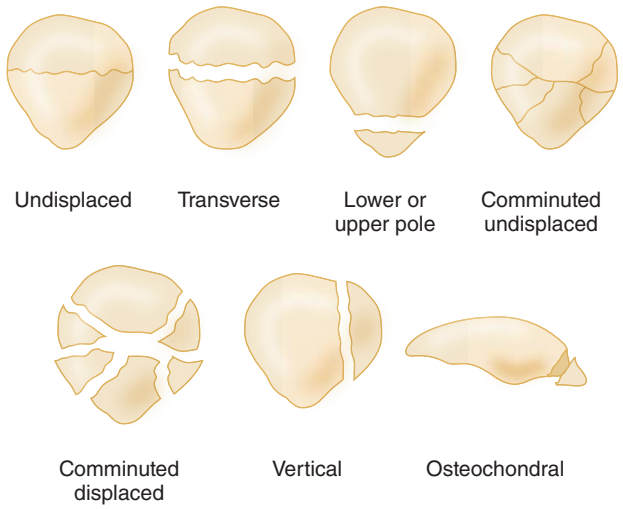

FIGURE 274-5. Classification of patellar fractures.

SPECIFIC INJURIES

PATELLA FRACTURES

Table 274-2 reviews the mechanisms of injury and treatment of patellar fractures. Patellar fractures may be transverse, comminuted, or of the avulsion type when the quadriceps or patellar tendon pulls off a small portion of the patella (**Figure 274-5**).

Transverse fractures of the patella are most common, followed by stellate and comminuted fractures. Patients with nondisplaced fractures may be ambulatory. On examination, there is focal patellar tenderness, swelling, and effusion. Check the integrity of the extensor mechanism of the knee by having the patient perform a straight-leg raise against gravity. Nonoperative management is indicated for fractures with an intact extensor mechanism and <2 mm of step-off and <3 mm of fracture displacement.[8,13] Transverse fractures are more likely to be displaced and to be associated with a disrupted extensor mechanism. Differential diagnosis of patellar fractures radiographically includes bipartite patella. This condition involves the superior lateral corner of the patella, is typically bilateral, and is differentiated from fracture by the smooth cortical margins.

FEMORAL CONDYLE FRACTURES

Fractures of the femoral condyles account for 6% of femur fractures and include supracondylar, intercondylar, condylar, and distal femoral epiphyseal fractures (Figure 274-1). Table 274-2 reviews the mechanisms of injury and treatment for femoral condyle fractures. Examination reveals pain, swelling, deformity, rotation, shortening, and an inability to ambulate. Although neurovascular injuries are uncommon, the potential for popliteal artery injury exists, so the status of distal sensation and pulses must be checked. Test the space between the first and second toes, innervated by the deep peroneal nerve, for sensation. In addition, search for associated injuries, including ipsilateral hip

TABLE 274-2 Mechanisms of Knee Injury and Treatment

Fracture	Mechanism	Treatment
Patella	Direct blow (i.e., fall, motor vehicle crash) or forceful contraction of quadriceps muscle	Nondisplaced fracture with intact extensor mechanism: knee immobilizer, rest, ice, analgesia. Follow-up for serial radiographs. Displaced >3 mm, articular incongruity >2 mm, or with disruption of extensor mechanism: above treatment plus early referral for ORIF.[8] Severely comminuted fracture: surgical debridement of small fragments and suturing of quadriceps and patellar tendons. Open fracture: irrigation and antistaphylococcal antibiotics in the ED; debridement and irrigation in the operating room.
Femoral condyles	Fall with axial load with valgus/varus/rotational forces, or a blow to the distal femur	Incomplete or nondisplaced fractures in any age group or stable impacted fractures in the elderly: long leg splinting and orthopedic referral. Displaced fractures or fractures with any degree of joint incongruity: splinting and orthopedic consult for ORIF.[9,10]
Tibial spines and tuberosity	Force directed against flexed proximal tibia in an anterior or posterior direction (i.e., motor vehicle crash, sporting injury)	Incomplete or nondisplaced fractures: immobilization in full extension (knee immobilizer) and orthopedic referral in 2–7 d. Complete or displaced fracture: early orthopedic referral, often requires ORIF.[11]
Tibial tuberosity	Sudden force to flexed knee with quadriceps contracted	Incomplete or small avulsion fracture: immobilization. Complete avulsion: ORIF.[8]
Tibial plateau	Valgus or varus forces combined with axial load that drives the femoral condyle into the tibia (i.e., fall, leg hit by car bumper)[12]	Nondisplaced, lateral fracture: knee immobilizer with non–weight bearing and orthopedic referral in 2–7 d. Depression of articular surface: early orthopedic consult for ORIF.[12]

Abbreviation: ORIF = open reduction internal fixation.

dislocation or fractures and damage to the quadriceps apparatus. The overall outcome of these injuries is fair. Complications include deep venous, fat embolus syndrome, delayed union or malunion, and the subsequent development of osteoarthritis.[9]

TIBIAL SPINE AND TUBEROSITY FRACTURES

Although isolated injuries of the tibial spine are uncommon, they usually result in cruciate ligament insufficiency. Table 274-2 reviews the mechanism of injury and treatment for tibial spine and tuberosity fractures. Fracture of the anterior tibial spine is about 10-fold more common than fracture of the posterior spine. Examination shows a painful, swollen knee secondary to hemarthrosis, inability to extend fully, and a positive finding on the Lachman test (see "Ligamentous and Meniscal Injuries" below).[11] The quadriceps mechanism inserts on the tibial tubercle. A sudden force to the flexed knee with the quadriceps muscle contracted may result in a complete or incomplete avulsion of the tibial tubercle. The fracture line may extend into the joint. Examination reveals pain and tenderness over the proximal anterior tibia with pain on passive or active extension.

TIBIAL PLATEAU FRACTURES

Fractures of the tibial plateau are seen more commonly in the older population and can be very difficult to detect. Table 274-2 reviews the mechanism of injury and treatment for tibial plateau fractures. Both medial and lateral plateaus may be fractured simultaneously, although the lateral plateau is more often fractured.[12] Direct trauma to the lateral aspect of the knee may account for the preponderance of lateral tibial plateau fractures. The patient may experience painful swelling of the knee and limitation of motion. Radiographs may demonstrate a fracture, but often show only a lipohemarthrosis on the lateral view. Consider adding an anteroposterior view in the plane of the plateau (10 to 15 degrees caudal) or oblique views to help assess for displacement. If the patient cannot tolerate the additional views, or there are negative radiographs but the patient cannot bear weight, consider obtaining a CT scan.[5] Soft tissue injuries associated with tibial plateau fractures may influence outcomes. Anterior cruciate ligament and medial collateral ligament injuries are associated with lateral plateau fractures, whereas posterior cruciate and lateral collateral ligament injuries occur with medial plateau fractures. A Segond's fracture (see below) is pathognomonic for an anterior cruciate ligament injury, and it is important recognize and treat the ligament injury, rather than just the plateau fracture.[12] Potential complications of tibial plateau fractures include popliteal artery injury with high-energy displaced fractures, the development of deep venous thrombosis, and osteoarthritis.

LIGAMENTOUS AND MENISCAL INJURIES

The knee joint depends on ligaments and muscles for support (Figure 274-2). It is frequently subjected to injuries from traumatic forces, including hyperextension, valgus and varus stresses, and anteroposterior displacement. By far the most common forces are valgus, which produce injuries to the medial side of the knee. Injuries to the lateral side of the knee are produced by varus stresses. Such forces may result in a strain or rupture of the medial or lateral collateral ligaments, the anterior or posterior cruciate ligaments, or the capsular structures, or a tear in the medial or lateral meniscus or both. Functional instability of the knee is determined by stress testing, which may demonstrate abnormal laxity when properly done. **Table 274-3** summarizes the reported sensitivity, specificity, and positive and negative likelihood ratios for diagnosis of ligamentous and meniscal injury.[14]

MEDIAL COLLATERAL LIGAMENT AND LATERAL COLLATERAL LIGAMENT INJURIES

The medial stabilizers of the knee are tested by applying a valgus stress (**Figure 274-6**) to the knee in approximately 30 degrees of flexion to determine the integrity of the medial capsular and ligamentous structures. The medial collateral ligament supplies the majority of restraint to valgus deformities of the knee in all stages of flexion. A varus force is then applied to the lateral aspect of the knee, again with approximately 30 degrees of flexion, to ascertain the integrity of the lateral structures. The lateral collateral ligament, analogous to the medial collateral ligament, is the major restraint to varus laxity on the knee at all positions of flexion. Injuries to these ligaments can include a strain, partial tear, or

TABLE 274-3 Reliability of Physical Examination for Diagnosis of Knee Ligamentous and Meniscal Injuries

Structure	Maneuver	Mean Sensitivity (range)	Mean Specificity (range)	Positive LR (95% CI)	Negative LR (95% CI)	Comments
Anterior cruciate ligament	Composite examination*	82% (62–100)	94% (56–100)	25 (2.1–306)	0.04 (0.01–0.48)	When limited to acute injury (one study), 62% sensitivity and 56% specificity.
	Anterior drawer test	62% (9–93)	67% (23–100)	3.8 (0.7–22.0)	0.3 (0.05–1.5)	Variability of studies may be due to small sample sizes.
	Lachman test	84% (60–100)	100% (100)	42 (2.7–651.0)	0.1 (0.0–0.4)	Only one study commented on specificity. Therefore specificity and LRs may be inaccurate.
	Lateral pivot shift	38% (27–95)	NA	NA	NA	No study commented on specificity.
Posterior cruciate ligament	Composite examination*	95.5% (91–100)	89.5% (80–99)	21 (2.1–205.0)	0.05 (0.01–0.50)	Results limited to two studies.
	Posterior drawer test	55% (51–86)	NA	NA	NA	No study commented on specificity.
Medial collateral ligament/lateral collateral ligament	NA	NA	NA	NA	NA	No study was identified that adequately examined diagnostic accuracy for these injuries.
Meniscal injury	Composite examination*	77% (64–82)	81% (78–84)	NA	NA	Only three of five studies commented on specificity.
	Joint-line tenderness	79% (76–85)	15% (11–43)	0.9 (0.8–1.0)	1.1 (1.0–1.3)	Only two of four studies included acute injuries, all four included chronic injuries; consequently, applicability to ED is limited.
	McMurray test	53% (29–63)	59% (29–100)	1.3 (0.9–1.7)	0.8 (0.6–1.1)	

Abbreviation: LR = likelihood ratio; NA = not applicable.

*These studies reported a "composite examination" without giving data on the specific examination maneuvers.

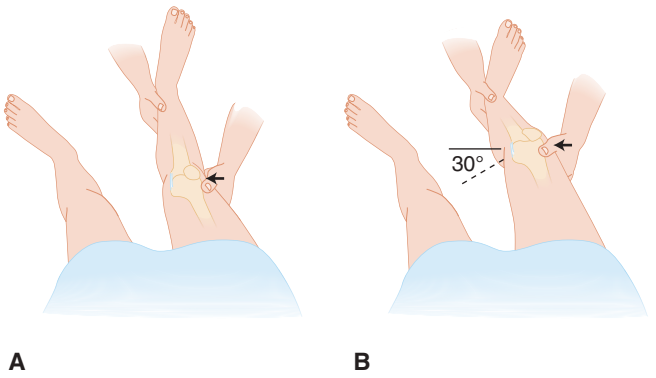

FIGURE 274-6. Valgus stress in full extension (**A**) and in 30 degrees of flexion (**B**).

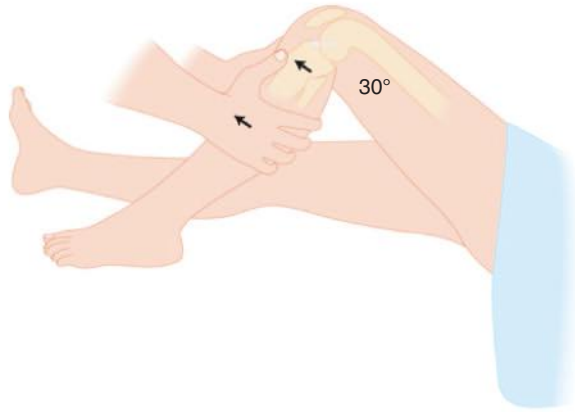

FIGURE 274-8. Anterior drawer test, performed with 45-degree flexion at the hip and a 90-degree flexion at the knee. Try to displace the tibia from the femur in an anterior direction.

complete rupture. If there is no demonstrated laxity but the valgus or varus test reproduces pain, a strain has likely occurred. If there is a laxity demonstrated without a firm end point compared with the other knee, this is concerning for a complete tear of the medial or lateral collateral ligament. If there is laxity with the varus or valgus test performed with 30 degrees of flexion, similar maneuvers should be applied with the leg in full extension, if possible. Laxity to valgus stress while in full extension indicates a significant lesion involving the entire medial collateral ligament complex and/or in association with a cruciate ligament and posterior capsule tear.[15] Laxity to varus stress in full extension likewise indicates a significant injury that may involve the posterolateral corner of the knee as well as the cruciate ligaments. Peroneal nerve injuries may also occur in lateral injuries. Although these tests may aid in the diagnosis of medial collateral ligament and lateral collateral ligament injuries, there are no adequate published reports to allow comment on their sensitivity and specificity.[14]

ANTERIOR CRUCIATE LIGAMENT INJURIES

The mechanism of injury to the anterior cruciate ligament is usually noncontact—a deceleration, hyperextension, or marked internal rotation of the tibia on the femur resulting in an injury to this ligament. Injury is often associated with a "pop," swelling that develops within hours, and a sense of instability. The pop is considered pathognomonic for anterior cruciate ligament injury.[16] The history of this mechanism of injury combined with the presence of a traumatic effusion is very suggestive of an anterior cruciate ligament disruption.

The diagnosis of an anterior cruciate ligament injury is made using the **Lachman test** (**Figure 274-7**), the anterior drawer sign (**Figure 274-8**), and the pivot shift (**Figure 274-9**). The Lachman test is the most sensitive and specific test (84% and 100%, respectively).[14] For this test the examiner places the knee in 30 degrees of flexion and stabilizes the femur above the knee with his or her nondominant hand. The dominant hand is placed grasping the lower leg at the level of the tibial tubercle, and the examiner introduces an anterior force, attempting to displace the tibia anteriorly on the femur. If a displacement compared with the opposite knee is found, or if there is a soft end point, then a tear in the anterior cruciate ligament has occurred. Although the **anterior drawer sign** has been used for a long time, its sensitivity is only approximately 62%. The maneuver is done with a 45-degree flexion at the hip and a 90-degree flexion at the knee. Then attempt to displace the tibia from the femur in an anterior direction. A displacement of >6 mm compared with the normal, opposite knee indicates an injury to the anterior cruciate ligament. False-negative findings may be associated with this maneuver. False-positive results may occur when there is a posterior cruciate ligament tear as the tibia will start out in a more posterior position, thus allowing for a perceived increase in translation when moved anteriorly. Although the Lachman test is more sensitive than the anterior drawer test and is able to identify partial tears in the anterior cruciate ligament when the examiner is skilled, it can be difficult to perform on patients with large legs. The **pivot shift** (Figure 274-9) is the third maneuver by which the examiner can determine the integrity of the anterior cruciate ligament. The pivot shift may be somewhat painful to the patient and is often most easily tested in the operating room. The pivot shift test

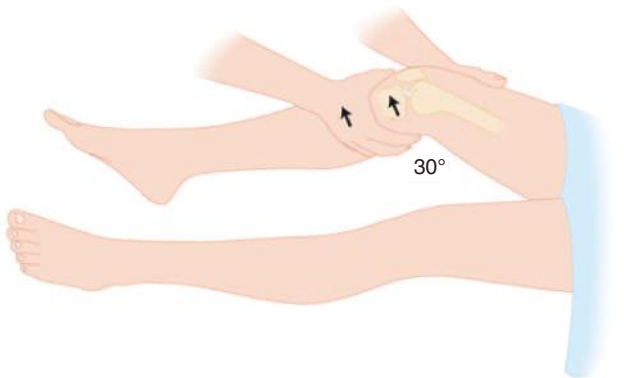

FIGURE 274-7. Lachman test, performed with the knee flexed between 15 and 30 degrees. One hand stabilizes the thigh while the other moves the tibia anteriorly.

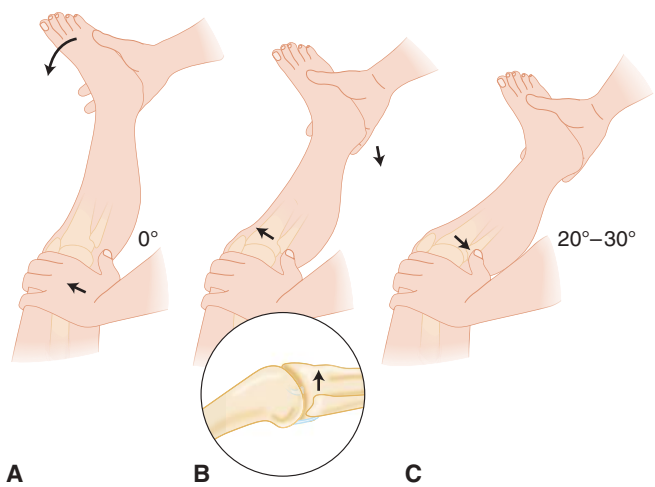

FIGURE 274-9. A through C. In the pivot shift of Galway and MacIntosh, the test is done with the knee in full extension with application of a valgus and internal rotation stress. The "clunk" of reduction is felt in the first 20 to 30 degrees of flexion.

without anesthesia was found to be only 24% sensitive but 98% specific.[17] With the patient supine and relaxed, lift the heel of the foot to approximately 45 degrees of hip flexion with the knee fully extended. The opposite hand grasps the knee with the thumb behind the fibular head. Then internally rotate the ankle and knee, apply a valgus force to the knee, and flex the knee. If an anterior subluxation of the tibia is present, a sudden visible, audible, and palpable reduction of the subluxation occurs at about 20 to 30 degrees of flexion. This indicates a deficit in the anterior cruciate ligament, which is required to stabilize the knee in this position. Other tests are described in the literature to determine the integrity of the anterior cruciate ligament, including the jerk test and dynamic extension testing.

POSTERIOR CRUCIATE LIGAMENT INJURIES

The posterior cruciate ligament can be injured in isolation or in combination with other ligamentous structures of the knee. In contrast to anterior cruciate ligament injuries, isolated posterior cruciate ligament injuries are much less common. The posterior cruciate ligament provides initial resistance to posterior translation at all angles of flexion of the knee. The mechanism of injury then is usually an anterior-to-posterior force applied to the tibia or lower leg. Posterior cruciate ligament injuries are seen in association with other ligamentous injuries when a serious injury has occurred to the knee. A deficit of this ligament is identified by the posterior drawer test (**Figure 274-10**) and the sag sign. The posterior drawer test is performed with the knee and hip in flexion as described for the anterior drawer test. The physician applies a posterior force to the tibial tubercle. If there is displacement posteriorly, then the examiner can diagnose an injury to this ligament. One might also notice a sag sign, where there is a posterior sag or drop back of the tibial tubercle because of loss of integrity of the posterior cruciate ligament when observing the knee with 45-degree flexion at the hip and 90-degree flexion at the knee. Results of this test can be misleading, however, if there is a straight anterior instability resulting in a subluxation of the knee forward. This abnormal position gives the false impression of too much posterior play when the posterior drawer test is performed, because the knee is reduced to its normal anatomic alignment from the forwardly subluxed position. Although the posterior drawer test has only a 55% sensitivity, the composite history and physical examination findings are much more accurate in the diagnosis of posterior cruciate ligament injuries.[14,18]

Combined ligamentous laxity of the knee is often seen, especially in acute athletic injuries. Combined anteromedial and anterolateral laxity occurs most frequently, but virtually any combination of medial and lateral laxity of the knee can occur.

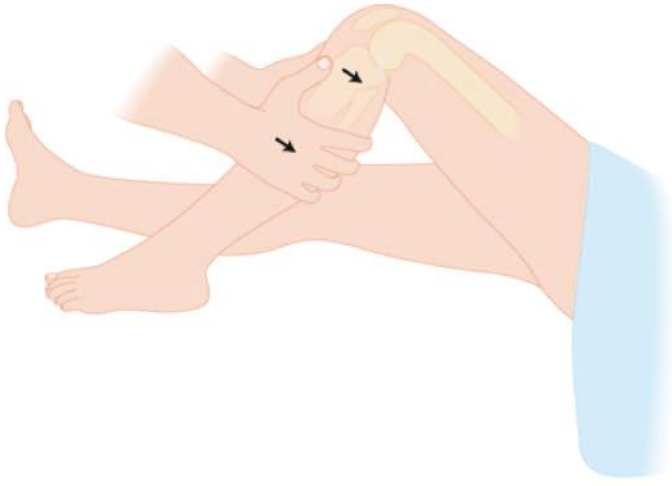

FIGURE 274-10. Posterior drawer test.

POSTEROLATERAL INJURY

One knee injury that is especially difficult to detect is injury to the posterolateral structures. Posterolateral instability usually involves a tear of the popliteus–arcuate complex, which may occur in combination with lateral ligament injury and possible anterior cruciate ligament or posterior cruciate ligament injury. Isolated injuries to the popliteus–arcuate complex are rare. Isolated posterolateral instability is demonstrated by testing at 0 to 30 degrees of flexion for maximal posterior translation and at 90 degrees of flexion for maximal external rotation compared with that of the normal opposite knee. Further testing to determine the integrity of the lateral collateral ligament and anterior or posterior cruciate ligaments must be done as well.

HEMARTHROSIS OR EFFUSION

The presence of a hemarthrosis can suggest an underlying ligamentous injury to the knee, most commonly the anterior cruciate ligament. Serious ligament injuries, however, may present with minimal pain and no hemarthrosis because of complete disruption of the ligamentous and capsular fibers, which allows leakage of the blood into the soft tissue spaces. Hemarthrosis can also be caused by osteochondral fractures or fractures that extend into the joint line, or peripheral meniscal tears. Traumatic hemarthroses usually occur within minutes to hours of injury, in contrast to chronic effusions of the knee due to synovial inflammation, which occur 1 to 2 days after strenuous use of the joint.

With ligamentous injuries, plain radiographs are typically normal or reveal only an effusion. An avulsion fracture at the site of attachment of the lateral capsular ligament on the lateral tibial condyle (Segond's fracture) is a marker for anterior cruciate ligament rupture.[7,12] Cortical avulsion of the medial tibial plateau (very uncommon) is associated with tears of the posterior cruciate ligament and medial meniscus.[19] Continued refinements in MRI have enabled this imaging method to produce high-quality images of the ligamentous and meniscal structures of the knee, which results in an accuracy rate of close to 90% to 95% in identifying meniscal and cruciate ligament disruption.[20] Such an MRI examination, however, is typically ordered by the patient's primary care provider, sports medicine physician, or orthopedist in follow-up.

TREATMENT OF SPECIFIC INJURIES

LIGAMENTOUS INJURIES

Injuries involving a single ligament with a minor strain can be managed with a knee immobilizer, ice packs, elevation, nonsteroidal anti-inflammatory drugs, and ambulation as soon as is comfortable for the patient.[21] When knee immobilizers are placed, instruct the patient to perform daily range-of-motion exercises to avoid contracture and maintain mobility. Contractures are more common in the elderly and can occur after only a few days of immobilization. Although there is no universally accepted regimen for range-of-motion exercise, one procedure is first to apply ice to relieve pain and then to perform 10 to 20 knee flexion-extensions (no weights should be added) three or four times a day. Refer patients to an orthopedic surgeon, sports medicine physician, or primary care provider within the next few days to a week for follow-up examination.

Complete rupture of an isolated ligament can initially be treated conservatively in the same fashion, with straight leg quadriceps strengthening, range-of-motion exercises, and functional bracing included as a part of the follow-up care. Professional athletes with single-ligament ruptures or patients with more than one torn ligament need urgent orthopedic consultation so that definitive surgical management can be planned.

Arthrocentesis may be of therapeutic benefit in patients with large, tense effusions of the knee; however, good evidence of its efficacy has not been reported. A systematic review to ascertain whether aspiration

improves symptoms in patients with acute traumatic hemarthrosis found no conclusive data.[22] Furthermore, recurrence of the effusion following aspiration is common. Arthrocentesis may be of assistance diagnostically if the effusion is not clearly due to trauma. The presence of blood and glistening fat globules is pathognomonic of lipohemarthrosis, which indicates intra-articular knee fracture. The major complication of arthrocentesis is septic arthritis.

MENISCAL INJURIES

Meniscal injuries of the knee occur by themselves or in combination with ligamentous injuries. For example, anterior cruciate ligament injuries are commonly associated with meniscal injuries. Cutting, squatting, or twisting maneuvers may cause injury to the meniscus. The medial meniscus is approximately twice as likely as the lateral meniscus to be injured. Four fifths of the tears involve the peripheral posterior aspect of the meniscus.[23] Many maneuvers have been described in the literature to determine whether a meniscus has been injured. Most of these tests, however, have an unacceptable sensitivity and specificity (e.g., joint line tenderness has a sensitivity of 70% and specificity of 15% in the ED population).[14] Although the diagnosis of a meniscal tear is difficult to make in certain patients, the combination of a suggestive history and physical findings on examination should lead the emergency physician to consider the diagnosis. Ask if the patient experiences painful locking of the knee joint on either flexion or extension and if this limits further activity. This sign clearly points to the diagnosis of a torn meniscus. Effusions that occur after activity; a sensation of popping, clicking, or snapping; a feeling of instability in the joint, especially with activity; and tenderness in the anterior joint space after excessive activity suggest the diagnosis of a meniscal tear.

At physical examination, attempt to identify atrophy of the quadriceps muscle because of disuse and joint-line tenderness. Various maneuvers, such as the McMurray test or the grind test, have been described but yield positive results only about 50% of the time.[14,24] If a tentative diagnosis of a meniscal tear is considered, refer to an orthopedic surgeon or the patient's primary care provider and instruct partial weight bearing, as tolerated. Definitive diagnosis can be made by MRI or arthroscopy, with the latter also allowing for definitive surgical treatment (usually partial meniscectomy or meniscal repair).

LOCKED KNEE

The "locked knee" describes when a knee cannot actively or passively fully extend. A patient who presents to the ED with a locked knee can experience a great deal of pain along with loss of mobility. The most common cause of an acutely locked knee is a torn meniscus. The differential diagnosis also includes anterior cruciate ligament rupture, patella dislocation, loose bodies, or foreign body. Historically the treatment includes one attempt at closed reduction under procedural sedation. After procedural sedation is initiated, one can attempt to unlock the knee. Position the patient with the leg hanging over the edge of the table and the knee in 90 degrees of flexion. After a period of relaxation, apply longitudinal traction to the knee, along with internal and external rotation, in an attempt to unlock the joint. If this maneuver is unsuccessful, orthopedic consultation for operative arthroscopy is indicated. If the unlocking is successful, referral to an orthopedist for MRI and/or arthroscopy is appropriate.[25]

KNEE DISLOCATION

Knee dislocation (**Figure 274-11**) is a result of tremendous ligamentous disruption due to hyperextension or application of direct posterior force to the anterior tibia, force to the fibula or medial femur, force to the tibia or lateral femur, or rotatory force resulting in anterior, posterior, lateral, medial, or rotatory dislocation. This injury typically occurs following high-velocity mechanisms such as motor vehicle crashes or low-velocity mechanisms in sports; however, dislocations can also occur spontaneously in morbidly obese patients.[1,26] An anterior

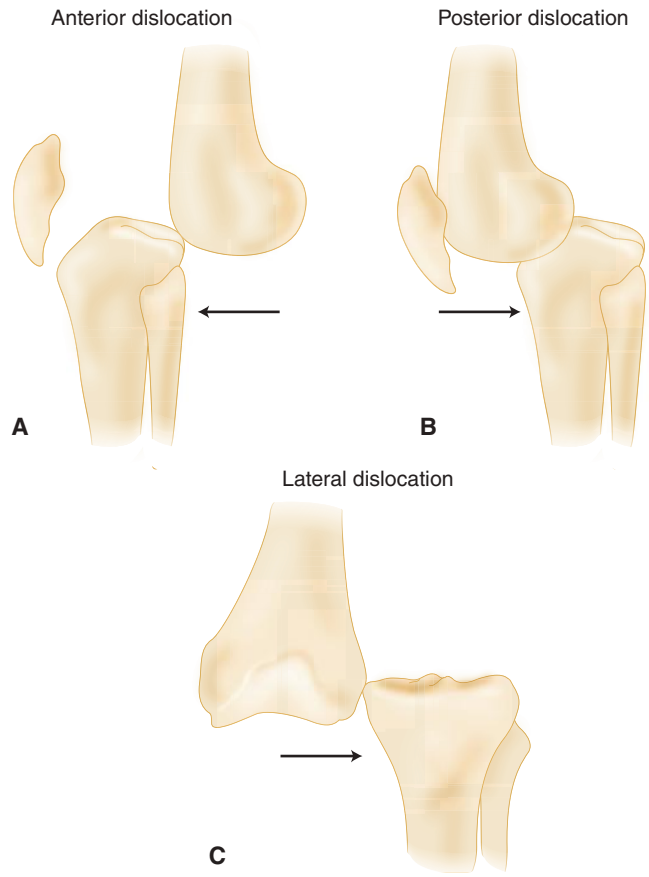

FIGURE 274-11. Types of knee dislocation: anterior (**A**), posterior (**B**), and lateral (**C**).

dislocation is most common, occurring about 40% of the time, with posterior dislocations (33%), lateral dislocations (18%), medial dislocations (4%), and rotary dislocations also occurring.[2,26] Because of severe ligamentous damage, spontaneous reduction occurs in up to 50% of knee dislocations.[2] Therefore, **a severely injured knee that is unstable in multiple directions raises suspicion of a spontaneously reduced knee dislocation.** Maintaining awareness of the possibility of this injury is important because of the high incidence of associated complications, including popliteal artery injury and peroneal nerve injury (mostly with posterolateral dislocations), in addition to ligamentous and meniscal injury.

Timely reduction of the dislocated knee is essential. Apply longitudinal traction to the affected knee. Document neurovascular status of the extremity before and after reduction. **Splint the lower extremity with the knee at 20 degrees of flexion after dislocation reduction** to prevent redislocation. Reimage after splint application. Hospitalization is required along with emergent orthopedic and vascular surgery consultation. If the patient is neurovascularly intact and vascular and/or orthopedic surgery consultation is unavailable, then transfer the patient prior to reduction to the nearest hospital with those clinical services. Timely reduction can occur at that time.

There are no clear guidelines for arteriography in patients with knee dislocation. Because of the high incidence of popliteal artery injury (up to one third of patients) and poor outcomes associated with delays in vascular reconstruction, some authors recommend arteriography for all patients with confirmed knee dislocations.[1,27] Another option after reduction of a knee dislocation is to repeat the neurovascular exam and perform Doppler pressure indices[28] (ankle-brachial index; see chapter 61, "Arterial Occlusion"). Patients with distal pulses present before and after reduction and an ankle-brachial index >0.9 can be observed with serial neurovascular checks. The orthopedist may want a CT angiogram prior to ligamentous reconstruction. For patients in whom distal pulses are asymmetric, the ankle-brachial index is <0.9, or there is any other

clinical concern of vascular injury (including ischemia, hemorrhage, or an expanding hematoma), proceed with CT angiogram or angiography. Patients with absent pulses before reduction with a return of a pulse after reduction need measurement of an ankle-brachial index and emergent vascular surgery consultation.[2] Patients with an open knee dislocation, absent distal pulses after reduction, or any other signs of vascular injury, as above, need emergent vascular surgery consultation for surgical exploration and possible angiography in the operating room.[2,26,28]

Close observation of patients with suspected knee dislocation is essential, because the presence of normal distal pulses does not rule out a popliteal artery injury. Splint the affected knee in 20 degrees of flexion, with care taken to construct the splint in a manner that allows for serial vascular examinations.

PATELLAR DISLOCATION

Dislocation of the patella usually occurs from a twisting injury to the extended knee. The patella is displaced laterally over the lateral condyle, which results in pain and deformity of the knee (**Figure 274-12**). Tearing of the medial knee joint capsule often occurs. Reduction is accomplished with the patient under conscious sedation by flexing the hip, hyperextending the knee, and sliding the patella back into place. This results in immediate relief of pain; however, caution patients that they will have residual soreness from the medial patellofemoral retinacular tissue injury. Obtain x-rays of the patella and knee to exclude a fracture, and place a knee immobilizer after reduction[10] and provide crutches. Give instructions for partial weight bearing and straight leg raises to strengthen the quadriceps. Arrange follow-up with an orthopedist within 1 week. Recurrent lateral dislocation of the patella occurs in approximately 15% of patients, and superior, horizontal, and intercondylar dislocations require referral to an orthopedic surgeon for possible surgical intervention.[29]

In the case of irreducible patellar dislocation, surgical correction is needed. Clues that a patient may have an irreducible patellar dislocation include older age, preexisting patellofemoral arthritis, flexion of <45 degrees, anterolateral (rather than pure lateral) patellar position, and internal rotation of the patellar axis.[30]

FIGURE 274-12. Lateral dislocation of the right patella. [Photo contributed by Rob Hendrickson, MD, and Michael Martinez, MD.]

QUADRICEPS OR PATELLAR TENDON RUPTURE

Rupture of the quadriceps or patellar tendons can occur from forceful contraction of the quadriceps muscle or falling on a flexed knee. Quadriceps tendon rupture is most frequent in those >40 years of age. Patellar tendon rupture occurs most commonly in individuals <40 years of age. A history of tendinitis or past oral or injected steroid can increase risk of rupture.[8] Quadriceps or patellar tendon rupture disrupts the extensor mechanism of the knee. There is severe pain and diffuse swelling, and the patient is unable to actively extend the knee or maintain a passively extended knee against gravity in both types of tendon rupture. Depending on the tendon ruptured, a defect may be palpable proximal or distal to the patella. **Figure 274-13** shows a quadriceps tendon rupture. A high-riding patella (patella alta) may be seen on a lateral radiograph of the knee in the setting of a patellar tendon rupture (**Figure 274-14**). The treatment of a complete tear is surgical repair of the involved tendon. Orthopedic consultation in the ED is indicated. Incomplete tears with an intact extensor mechanism can be treated with immobilization and close follow-up.[8]

PATELLAR TENDINITIS

Also known as jumper's knee, patellar tendinitis is primarily seen in runners, high jumpers, and basketball and volleyball players. Pain is located at the patellar tendon and is worsened when going from sitting to standing, jumping, or running up hills. Evaluate the extensor mechanism to rule out tendon rupture. Point tenderness can be found at the distal aspect of the patella or proximal part of the patellar tendon. Treatment consists of nonsteroidal anti-inflammatory drugs, eccentric quadriceps-strengthening exercises, and activity modification. Steroid injections predispose to tendon rupture and thus should be avoided.

POSTARTHROSCOPY PROBLEMS

Patients may present to the ED following arthroscopy because of pain and swelling. Effusions are common after arthroscopy, but joint infection

FIGURE 274-13. Quadriceps tendon rupture. Note the defect above the patella and prominence of the proximal edge of the patella. [Reproduced with permission of the Department of Emergency Medicine, Feinberg School of Medicine, Northwestern University.]

FIGURE 274-14. Patella alta.

is very uncommon. Perform diagnostic arthrocentesis if joint infection is suspected. Arthrocentesis and then injection of bupivacaine may be helpful therapeutically for large, tense effusions and may reduce the need for systemic analgesia.

PENETRATING KNEE INJURY AND JOINT FOREIGN BODIES

The history should elicit information to re-create the position of the knee when the penetrating injury occurred. Many occupational injuries occur with the knee flexed, and failure to appreciate the trajectory of injury with the knee flexed can lead to misdiagnosis and failure to anticipate joint penetration. Management of lacerations in proximity to joint spaces is discussed in chapter 44, "Leg and Foot Lacerations," in the section "Wound Management."

Radiopaque foreign bodies (i.e., metal, glass) can be visualized on conventional radiographs. In general, foreign bodies in the knee joint need to be removed. A bullet in the joint can destroy the cartilage, and lead poisoning can occur.[31] Antibiotics to cover streptococci and staphylococci are generally indicated for both penetrating knee wounds and foreign bodies. Administer tetanus prophylaxis as indicated.

CHAPTER 275

Leg Injuries

Paul R. Haller

ANATOMY

BONE

The tibia provides primary support for weight bearing. The tibia has a thick cortex, and significant force is required to fracture it. Proximally, the tibia splays out to form the medial and lateral plateaus that articulate with the femoral condyles. The lateral plateau is higher and smaller than the medial and is more susceptible to fracture. The distal tibia articulates with the fibula laterally and the talus inferiorly. A dense interosseous membrane connects the tibia and fibula. The distal tibial articulation is supported by the ankle syndesmosis, a series of ligaments inferior to the interosseous membrane. The fibula has a small diameter and lies lateral and posterior to the tibia. It bears little weight but is more easily fractured than the tibia.

COMPARTMENTS

The lower leg is divided into four compartments, each coursing parallel to the tibia (**Figure 275-1**). The compartments are enclosed by nonexpandable bones and connective tissue that limit the compartment size and prevent compartment expansion if its volume increases. Each compartment contains muscles and nerves that may sustain permanent damage with elevated tissue compartment pressure (**Table 275-1**). (See also chapter 278, "Compartment Syndrome.")

A cross-section at the midcalf level shows the anterior compartment enclosed by the tibia, interosseous membrane, and anterior crural septum (Table 275-1 and Figure 275-1). Muscles in the anterior compartment group dorsiflex the foot and ankle. The deep peroneal nerve courses within the anterior compartment and exits to provide sensation to the dorsal web space between the first and second toes.

The lateral compartment is bordered by the anterior crural septum, the fibula, and the posterior crural septum. Its muscles plantarflex and evert the foot. The superficial peroneal nerve in this compartment provides sensation to the dorsum of the foot. The superficial posterior compartment contains muscles that flex the knee and the tibiotalar joints. Its sural nerve provides sensation for the lateral aspect of the foot and the distal calf. The muscles of the deep posterior compartment plantarflex the foot and toes and invert the foot. The posterior tibial nerve that exits this compartment provides sensation to the sole of the foot.

CLINICAL FEATURES

The history may give clues about the mechanism of injury and nontraumatic soft tissue injuries. Evaluate the nerves by checking sensation in the web space, lateral heel, and sole of the foot. Plantarflex and dorsiflex the foot, and evert the foot to test motor function. Evaluate the extent of soft

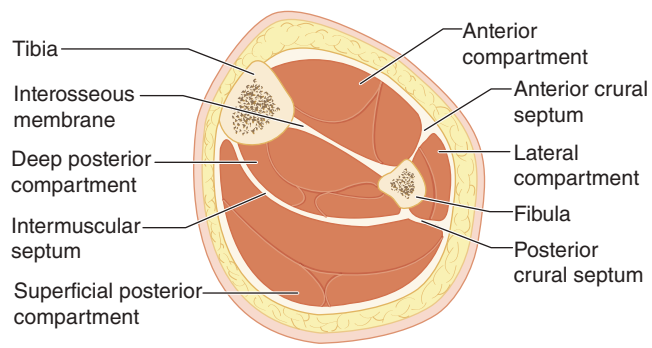

FIGURE 275-1. Lower leg anatomy.

Artery	Anterior tibial	—	—	Posterior tibial

tissue injury visually and by palpating the compartmental muscle groups. It is often the extent of soft tissue injury, rather than the fracture itself, that determines the outcome. Palpate the knee, and the tibia and fibula along their entire lengths. Palpate the popliteal, dorsal pedal, and posterior tibial pulses. An absent or decreased pulse may indicate the need for urgent fracture reduction and further vascular evaluation.

DIAGNOSIS

Anteroposterior and lateral radiographs of the leg that include the knee and ankle are sufficient to evaluate bony injuries. If ankle or knee injuries are suspected, then further imaging is needed. If a tibial shaft fracture is suspected, splint the leg with a radiolucent device to control pain and prevent further soft tissue damage before obtaining films. Check pulses, movement, and sensation before and after splinting the leg.

TREATMENT

Cleanse wounds and debride loose tissue and foreign material. Administer tetanus immunization as indicated. Splint fractures before obtaining radiographs; this will prevent further damage to soft tissue caused by movement of bone fragments. Irrigate open wounds and administer parenteral antibiotics (such as cefazolin, 1 gram IV) for open fractures. If compartment syndrome is suspected, measure compartment pressure (see chapter 278, "Compartment Syndrome"). Treatment of compartment syndrome is fasciotomy of the involved compartment. Details of suturing pretibial lacerations are provided in the chapter 44, "Leg and Foot Lacerations."

COMPLICATIONS

Wounds that are not adequately cleansed and debrided are prone to infection. Patients with compartment syndromes may develop permanent disability if elevated tissue pressures are not suspected or diagnosed in a timely fashion. Fractures that are not adequately aligned or immobilized heal poorly or not at all.

SPECIFIC INJURIES

TIBIAL SHAFT FRACTURES

The tibia is the most commonly fractured long bone. Fractures often result in open injuries because of the minimal amount of subcutaneous tissue between the tibia and the skin. The fracture pattern seen on radiographs will give a clue to the force that caused the injury. Transverse shaft fractures typically result from a direct blow to the bone. Spiral fractures are the result of rotational forces. A comminuted fracture suggests the mechanism had a very-high-energy impact. A force powerful enough to shatter the dense cortex of the tibial shaft will often be transmitted through the interosseous membrane to the fibula, fracturing that bone as well.

Open tibial shaft fractures have been classified (**Table 275-2**).[1] A grade 1 injury has minimal soft tissue contusion and a skin laceration that is 1 cm in length or less. A grade 2 injury involves a wound with a >1-cm laceration with moderate soft tissue injury and moderate contamination; the tibia is moderately comminuted. A grade 3 injury can involve segmental injury to the tibia, a vascular injury, a highly contaminated wound, or a >10-cm laceration. This classification system is prognostic in terms of healing time and rate of nonunion. The soft tissue injuries often are determinants of the immediate treatment plan.

The initial management of tibial fractures involves administration of analgesics. Promptly splint the leg with radiolucent material to avoid further soft tissue injury from the movement of the bony fragments. Assess for possible compartment syndrome. Some closed injuries may be treated simply by casting if reduction is able to achieve adequate alignment. Parameters for acceptable reduction include 50% or more of cortical contact, <10 to 15 degrees of angulation on the lateral film, <10 degrees of angulation on the anteroposterior film, and <5 degrees of rotational deformity.[2] Injuries with significant edema and spiral fractures often require surgical fixation. An intact fibula may make obtaining or maintaining reduction of the tibial fracture more difficult.

A *long leg splint* from high above the knee with the knee at 5 degrees of flexion and the foot in slight plantarflexion can be applied. **Tight-fitting splints or casts may increase the risk of compartment syndrome.** Injuries amenable to casting often heal in 4 to 5 months. Initiate weight bearing as soon as possible to facilitate bone union. Patients usually can achieve full weight bearing with crutches in 7 to 14 days.[2]

Patients who can be discharged home after splinting include those who suffered low-energy injuries, have their pain well controlled, and are not at risk of compartment syndrome.

The patient with an open tibial fracture requires orthopedic consultation. Injuries with type 1 soft tissue damage may be cleaned in the operating room and medullary nails inserted to maintain reduction. Those

TABLE 275-2 Gustilo Classification of Open Tibia Shaft Fractures

	Gustilo Grade				
	1	2	3A	3B	3C

Skin coverage	Local coverage	Local coverage	Local coverage	Requires replacement of exposed bone with a free flap for coverage	Local coverage
Neurovascular injury	Normal	Normal	Normal	Normal	Exposed fracture with arterial damage that requires repair

with more extensive injuries may require external fixation or medullary nailing after debridement in the operative room.

SEVERELY INJURED TIBIAL SHAFT

Some patients suffer such extensive damage to their leg that they may be better served by amputation of the leg rather than an attempt to salvage the limb. There are four functional components of the leg: bone, vessels, nerves, and soft tissue. Severe injury to any three of these puts the limb at risk. Most severe injuries are caused by a crushing mechanism. Motor vehicle crashes or farm or industrial accidents are most common, followed by falls. Penetrating injuries caused by gunshot wounds or explosives may also put a limb at risk. There are about 3700 amputations per year performed due to these extensive injuries.

Initial management of the patient with a mangled extremity should include attention to life-threatening injuries, immobilization of the leg, diagnostic imaging, pain control, IV antibiotic administration, and tetanus prophylaxis as needed.

PILON FRACTURES

Pilon is a French word for pestle, a tool used to grind substance in a mortar. In the lower leg, an axial force on the foot can drive the talus into the articular surface of the tibia, grinding or crushing the distal tibia. This injury is also called a *tibial plafond fracture* (**Figure 275-2**).

The amount of energy involved in the accident often predicts the type of injury and is important in planning treatment. A high-energy mechanism (motor vehicle crash) often results in significant soft tissue damage with extensive fragmentation of the bone. By contrast, low-energy injuries (skiing) have minimal surrounding soft tissue damage and less comminution of the bone. Radiographs may show at least one fracture plane that extends proximally from the articular surface of the ankle. There are often several fracture planes present. Obtain a CT scan while the leg is in a splint or cast. The scan will help determine the direction of the fracture planes, reveal the amount of articular surface displacement that exists, and aid in the development of a treatment plan. **Pilon fractures may be accompanied by compartment syndrome or by vertebral body fractures, particularly a fracture of the first lumbar vertebrae (L1).**[3]

FIGURE 275-2. Plafond fracture. Tibial plafond fracture (pilon fracture) due to an axial compression force. [Reproduced with permission from Simon RR, Sherman SC, Koenigsknecht SJ: *Emergency Orthopedics: The Extremities*, 5th ed. © The McGraw-Hill Companies. All rights reserved. Part III: Lower Extremities, Chapter 17 Ankle, Fractures, Axial Compression, Imaging, Figure 17-24.]

The goal of treatment is reduction of the fracture fragment and optimal alignment of the articular surfaces. The extent of soft tissue damage may determine when surgical repair occurs. In the setting of significant soft tissue damage, an external fixation device may temporarily be used to allow this tissue time to heal before definitive surgery.

TRIPLANE FRACTURES

The distal tibial growth plate begins to fuse when adolescents are between the ages of 12 and 15 years old. The process takes about 18 months. The medial portion of the growth plate fuses before the lateral. It is this relatively weak lateral growth plate that makes them susceptible to a triplane fracture.

An external rotational force applied to the foot causes stress and a fracture of the tibia. The fracture plane extends from the lateral side of the tibia through the growth plate until it reaches the already fused medial aspect of the physis. At that point, the fracture planes are redirected into sagittal and coronal planes. The resulting injuries can appear to be a Salter III fracture on the anteroposterior radiographic view and a Salter II injury on the lateral view. **Evaluate this injury with a CT scan, which often can reveal further deformity of the articular surface.**

The treatment goal is producing good articular surface alignment, which can be obtained with closed reduction in most cases.[4] With a complex fracture pattern, some patients will require surgery to attain optimal joint surface alignment.

PROXIMAL FIBULA FRACTURE (MAISONNEUVE'S FRACTURE)

Maisonneuve's fracture results from an external rotation force applied to the foot. This creates a plane of injury that starts at the medial ankle as either a deltoid ligament rupture or a medial malleolus injury. The injury is then directed upward and laterally, tearing the interosseous membrane that tethers the distal tibia to the fibula. The third component of this injury is a fracture of the proximal fibula. The word *proximal* is relative; the fibula may be fractured at its head or as far down as 6 cm above the ankle joint (a Weber C ankle fracture).

The surgical treatment for this injury is to reduce and stabilize the fractured medial malleolus and to secure the fibula to the distal tibia, allowing the ruptured interosseous membrane to heal.

MIDSHAFT FIBULA FRACTURES

The shaft of the fibula is most often fractured by a force that has also fractured the tibia; in these cases, treatment is directed by the tibial injury. A direct blow to the fibula can result in an isolated injury to this bone. The patient typically presents with pain or tenderness over the fracture site. With the tibia intact, the patient is often able to bear weight and should be treated with a short leg cast and crutches. Patients with less intense pain may be immobilized with a knee immobilizer (proximal fibula) or elastic wrap (distal fibula) and directed to bear weight as tolerated.

STRESS FRACTURE

Stress fracture occurs when there is increased muscle activity on bones that are not able to tolerate the additional forces. Extrinsic causes may include a recent increase in activity, running over hard surfaces, or excessive wear on the athlete's shoes. Adolescent female athletes with eating disorders and military recruits are at high risk for stress fractures. As our population ages, the elderly are taking up activities that may result in stress fractures. The prototypical patient is the Caucasian

woman with demineralized bone. Stress fractures are twice as common in women compared with men. About half of stress fractures in athletes occur in the tibia. Less common sites are the tarsals and fibula. Stress fractures may be bilateral. In adolescents, the site is often the proximal third of the tibia. Runners typically sustain fractures at the junction of the middle and distal third of the tibia. The distal fibula is another common site.

The history typically involves a change in the patient's training pattern. In an early stage of stress fracture, the patient notices activity-induced pain that is relieved by rest. This can progress to constant pain. On examination, there is pain on palpation over the fracture site, and there may be edema. The pain may be intensified by load bearing on the affected bone.

The radiographs of the site are often normal on initial presentation. They may reveal the fracture, which can have the appearance of sclerosed areas oriented linearly. Radiographs obtained 10 to 15 days later may show periosteal elevation or demineralization at the fracture line. Plain films that are initially normal do not exclude the diagnosis. More sensitive tests for stress fracture are the bone scan and MRI. Although these studies are typically ordered at follow-up and not in the ED setting, they can demonstrate the severity of the change and can be used to predict time to recovery.[5]

Treatment of a suspected stress fracture includes discontinuation of the activity. A cast can be applied if significant pain continues. It is not unusual to have pain lasting up to a year despite treatment.

ACHILLES TENDON RUPTURE

The Achilles tendon is the largest and strongest tendon in the human body. The gastrocnemius and soleus muscles of the calf have tendinous complexes that coalesce to the Achilles tendon that extends about 15 cm to where it inserts on the calcaneus. **Its vascular supply is the weakest in the area 2 to 6 cm above the calcaneus, and this is the area that is most frequently ruptured.** A typical patient is a 30- to 50-year-old man who participates in strenuous activities on an occasional basis ("weekend warrior"). **Risk factors for rupture include older age, prior quinolone use, and prior steroid injection.** The injury often occurs when eccentric force is suddenly applied to a dorsiflexed foot. The patient suffers sudden severe pain and is unable to run, stand on toes, or climb stairs. The most notable finding on examination is a palpable gap in the Achilles tendon 2 to 6 cm proximal to the calcaneus. The calf may be swollen. The patient will be unable to stand on toes. The Thompson test (see Figure 44-6 in chapter titled "Leg and Foot Lacerations") will help demonstrate the tendon rupture. The patient lays prone with the knee bent at 90 degrees. The examiner squeezes the calf: an intact Achilles tendon will transmit this force to the foot resulting in its plantarflexion. **If the Achilles tendon is ruptured, the foot will not plantarflex when the calf is squeezed.** The diagnosis of Achilles tendon rupture can be made without radiographs. When the diagnosis is not clear, an US or MRI of the Achilles tendon may be obtained. The reliability of US is largely dependent on the operator's skill. Initial care for Achilles tendon rupture involves immobilization from just below the knee to the metatarsals with the ankle in some plantarflexion. Crutches are necessary for non–weight-bearing status. Ice and analgesics are also used.

Subsequent therapy may involve either surgical repair of the ruptured tendon or immobilization and gradual physical therapy to regain range of motion. There has been controversy about whether surgery is superior to conservative management. In both treatment modalities, the rerupture rate is less than 5%, but there was some suggestion that conservative care was associated with a slightly higher rate of rerupture. Two studies have shown equivalent rates of rerupture in those treated surgically versus conservatively.[6,7] Refer patients with Achilles tendon rupture to an orthopedist or sports medicine specialist. They will typically be immobilized for 2 to 3 months and be able to return to their sport in 3 to 6 months.

MEDIAL GASTROCNEMIUS MUSCLE STRAIN

The medial gastrocnemius originates from the medial femoral condyle, crosses the knee, and joins the lateral gastrocnemius. The tendon complex of this muscle merges with that of the soleus muscle to form the Achilles tendon, which inserts on the calcaneus to act in plantarflexion of the foot. Injury to the medial gastrocnemius muscle usually occurs when a person forcefully plantarflexes the foot while the knee is extended, occurring when the gastrocnemius is at its maximal length. The typical patient is 40 to 60 years old and an intermittently active athlete. A sharp pain is suddenly felt in the calf as if a stick had struck the person. An audible "pop" may be heard. The pain is severe enough to cause an immediate cessation of the activity, as plantarflexion of the ankle is too painful.

On examination, there may be asymmetric calf swelling and tenderness of the calf. The Achilles tendon is intact. The patient's pain can be elicited by passive dorsiflexion of the ankle. Differential diagnosis can include deep vein thrombosis, ruptured Baker's cyst, and compartment syndrome. Radiographs are not necessary for making the diagnosis. Nonurgent MRI can be obtained to confirm the diagnosis. Treatment includes immobilization with the foot maximally plantarflexed. Rest, ice, and elevation may decrease swelling.

SHIN SPLINTS

Shin splints is a complex syndrome that may eventually be found to include several different injuries. The patient presents with exercise-induced pain over the medial aspect of the tibia. This is also referred to as a *medial tibial stress syndrome*. It may be caused by a repetitive trauma–induced periostitis of the tibia.

The population at risk includes runners, military recruits, and those with flat feet. It is uncommon before the age of 15 years old. The condition typically starts after a sudden increase in training, particularly running on hard surfaces. Physical examination findings may include tenderness over the medial or posterior tibia. Radiographs are normal. A bone scan may be needed to exclude the possibility of a stress fracture. The diagnosis is primarily a clinical one based on history and an examination that excludes other pathology. The mainstay of treatment is a several-week cessation of the activity that precipitated the pain.

CHAPTER 276

Ankle Injuries

Daniel A. Handel
Sarah Andrus Gaines

INTRODUCTION AND EPIDEMIOLOGY

Given the mobility of the ankle joint and our bipedal existence, ankle injuries are a common complaint. They represent 14.6% of all visits to the ED.[1] Fractures of the lateral malleolus are more prevalent in men younger than 50 years old and in women older than 50 years old.[2,3] Previous ankle sprain and participation in sports like soccer, basketball, rugby, and football are risk factors for ankle injuries.[4-7] A review of the National Electronic Injury Surveillance System in 2009 reported an incidence of ankle sprains of 206 per 100,000 people in the United States.[8]

ANATOMY

The proximal part of the ankle mortise is comprised of the distal fibula and tibia that fits on top of the talus. These bones are wider anteriorly than posteriorly. Joint stability is provided by medial and lateral malleoli extending on either side of the talus. The **medial deltoid ligament**, **lateral ligament complex**, and **syndesmosis** are the three distinct groups of ligaments that stabilize the ankle[9] (**Figure 276-1**). The deltoid ligament is the strongest of these ligaments and is a thick, triangular band of

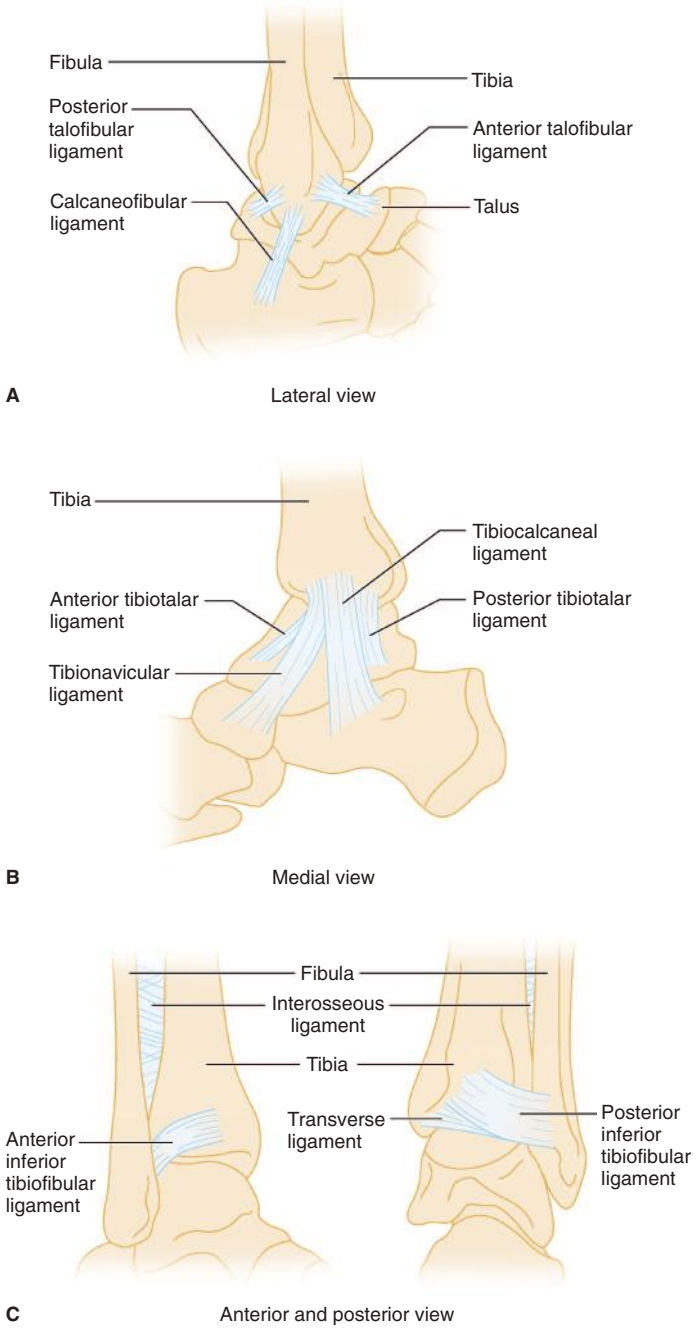

FIGURE 276-1. Ligaments of the ankle joint. **A.** The three lateral ligaments: the anterior and posterior talofibular ligaments and the calcaneofibular ligament. **B.** The four bands of the deltoid ligament: the anterior and posterior tibiotalar, the tibiocalcaneal, and the tibionavicular. **C.** Anterior and posterior view of the ankle syndesmosis. The ligaments of the syndesmosis are the anterior inferior tibiofibular ligament, the posterior inferior tibiofibular ligament, the transverse ligament, and the interosseous ligament, which connects the entire length of the tibia and fibula.

tissue originating from the medial malleolus. The lateral ligament complex consists of the lateral malleolus that attaches to the anterior and posterior aspects of the talus and calcaneus by the anterior talofibular, posterior talofibular, and calcaneofibular ligaments, respectively. This ligament complex, the anterior talofibular ligament in particular, is the weakest and most commonly injured in lateral sprains and represents 85% of all ankle sprains.[10] The syndesmosis, which holds the tibia and fibula together, is a group of four distinct ligaments attaching the distal tibia to the fibula just above the talus (Figure 276-1). The syndesmosis allows the fibula to rotate and carries approximately 16% of the axial load.[9]

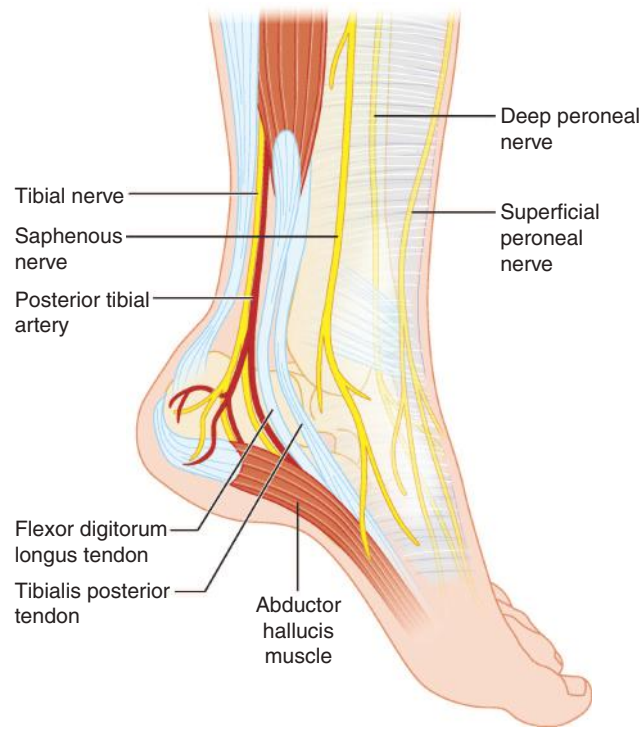

FIGURE 276-2. Neurovascular anatomy of ankle.

The ankle is considered a hinged joint, but ligamentous attachments allow for some rotation and translation within the mortise of the talar dome.[9] Branches of the sciatic nerve, the superficial peroneal, deep peroneal, peroneal, and tibial, innervate the four muscle groups of the ankle joint with branches of the popliteal artery serving as the blood supply (**Figure 276-2**). The tibialis anterior, extensor digitorum longus, and extensor hallucis longus muscles run over the anterior aspect of the joint and are responsible for dorsiflexion. Inversion is accomplished by the tibialis posterior, flexor digitorum longus, and flexor hallucis longus. The peroneus longus and brevis muscles, sharing a common synovial sheath held in place by a groove on the posterior aspect of the lateral malleolus and superior retinaculum, run laterally to evert and plantarflex the joint. Plantarflexion is primarily accomplished by the gastrocnemius and soleus muscles.

CLINICAL FEATURES

HISTORY

Understanding the mechanism and timing of the injury is important. Document these details along with any previous bony or soft tissue injuries. Patients with signs of neurovascular compromise, including coldness and numbness of the foot, a rapid onset of swelling, extreme pain, and complicating conditions such as diabetes, require urgent evaluation.[5] A normal-appearing ankle does not preclude the need for further inquiry. Due to the significant swelling typically present after acute injuries, examining the ankle is challenging but can be helped by elevation of the injured extremity and ice applied at triage. Peroneal spasms may mask any instability in the joint.[9]

PHYSICAL EXAMINATION

Place the patient on a stretcher to perform a thorough evaluation. A systemic approach to the examination decreases the chance of missed injuries. Starting with the skin and soft tissues, note any ecchymosis, abrasions, or swelling. Note the position, swelling, and skin integrity of the joint as well as any areas of tenderness or crepitus. Joints above and below the ankle need to be examined for any concomitant injuries. Suspect a **Maisonneuve fracture** (or fibulotibialis ligament tear) if

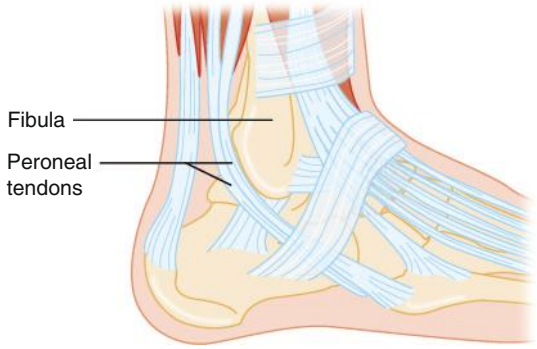

FIGURE 276-3. Peroneal tendon of the foot, lateral view.

there is tenderness of the fibular head or proximal fibular shaft. Palpate the area of obvious injury last. Test the functionality of the joint with both active and passive plantarflexion, dorsiflexion, and full range-of-motion exercises. **Peroneal tendon injuries** can occur from forced dorsiflexion, which presents as weakness on eversion (**Figure 276-3**). Check stability in external rotation, varus, and valgus. Palpate the posterior aspects of the lateral and medial malleoli, starting proximally to the joint and working distally. If there is a concern for isolated fibular fractures, check for evidence of injury to the syndesmosis or deltoid ligament.[9] A positive anterior drawer test (**Figure 276-4**) is indicative of a torn anterior talofibular ligament. A positive anterior drawer test, swelling, and a hematoma are signs of a grade III sprain. **Syndesmosis injuries** can be deceiving because the patient describes ankle pain, but there is typically little ankle edema or ecchymosis. The **crossed-leg test** (compressing the fibula toward the tibia just above the midpoint of the calf[11]) can detect a syndesmosis injury and is indicated if pressure to the medial aspect of the knee elicits pain in the syndesmosis (**Figure 276-5**). The **squeeze test** is performed by squeezing the calf just above the ankle joint. Pain indicates syndesmosis injury. Calcaneofibular ligament instability can be detected with the **inversion stress test** or **talar tilt**.[6] If the examination is uncomfortable for the patient, consider a hematoma block, sedation, or both to perform a more thorough examination.[11]

Examine areas in close proximity to the ankle as well. What may be described as an ankle injury may end up being an injury to the Achilles tendon or foot and cannot be excluded by ankle radiographic imaging. Assess the integrity of the **Achilles tendon**. Fluoroquinolones and corticosteroids increase the risk of such an injury.[12] Perform the **Thompson test** (see Figure 44-4 in chapter titled "Leg and Foot Lacerations") if there is tenderness or a defect. Place the patient prone on the stretcher and squeeze the calf. Loss of plantarflexion indicates a complete Achilles tendon rupture. Palpate the hindfoot and midfoot over the calcaneus, tarsals, and base of the fifth metatarsal to check for areas of tenderness that may require further investigation.

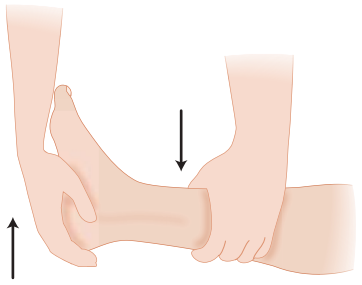

FIGURE 276-4. Technique for performing the anterior drawer stress test of the ankle. [Reproduced with permission from Simon RR, Sherman SC, Koenigsknecht SJ: *Emergency Orthopedics, The Extremities*, 5th ed. © 2007, McGraw-Hill Inc., New York.]

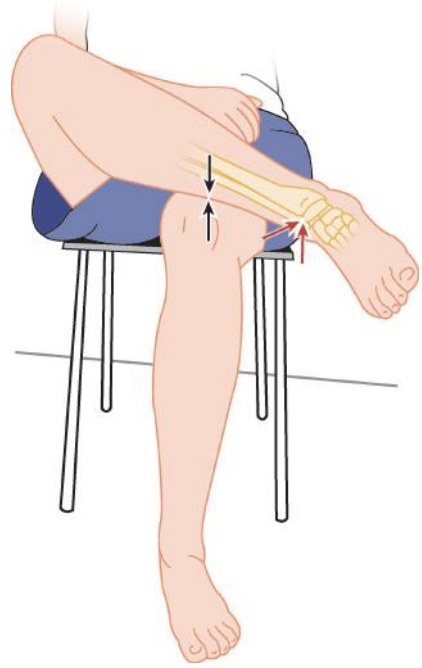

FIGURE 276-5. The crossed-leg test. The affected leg is crossed over the opposite leg as demonstrated. If pain results at the arrow sites when pressure is applied to the medial side of the affected knee, the test is positive and indicates syndesmosis injury. [Copyright © 2010 by the American Orthopaedic Foot and Ankle Society, Inc., originally published in *Foot & Ankle International* in Kiter E, Bozkurt M: The crossed-leg test for examination of ankle syndemosis injuries. *Foot Ankle Int* 2: 187, 2005, and reproduced here with permission.]

Perform a neurovascular examination. Check dorsalis pedis and posterior tibial pulses and document digital capillary refill. Inability to dorsiflex the toes suggests a tibial nerve injury. Inability to plantarflex the great toe is suspicious for peroneal nerve injury.

If there are any significantly displaced fractures or dislocations, immobilize the joint in a neutral position with a well-padded splint to reduce further soft tissue injury. Follow this with elevation and application of ice to reduce edema. Emergently reduce any displaced fractures or dislocations with neurovascular compromise (see later treatment section under "Dislocations").

DIAGNOSIS

IMAGING

The Ottawa Ankle Rules for Ankle and Midfoot Injuries[2,13-17] are easily applied by physicians and triage nurses.[18,19] The rules are summarized in **Figure 276-6**.

The rules were originally developed for patients older than age 18 years who were able to cooperate, were not intoxicated, and had no distracting injuries or decreased sensation. Assuming the patient does not have any bony tenderness, assess the ability to bear weight by having the patient take four steps, resulting in two transfers to and from the injured ankle. The initial studies demonstrated a 30% reduction for the need of ankle radiographs.[16,20]

The standard ankle trauma series consists of three views: anteroposterior, 15-degree internal oblique, and lateral views. See **Figure 276-7** for normal anatomy. About 95% of all ankle fractures can be detected with any two of these views.[9]

When there is an abnormal motion of the talus within the mortis, there is stress on the malleoli and ligaments, which causes the injury. Fractures above the talus and those that cause disruption of both sides of the joint have the potential to create an unstable injury. Instability of the joint is usually diagnosed based on plain radiographs because pain and swelling make it difficult to determine true stability of an acutely injured ankle. If radiographs are normal but there is concern about sta-

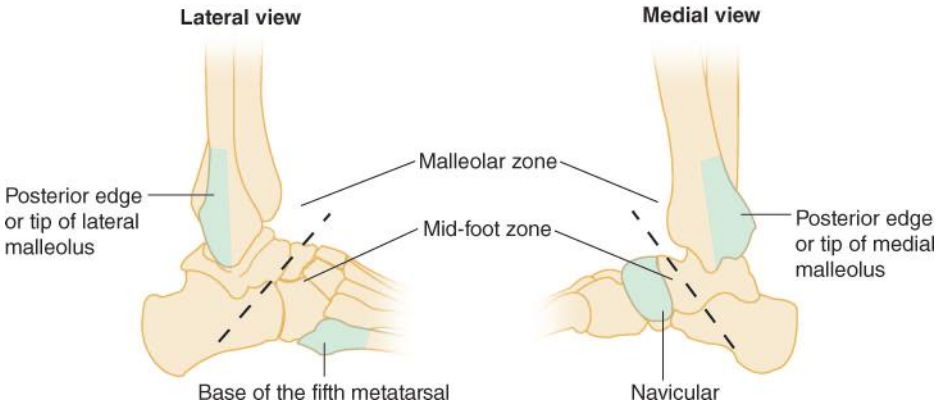

FIGURE 276-6. Ottawa Ankle Rules for Ankle and Midfoot Injuries. Ankle radiographs are required only if there is any pain in the malleolar zone or midfoot zone along with bony tenderness in any of these four locations or the inability to bear weight both immediately and in the ED.

bility, weight-bearing ankle films can be helpful. US can detect Achilles tendon injuries[21] and ankle fractures.[22]

CT and MRI may play a role in better delineating pathology. Ideal imaging for a CT includes both axial and direct coronal images with sagittal reformations. To obtain these images, keep the ankle between neutral and 20 degrees of plantarflexion when possible, similar to that for plain radiographs. CT can be used for operative planning by orthopedic surgeons and to evaluate comminuted fractures and complex bony injuries like pilon fractures and malunions.[7] MRI can help define soft tissue, muscle, ligamentous, and tendon injuries and is used more in the outpatient setting for subacute and chronic pain presentations.[9,23]

TENDON INJURIES

CLINICAL FEATURES

A **peroneal tendon** subluxation and dislocation occurs when there is a sudden hyperdorsiflexion of the foot in a position of eversion, as in skiing. The superior retinaculum, which holds the peroneal tendons in place, is torn from the posterolateral malleolus. This leads to a small avulsion fracture in more severe injuries with a dislocation or anterior subluxation of the peroneal tendon over the tip of the fibula. Consider this injury when there is ecchymosis or tenderness over the posterior edge of the lateral malleolus and no tenderness over the talofibular ligament.

Achilles tendon ruptures happen with sudden plantarflexion of the foot. A complete tendon rupture will become apparent with palpation of a defect over the Achilles tendon and is identified by the Thompson test (**Figure 276-8**). US can also identify Achilles tendon ruptures (**Figure 276-9**).

TREATMENT

The treatment for both types of tendon rupture is often operative repair, especially for those who wish to return to full activity.

LIGAMENT INJURIES

CLINICAL FEATURES

The most common type of ankle sprains is one to the **lateral ankle**. Typically, these are minor and are due to an inversion injury when the ankle is plantarflexed. Sprains are categorized into three grades. Grade I involves no tearing of the ligaments with minimal functional loss, pain, swelling, and ecchymosis. Weight bearing is tolerable. Grade II sprains occur with a partial tear and some loss of functional ability. Grade II sprains tend to be more painful, with swelling, ecchymosis, and difficulty bearing weight. Grade III sprains result from a complete tear, with significant functional loss, pain, swelling, and bruising, and almost a universal inability to bear weight.[6] It has been argued, however, that assigning a grade to the sprain is less important than the stability of the joint.[24] Joint stability is the primary determinant of a treatment plan for a sprain.

An isolated sprain of the medial deltoid ligament is rare. **Medial deltoid ligament** tears are usually associated with a fibular fracture or tear of the tibial-fibular syndesmosis from an eversion injury. If there is significant medial malleolus tenderness and swelling, suspect a Maisonneuve fracture of the proximal fibula and fibular shaft. Negative radiographs should suggest syndesmosis tears.

Injuries to the tibiofibular syndesmotic complex are associated with hyperdorsiflexion injuries when the talus moves superiorly and separates the tibia and fibula. This leads to a partial or complete tear of the syndesmosis with complaints of pain just above the talus.

If there is concern for an unstable ligamentous injury, weight-bearing views of the ankle can help diagnosis—an unstable ligamentous injury may demonstrate talar shift.

TREATMENT

The immediate goals are to decrease pain and swelling and protect ligaments from further injury. The **PRICE protocol** (protection, rest, ice, compression, elevation) involves elevating the ankle and protecting it with a compressive device along with applying ice and resting up to 72 hours to allow the ligaments to heal.[6] There is controversy as to whether or not early immobilization versus functional treatment results in the best outcomes. There is a trend toward favoring early functional treatment over immobilization.[7] Patients returned to mobility anywhere between 4.6 and 7.1 days sooner with functional treatment when compared with immobilization.[25] Functional treatment usually consists of three phases: (1) PRICE protocol within the first 24 hours of injury; (2) motion and strength exercises to begin within 48 to 72 hours; and (3) endurance training, focused toward specific sports when applicable, and training to improve balance after the second phase begins.[6]

In patients with a lateral ligament sprain, a stable joint, and the ability to bear weight, treatment consists of analgesics, an elastic bandage or ankle brace, and no sports involvement, with follow-up in a week if no improvement. Lace-up supports may reduce persistent swelling when compared to elastic bandages or rigid ankle supports.[26] For patients who are unable to bear weight but have a stable joint, provide an ankle brace and crutches and have them follow-up with either their primary care provider or orthopedic surgeon within 1 week for repeat evaluation. Given the trend for early immobilization, functional braces, such as semirigid (e.g., Aircast) and soft, lace-up braces, are commonly used. There is no consensus as to which leads to a more favorable outcome,[27] although early rehabilitation of low-grade ankle sprains results in a good outcome.[28] Another option is an inflatable cast boot (also called walking fracture boot or air cast boot) that molds to the foot with inflatable air bladders. This device can also be used for stable ankle fractures.

Treat medial ligament sprains with PRICE and early referral to an orthopedic surgeon given the risk for undetected underlying fractures. Consider early orthopedic referral for **syndesmotic complex sprains** given the expected prolonged recovery time.

A

B

C

FIGURE 276-7. Normal ankle radiograph. **A.** Anteroposterior view. **B.** Lateral view. **C.** Oblique view. [Image used with permission of Robert DeMayo, MD.]

Refer patients with an unstable joint to an orthopedic surgeon after placement of a posterior splint for stabilization. Establish contact with the orthopedic surgeon early because the timing of treatment and follow-up is ultimately at his or her discretion.

There is no consensus as to whether surgery versus conservative treatment results in more favorable outcomes.[29] Cryotherapy with ice will help decrease pain and limit swelling and should be applied directly to the ankle or splint but not left on for >20 minutes at a time. Therapeutic ultrasonography is not helpful.[5]

FIGURE 276-8. Thompson test. There is no plantarflexion with squeezing the calf of the affected leg, or less plantarflexion compared with the normal leg. DISLOCATIONS

CLINICAL FEATURES

Most ankle dislocations are associated with a fracture and can occur in one of four planes. Posterior dislocations are the most common and occur with a backward force on the plantarflexed foot, usually resulting in rupture of the tibiofibular ligaments or a lateral malleolus fracture. The less common anterior dislocation results from a force on the dorsiflexed foot with an associated anterior tibial fracture. A lateral dislocation results in ligamentous disruption and fracture of one or both malleoli (**Figure 276-10**). An axial compression force can drive the talus upward with an associated fracture of the talar dome and disruption of the syndesmosis.

TREATMENT

There is a significant concern for neurovascular compromise. Check carefully for an open fracture in these instances. If the patient has intact pulses, dislocations associated with fractures should be reduced by an orthopedic surgeon. If vascular compromise is present, as evidenced by a dusky foot or absent pulses, or there is tenting of the skin, an immediate reduction by the emergency physician is warranted without any pre-reduction radiographs.

First provide appropriate sedation and analgesia before attempts at reduction. Grasp the heel and foot with both hands, and gently apply traction and rotation opposite to the direction of the mechanism of injury. Confirm pulses and distal perfusion, and then apply a splint and elevate the foot while waiting for orthopedic evaluation. Confirm and document distal perfusion again after splint application. Any dislocations that cannot be reduced using closed techniques will require open reduction.

MUSCULAR INJURIES

CLINICAL FEATURES

Strains are injuries to muscle or tendons not usually associated with a specific injury but due to repetitive stress and overuse. Common muscles and tendons involved include the extensor digitorum longus, extensor hallucis longus, peroneus brevis and longus, and anterior tibial tendon (**Figure 276-11**). Strains can be due to athletics or poorly fitting footwear. Contusions are usually caused by direct trauma from a projectile like a baseball or hockey puck. Fractures associated with contusions are rare and usually involve only the bony cortex.

TREATMENT

For overuse injuries, analgesics, especially nonsteroidal anti-inflammatory drugs, will help, along with rest and cessation of the activities that are causing the strain. Targeted exercises may help in the recovery as well. Contusions are treated symptomatically with analgesia and ice.

FRACTURES

CLINICAL FEATURES

Radiographically, ankle fractures are described as unimalleolar, bimalleolar (**Figure 276-12**), and trimalleolar (**Figure 276-13**). A bimalleolar fracture is fracture of the lateral and medial malleoli; trimalleolar fracture additionally involves the posterior malleolus.

The ankle consists of a ring of bone and ligaments around the talus. The ring is composed of the tibia, tibiofibular ligament, fibula, lateral and medial ankle ligaments, and calcaneus.[30] A single ring disruption is typically a stable injury. Injuries involving two or more components of the ring are unstable injuries and usually need surgical fixation.

The Danis-Weber and Lauge-Hansen schemes are used by orthopedic surgeons to classify ankle fractures and help determine surgical repair. The Danis-Weber system classifies fracture patterns based on the level of the fracture of the fibula.[31-33] The Lauge-Hansen system classifies fractures based on the position of the foot at the time of injury.[34]

Critical aspects of the examination for ankle fractures are summarized in **Table 276-1**.

TREATMENT

The goal is to restore the anatomic relationship of the ankle, maintain reduction during the healing, and mobilize the ankle early. Treat small fibular avulsion fractures as stable ankle sprains (see earlier section, "Ligament Injuries") if they are minimally displaced (<3 mm in diameter) and there is no sign of medial ligament injury.

Most other ankle fractures require immobilization by either cast alone or surgical repair and casting.[35,36] Severe comminuted fractures are at risk for compartment syndrome, fat emboli, and poor healing. Urgent orthopedic consultations in the ED is necessary. Until definitive fracture treatment can be provided, apply a posterior splint and keep the patient non–weight bearing (see Figure 267-15 in chapter 267,

"Initial Evaluation and Management of Orthopedic Injuries, Posterior Ankle Mold). Provide analgesics, and remind the patient to elevate the leg and apply ice. **Table 276-2** provides guidelines for orthopedic consultation and follow-up.

OPEN FRACTURES

The most important prognostic factor in open ankle fractures is the amount of energy involved in the injury and amount of soft tissue damage involved. Open fractures require rapid surgical management that involves aggressive debridement of nonviable tissue and either internal or external fixation.[9] Administer empiric antibiotics, most commonly IV cefazolin, and add an aminoglycoside for contaminated wounds. Use clindamycin in patients with a penicillin allergy. Update the tetanus status of the patient as needed.

While waiting for the orthopedic surgeon, irrigate the wound with several liters of normal saline, then apply sterile gauze soaked in saline over the open wound, and secure it in place with a gauze roll. Do not use iodine solutions, as they are caustic to tissues. Splint the injury to stabilize it while obtaining radiographs and coordinating orthopedic care.

TABLE 276-2 Timing of Consultation

Immediate Consultation in ED	Deferred Consultation*	Within 1 Week
All open fractures	Stable unimalleolar fractures	Potentially unstable sprains
All fracture dislocations	Unstable ligamentous injuries	
All dislocations	Acute peroneal dislocations	
All trimalleolar fractures†		
All bimalleolar fractures†		
Unstable unimalleolar fractures†		
Maisonneuve fractures†		

*Implies that communication is established at time of diagnosis and specific time of consultation has been set.

Consultation can be delayed in the ED in fractures without neurovascular compromise and appropriate splinting.

DISPOSITION AND FOLLOW-UP

To date, there is no established standard of care regarding the time of orthopedic consultation and follow-up. Whether or not an orthopedic surgeon sees the patient in the ED depends on the specialist resources available. Table 276-2 can serve as a general guideline for local practice standards and resources. Most severe fractures require orthopedic consultation in the ED.

Acknowledgments: The authors would like to thank Drs. John A. Michael and Ian G. Stiell for their contributions to previous editions of this chapter. We would also like to thank Drs. Esther Choo and Robert DeMayo for the radiology images.

CHAPTER 277

Foot Injuries

Sarah Andrus Gaines
Daniel A. Handel

INTRODUCTION

Foot injuries occur most commonly in work and athletic environments.[1] Work-related foot injuries can be associated with substantial medical costs and lost wages.[2] Sport-related foot and ankle injuries require care so the athlete can return to the demands of the sport as quickly as possible.[3] Motor vehicle crash patients with a foot or ankle injury typically have a higher injury severity score than those without such injuries.[4]

ANATOMY

The foot is divided into three sections: the hindfoot, the midfoot, and the forefoot. The **Chopart joint** separates the hindfoot from the midfoot.

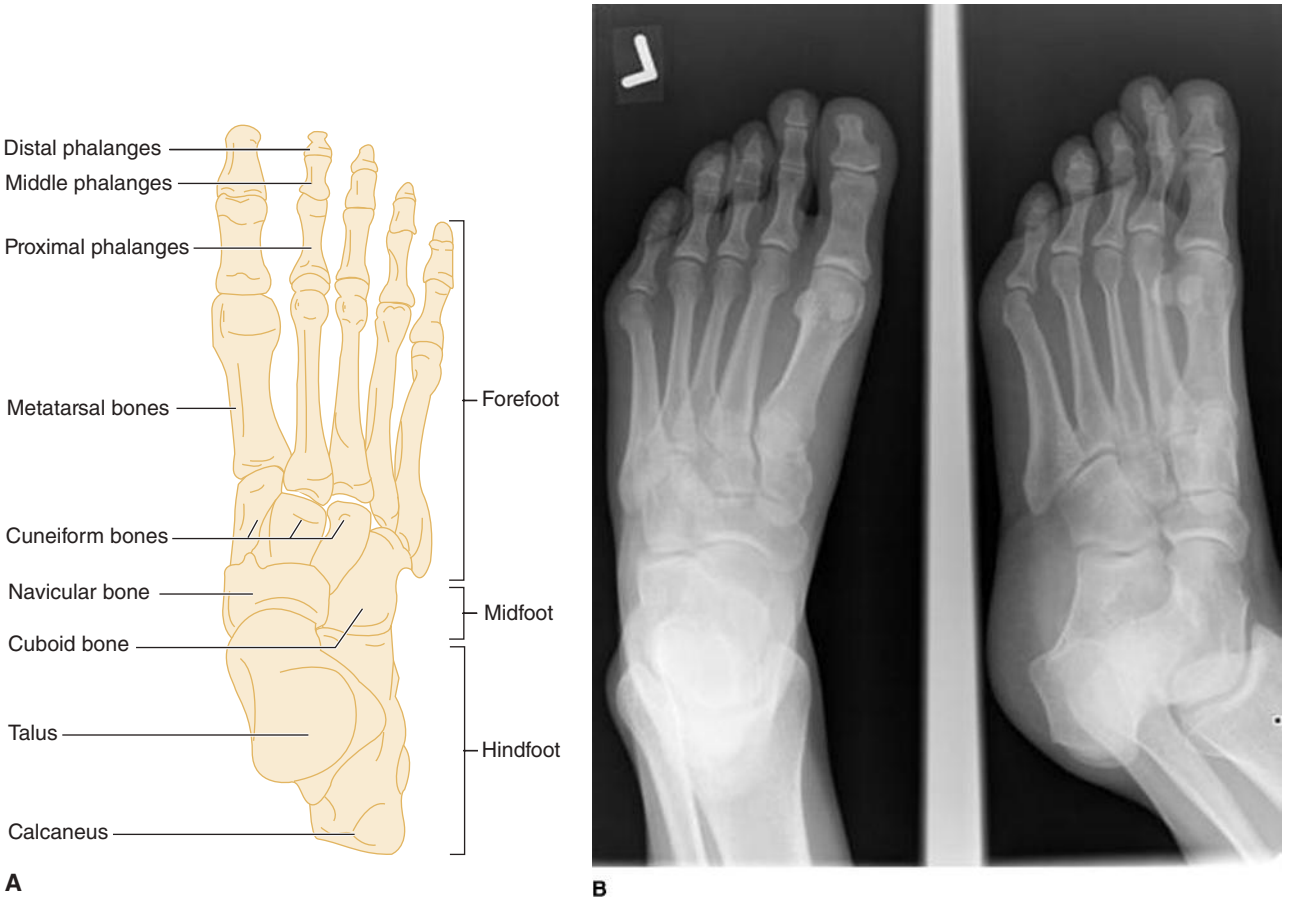

FIGURE 277-1. **A.** Diagram of normal bony anatomy of the foot. **B.** Radiograph of normal bony alignment of the foot. [Panel B image used with permission of Robert DeMayo, MD.]

The Lisfranc joint divides the midfoot and the forefoot. The hindfoot is comprised of the talus and the calcaneus. The midfoot encompasses the medial, middle, and lateral cuneiforms; the navicular; and the cuboid. The tarsus refers to the bones of the hind and midfoot. The forefoot includes the metatarsals and the proximal, middle, and distal phalanges (**Figure 277-1**). Ligaments and muscles enable foot movements of eversion, inversion, adduction, and abduction.

Vascular supply of the foot originates from branches of the popliteal artery: the anterior tibial artery, with its branch the dorsalis pedis supplying the dorsal aspect of the foot; and the posterior tibial and peroneal arteries supplying the sole (**Figure 277-2**).

The sural, saphenous, peroneal, and lateral plantar nerves innervate the foot for both motor and sensory function and originate in branches from the sciatic and femoral nerves.

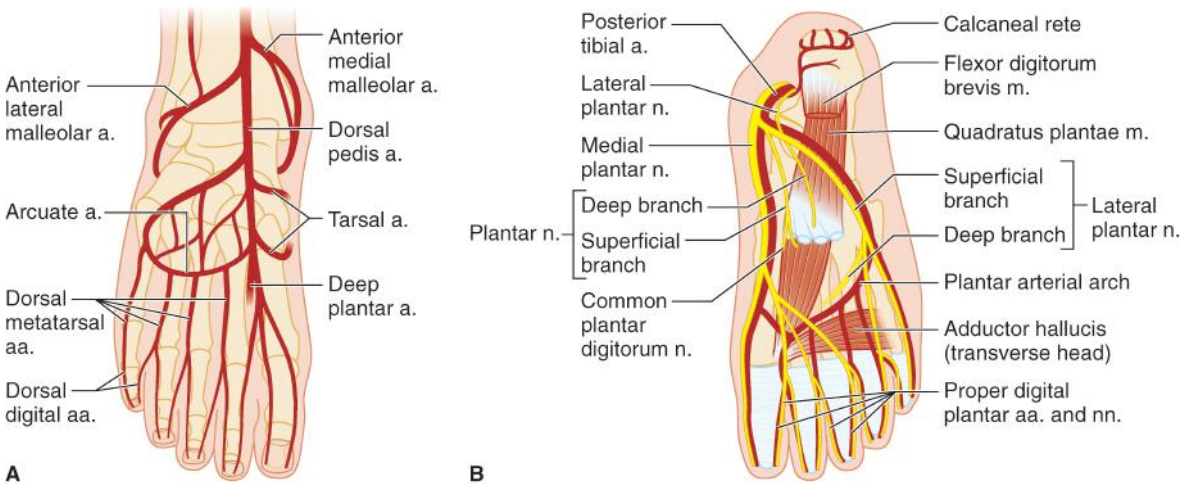

FIGURE 277-2. A. Arteries of the dorsum of the foot. B. CLINICAL FEATURES

HISTORY

Ask about the mechanism of injury and direction of force. Obtain key information, including ability to bear weight after the injury, prior injury or surgery to the area, and any other potential injuries. Because it requires great force to fracture the foot, other injuries can coexist, and foot pain can distract from other serious injuries.

PHYSICAL EXAMINATION

The foot examination does not necessarily begin with the foot, but with the entire lower extremity on the affected side. Examine the hip, knee, and ankle. Evaluate neurovascular integrity. Vascular compromise of the foot is identified with diminished pulses, a cool extremity, and mottled skin. Once the general examination is completed and the focused foot examination begins, start with the general appearance of the foot and compare it with the uninjured side. Look for obvious closed or open deformities. Ask the patient to identify painful areas. Palpate the foot for abnormal findings or tenderness. Pay particular attention to the base of the fifth metatarsal and the dorsal aspect of the base of the second metatarsal. Range the joint both passively and actively through all typical motions of the foot. Evaluate gait when possible.

HINDFOOT INJURIES

CALCANEUS INJURIES

Clinical Features The calcaneus is the most commonly fractured tarsal bone, whereas the talus is infrequently fractured.[5] Fractures in the hindfoot typically require a large force, like an axial load to the heel, to occur. Because of this force, associated injuries are common.

Calcaneal fractures are subdivided into intra-articular and extra-articular fractures, with intra-articular fractures being the more common of the two. A displaced intra-articular fracture is common and poses its own challenges for long-term care. Some surgeons advocate for open reduction and internal fixation; others prefer nonoperative closed reduction; and still others prefer primary arthrodesis.[6]

Diagnosis Plain radiographs, specifically the lateral view, are needed for fracture diagnosis. The Boehler angle is measured using the lateral view and represents the intersection of two lines: (1) the line drawn from the highest part of the anterior process of the calcaneus and the highest point of the posterior articular surface of this bone, and (2) the line between the highest point of the posterior articular surface of the calcaneus and the most superior part of the calcaneal tuberosity. The normal angle measures between 25 and 40 degrees. When the angle is <25 degrees, suspect a fracture (**Figure 277-3**). Because this angle varies widely between individuals, a comparison view is helpful if the diagnosis is in question. Although plain radiographs are helpful when the fracture is visible, a CT can provide detail and help clarify the management plan.

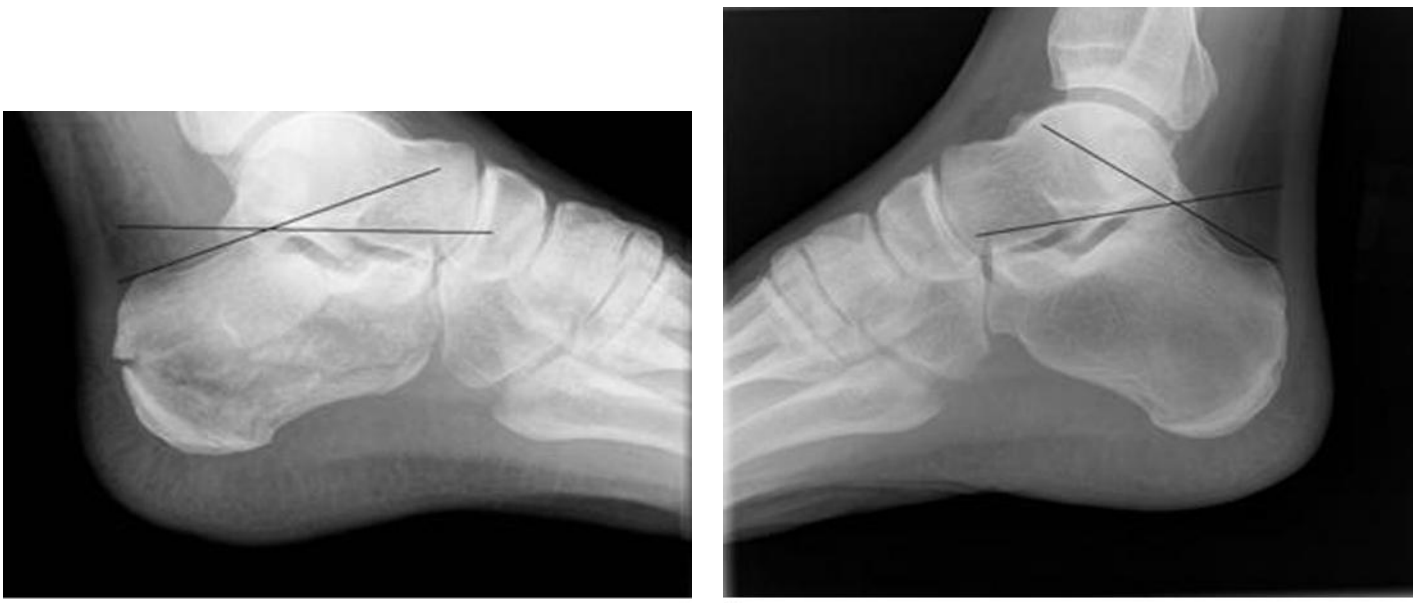
Treatment and Follow-Up For intra-articular fractures, obtain orthopedic consultation to determine the management plan. For nondisplaced fractures, treat an intra-articular fracture with immobilization, a well-padded posterior splint, strict elevation, non–weight-bearing status, and appropriate analgesia. Elevate the leg above the heart to minimize edema and the risk of compartment syndrome (see the chapter titled "Compartment Syndrome"). Displaced fractures may require surgical repair. Care for an extra-articular fracture is elevation, immobilization, analgesia, and orthopedic follow-up. Some of these will require outpatient surgical intervention, with less invasive, percutaneous approaches being adopted in more recent years.[7]

TALUS INJURIES

Clinical Features Fractures of the talus usually require a significant mechanism such as extreme dorsiflexion or a fall from a great height. "Major" talus fractures are those involving the head, neck, or body of the talus (**Figure 277-4**) and can result in avascular necrosis. "Minor" talus fractures are those that do not cross the central part of the talus (**Figure 277-5**). A lateral process talar fracture is sometimes called "snowboarder's ankle," and is commonly mistaken for a lateral ankle sprain.

Diagnosis, Treatment, and Follow-Up Diagnosis begins with plain radiography, but CT provides better visualization of the talus. Minor talus fractures can be treated on an outpatient basis with a posterior splint, non–weight-bearing status, analgesia, and orthopedic referral. Major talar fractures ideally require orthopedic consultation in the ED.

Dislocations of the talus, when the tibiotalar joint remains intact, are either peritalar or subtalar. The talocalcaneal and talonavicular joints are disrupted by a rotational-inversion force. Dislocations are rare but are orthopedic emergencies. Immediate orthopedic consultation and reduction are necessary to prevent neurovascular compromise to the foot.



A B

FIGURE 277-3. **A.** Calcaneal fracture with abnormal Boehler angle. **B.** Normal radiograph with normal Boehler angle. [Image used with permission of Robert DeMayo, MD.]

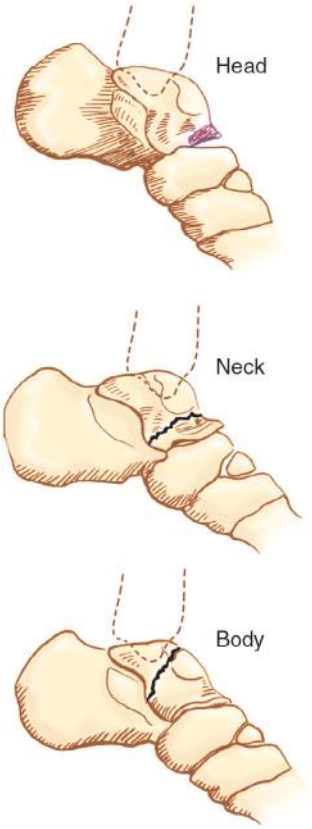


FIGURE 277-4. Major talus fractures. [Reproduced with permission from Simon RR, Sherman SC (eds): *Emergency Orthopedics*, 6th ed. New York: McGraw-Hill, 2011; Fig. 23-13, p. 525.]

MIDFOOT INJURIES

LISFRANC INJURIES

Clinical Features The midfoot is divided into two columns, with the medial column containing the navicular, cuneiforms, and the first three tarsometatarsal joints; the lateral column contains the cuboid and fourth and fifth tarsometatarsal joints (Figure 277-1). The midfoot is a vital bridge between the hindfoot and the forefoot. Injuries to the midfoot have the potential to dramatically affect an individual's daily function, including the ability to stand and walk. Untreated midfoot injuries in diabetics can lead to the development of **Charcot's foot** (collapse of the mid-foot arch) and lifelong complications with ambulating.[8]

The cornerstone of mechanism, diagnosis, and treatment of Lisfranc injuries lies in the anatomy of the second metatarsal and the Lisfranc ligament, which runs between the lateral base of the medial cuneiform and the medial base of the second metatarsal. Its strength exceeds that of the plantar ligament construct by severalfold.[9] Lisfranc injuries range from sprains to fracture-dislocations, with concurrent fractures of the hind and forefoot being relatively common, especially fractures of the second metatarsal. The usual mechanism of injury for sprains is a low-velocity indirect force, whereas plantar-flexion with an axial load (such as strenuous jumping over an obstacle) is seen in more significant injuries. Sports injuries (specifically football) and motor vehicle crashes are common situations for these injuries.[10,11]

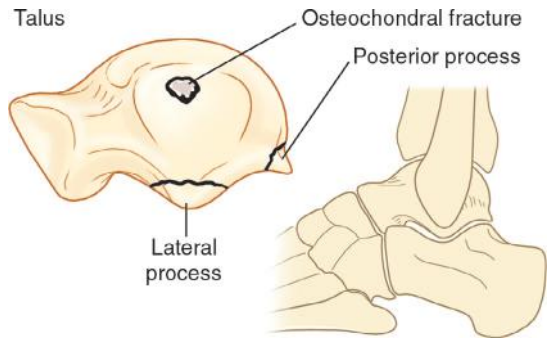

FIGURE 277-5. Minor talus fractures. [Reproduced with permission from Simon RR, Sherman SC (eds): *Emergency Orthopedics*, 6th ed. New York: McGraw-Hill, 2011; Fig. 23-14, p. 527.]

Diagnosis Pain elicited by torsion of the midfoot raises suspicion for a Lisfranc injury. Also, injuries about the tarsometatarsal joint, with pain on passive dorsi- or plantarflexion of the foot, should result in a specific evaluation of the midfoot for a Lisfranc injury. Radiographic studies should include at minimum bilateral weight-bearing anteroposterior (when tolerable), lateral, and 30-degree oblique views of the foot. Bony displacement of 1 mm or greater between the bases of the first and second metatarsals is considered unstable. CT imaging is the ideal imaging study for this injury.[12] It provides better delineation of bony structures and diagnoses occult fractures or subluxations that can be missed on plain radiographs (**Figure 277-6**).

Lisfranc injuries have multiple classification systems.[10] The Nunley classification groups low-energy ligamentous injuries by diastasis and preservation or loss of arch height: type I are nondisplaced, type II involve diastasis between the first and second metatarsal heads, and type III involve diastasis with loss of arch height.[11]

Treatment and Follow-Up Treatment of a nondisplaced injury (<1 mm between the bases of the first and second metatarsals) is with a non–weight-bearing splint, rest, ice, and elevation. Orthopedic reevaluation is usually scheduled within 2 weeks when repeat imaging will likely be obtained and a cast will likely remain on for an additional 4 weeks. At 6 weeks, gradual progressive weight bearing can be attempted.

Displaced Lisfranc injuries are unstable and require orthopedic consultant in the ED and anatomic reduction.[13] Whether the reduction is open or closed depends on the degree of the injury and is determined by the orthopedic consultant. Surgical options are variable and range from open reduction and internal fixation to primary arthrodesis.[14] Compartment syndrome is an acute complication of significant Lisfranc injuries (see the chapter titled "Compartment Syndrome").

NAVICULAR INJURIES

Navicular fractures are typically caused by a direct blow or axial loading. Avulsion injuries can also occur with a pulling or rotational force. On physical examination, tenderness and ecchymosis are found about the navicular. Imaging includes bilateral weight-bearing anteroposterior, lateral, and oblique radiographs. CT is best for evaluating the talonavicular joint surfaces. The goals of treatment are maintenance of anatomy and restoration of articular congruity. Nondisplaced fractures should be treated in a non–weight-bearing short leg cast for 6 to 8 weeks, with orthopedic reevaluation in approximately 2 weeks. Orthopedic consultation in the ED is usually required for displaced, and therefore unstable, fractures, to determine the management plan. Given that the central part of the navicular bone is avascular,[15] complications include avascular necrosis, nonunion, and instability, all of which can lead to a flatfoot deformity.

CUBOID INJURIES

The cuboid articulates with the calcaneus and the fourth and fifth metatarsals. Plantarflexion and abduction is the most common mechanism of injury. Imaging includes bilateral weight-bearing anteroposterior, lateral, and oblique radiographs. CT may be helpful. Nondisplaced fractures are treated with a short leg cast and initial non–weight-bearing status. Comminuted injuries are treated with surgery. Complications include foot instability and joint arthrosis.

CUNEIFORM INJURIES

The cuneiforms all articulate with the navicular. Isolated cuneiform injuries are very rare, but especially with a high-energy mechanism of injury, cuneiform fractures can coexist with other fractures of the foot.

A

B

FIGURE 277-6. **A.** Radiograph of Lisfranc injury. **B.** CT of Lisfranc injury. Note the metatarsal bones are fractured (*arrow*) and displaced from the tarsus. [Image used with permission of Robert DeMayo, MD.]

Imaging studies are the same as for the other bones of the midfoot. Treatment depends on which bone is injured: medial cuneiform injuries are typically treated with surgery, whereas closed reduction usually suffices for the middle and lateral cuneiform bones.

FOREFOOT INJURIES

Forefoot injuries cover a broad range from those requiring minimal intervention to those requiring operative repair. Fractures range from the minimally displaced to open, comminuted fractures.

FIFTH METATARSAL INJURIES

Clinical Features Fractures of the proximal fifth metatarsal occur in three forms and can be identified using the joint between the proximal fourth and fifth metatarsal as a guide: (1) tuberosity or styloid fractures, which are proximal to the joint; (2) Jones fractures, which are also known as metaphyseal-diaphyseal junction fractures; and (3) diaphyseal stress fractures.

Diagnosis Plain radiographs are usually adequate. CT scans should be considered for more detailed imaging in the high-performance athlete[17] (**Figure 277-7**).

Treatment and Follow-Up Patients with nondisplaced Jones fractures should be non–weight bearing in a cast for 6 to 8 weeks. Complications of a Jones fracture treated nonoperatively include bony nonunion, which may later require intramedullary screw fixation. Shock wave therapy has also been reported for treatment of nonunion.[17] Some orthopedic surgeons are advocating for early surgical correction, especially in athletes, so posterior splinting and outpatient referral to an orthopedic surgeon are appropriate initial treatment.[18] Nondisplaced avulsion fractures of the tuberosity, also known as a pseudo-Jones fracture, can be treated with a walking cast and pain control with weight bearing as tolerated.

METATARSAL INJURIES

Proximal fractures of the first through fourth metatarsals are typically caused by a crush injury or direct blow. **Take care to exclude an associated Lisfranc injury**. An isolated proximal metatarsal fracture can be treated with a posterior splint and non–weight-bearing status. Orthopedic follow-up within 2 to 3 days is needed for the likely placement of a more definitive cast.

Nondisplaced isolated fractures of the shaft of a metatarsal, usually caused by an acute direct blow or twisting force, can typically be seen on oblique or lateral foot films. These can typically be treated with a posterior splint or orthopedic shoe or walking boot (see chapter titled "Initial Evaluation and Management of Orthopedic Injuries"). Repeat imaging can be performed 1 week after injury and then again at 6 weeks. Fractures with displacement of 3 to 4 mm or angulation >10 degrees usually require surgical reduction[13] (**Figure 277-8**).

TABLE 277-1 Summary of Emergent Care of Bony Foot Injuries

Fracture or Injury Type	ED Imaging	ED Care*	Orthopedic Referral (immediate: within 24 h; early: within 2 wk)	Home Care/Weight-Bearing Status	Advice on Long-Term Care and Management	Special Considerations
Calcaneal, intra- and extra-articular	Plain films, Boehler angle; CT for subtle findings	Posterior splint	Intra-articular: immediate; extra-articular: early	NWBS; RICE	Possible surgery	
Talus fracture	CT	Posterior splint	Major: immediate; minor: early	NWBS; RICE	Possible surgery	Risk of avascular necrosis
Lisfranc	CT	Splint	Displaced: ortho consult in ED; nondisplaced: early	NWBS; RICE	Possible surgery	Risk of compartment syndrome; arthritis
Navicular fracture	Plain films or CT	Splint	Nondisplaced: early; displaced: immediate	NWBS; RICE	Possible surgery	Risk of avascular necrosis; nonunion
Cuboid fracture	Plain films or CT	Splint	Early	NWBS; RICE	Comminuted: possible surgery	
Cuneiform fracture	Plain films or CT	Splint	Early	NWBS; RICE	Medial: possible surgery	
Jones	Plain films; CT for athletes	Splint	Early	NWBS; RICE	Athletes: possible surgery	
Metatarsal fracture	Plain films	Posterior splint	Within a week for a cast	NWBS; RICE	Surgery not likely	
Stress fracture	Clinical			Cessation of causative activity		
Phalange fracture	Plain films	Buddy taping		Hard-soled shoe and weight bearing as tolerated		
Open fractures of any kind	Consider antibiotics, Td	Pain control	Ortho consult in ED			

*All patients with fractures should receive adequate analgesia, and splints should be well padded.

Abbreviations: NWBS = non–weight-bearing status; ortho = orthopedist; RICE = rest, ice, compression, elevation; Td = Tetanus booster.

STRESS INJURIES

Chronic direct forces cause stress fractures. Stress fractures typically occur in the setting of increasing activity or chronic overuse and are sometimes called "march fractures." Stress fractures are rarely visible on plain radiographs; MRI can be used when pain is persistent. A clinical diagnosis typically suffices. Cessation of the causative activity usually results in good outcomes for recovery.[18]

METATARSOPHALANGEAL INJURIES

Metatarsophalangeal joint injuries are caused by multiple mechanisms and occur in various forms, including sprains, subluxations, and dislocations. **Turf toe** is a form of a sprain that results when there is acute or chronic hyperdorsiflexion of the first metatarsophalangeal joint while the foot remains in plantarflexion. History usually yields the diagnosis. When radiographs are obtained, a capsular avulsion, the hallmark of this injury, is seen. On physical examination, passive ranging results in a pathologically increased range of motion. Treatment is rest, ice, and elevation. Upon returning to sports, a reinforced shoe can be helpful and protective from further injury.[19] MRI is useful and can diagnose subtle associated injuries.[20]

Dislocations of the metatarsophalangeal joint, usually dorsal, can also occur. A high-energy mechanism is the usual cause, and this injury often accompanies other foot injuries. Treatment ranges from closed reduction to operative repair, depending on the severity of injury.

PHALANGE INJURIES

Fractures of the phalanges are the most common fractures of the forefoot, with a stubbing mechanism of the hallucal proximal phalanx being the most common injury.[19] Radiographs are obtained if there is extensive injury, suspicion of foreign body or open fracture, or if the great toe is injured. Radiographs are not necessarily obtained for the distal phalanges of the other toes if the only injury is a closed isolated injury of the distal phalanx. Crush mechanisms can lead to distal phalanx fractures. Treatment is with buddy taping to the adjacent toe or application of tape about the forefoot for greater stability (taking care to avoid undue pressure from the tape) and a hard-soled shoe.

For general guidance regarding the care of patients with acute bony foot injuries, see **Table 277-1**.

TENDON INJURIES

Lacerations to the foot may result in injury to the **extensor hallucis longus tendon**, with inability to dorsiflex the great toe, or **tibialis anterior tendon**, with loss of dorsiflexion of the foot. Consult with the orthopedist. Treatment is primary repair if the tendon edges are opposable; otherwise, tendon reconstruction is necessary.[21]

Lacerations of the **flexor hallucis longus** are typically repaired. Lacerations to the **flexor tendons of the other toes** are generally left unrepaired, as there is little if any functional impact.

Dislocation of the **posterior tibial tendon** is uncommon and is often misdiagnosed as ankle sprain. Mechanism of injury is forced dorsiflexion of the foot and ankle eversion when the posterior tibial tendon is contracted, as may occur in snowboarding or ice skating.[22] Treatment is surgical repair.

Achilles tendon injuries are discussed in the chapters titled "Leg Injuries" and "Soft Tissue Problems of the Foot." Repair of lacerations of the foot is discussed in the chapter titled "Lacerations of the Leg and Foot."

Acknowledgments: The authors would like to thank Drs. John A. Michael, Ian G. Stiell, and Peter Ramsey for their contributions to previous editions of this chapter. We would also like to thank Drs. Esther Choo and Robert DeMayo for the radiographic images.

CHAPTER 278

Compartment Syndrome

Paul R. Haller

INTRODUCTION

Compartment syndrome occurs when increased pressure within a limited space compromises the circulation and function of the tissues within that space. It was first described in 1881 by Richard Van Volkmann, a German physician who noted that paralysis and contractures were the late sequelae of an interruption of the blood supply to the muscles in the forearm. In 1924, it was shown that the result could be prevented by prompt surgical decompression of the compartment.

Today, a high degree of clinical suspicion, coupled with timely surgery, can be used to save function of the muscles and nerves that are at risk of permanent damage from elevated compartment pressures.

ANATOMY

The borders of a confined space are often made up of bone or tissue that offers minimal capacity to stretch. Any increase in volume within that compartment results in an elevated intracompartmental pressure. In the lower extremity, the most common site is at the level of the tibia and fibula, where 40% of compartment syndromes occur. The lower leg has four compartments: anterior, lateral, superficial posterior, and deep posterior (**Figure 278-1**). (Also see Figure 271-1 in chapter 275, Leg Injuries.)

The upper leg has three compartments: anterior, posterior, and medial. Due to the larger size of these compartments and their interconnectivity, they are less predisposed to elevated tissue pressures. The foot and buttock region of the leg also have a lower incidence of compartment syndrome.

In the upper extremity, the forearm has three compartments: flexor, extensor, and mobile wad (**Figures 278-2** and **278-3**). These are the high-risk areas in the arm. The hand (**Figure 278-4**) or upper arm (**Figure 278-5**) is less likely to develop a compartment syndrome.

PATHOPHYSIOLOGY

Muscle death and nerve damage in the setting of compartment syndrome are caused by prolonged elevation of tissue pressures. This can result from external forces, such as a cast or tight dressing, which compress a compartment. It can also result from an increase in the volume of a compartment that exceeds the limits of the surrounding fascia's ability to stretch. This may be the result of hemorrhage into a compartment or edema caused by reperfusion injury (**Table 278-1**). In effect, any mechanism that increases the volume of blood or tissue within the compartment has the potential to cause a compartment syndrome. Tissue perfusion is determined by the difference between the arterial blood pressure and the pressure of the venous return. As tissue pressure increases within a compartment, the normal gradient between arterial and venous pressure decreases.

The normal pressure within a compartment is <10 mm Hg. Anoxia and muscle death occurs with prolonged elevated pressure. Pressures up to 20 mm Hg can be tolerated without significant damage. The exact level of pressure elevation that causes cell death is unclear and may be related to the length of time that the pressure remains high. Tissue pressures exceeding 30 to 50 mm Hg have traditionally been thought to be toxic if left untreated for several hours.[1] However, the difference between the diastolic pressure and the measured tissue pressure may be a better determinant of potential for irreversible muscle damage.[2] This "delta pressure" is the diastolic blood pressure minus the intracompartmental pressure, and the critical level has been found to range between 10 and 35 mm Hg.[3] **The delta pressure that is most commonly used to diagnose acute compartment syndrome is 30 mm Hg.**[4] Using the delta pressure as a threshold for surgical intervention may help avoid unnecessary fasciotomies and can correctly classify patients with pressures sufficient to cause tissue compromise. In one study, none of the patients with a delta pressure >30 mm Hg suffered clinically significant complications related to acute compartment syndrome when fasciotomy was withheld, although such clinical parameters may not be sufficiently sensitive to exclude all sequelae that may result from a compartment syndrome.[4] For example, a hypotensive patient may be less able to tolerate the same degree of pressure elevation when compared to a normotensive patient.

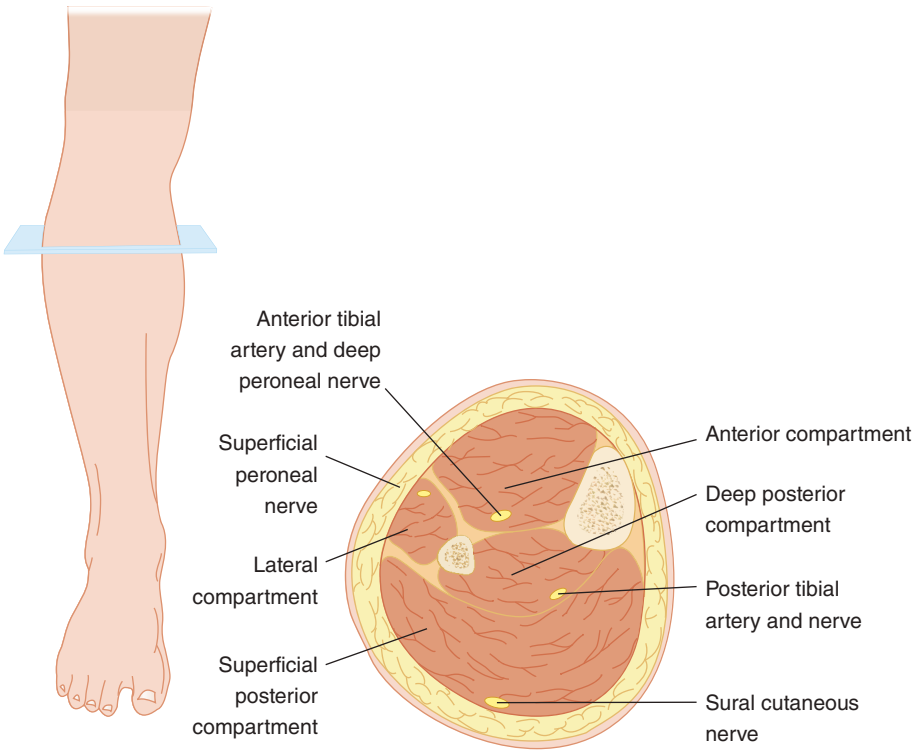

FIGURE 278-1. The four compartments of the lower leg.

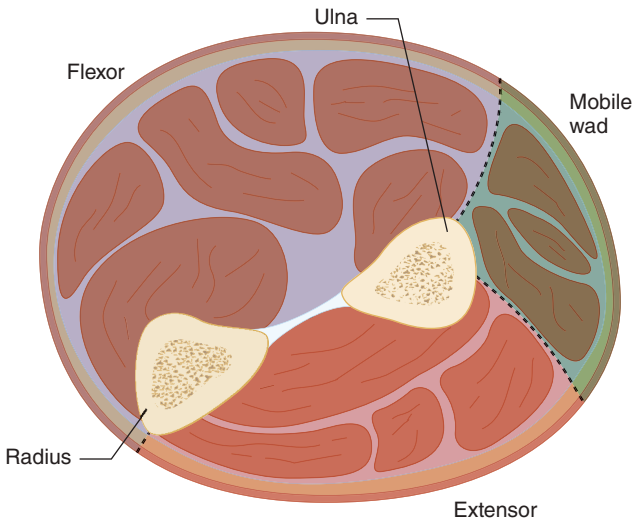

FIGURE 278-2. Forearm compartments.

Some tissues are more sensitive to the ischemic injury produced by elevated compartment pressures. Bone is relatively resistant to this ischemia. The muscles and nerves in the compartment are most susceptible to permanent damage. Short periods of elevated pressures may cause reversible damage, whereas longer periods lead to permanent deficits (see **Table 278-2**).

CLINICAL FEATURES

HISTORY

Compartment syndrome may occur with or without known trauma. For example, patients with hemophilia or rhabdomyolysis can develop compartment syndrome without direct trauma, and crush injury or tibial fracture can result in compartment syndrome to the affected extremity. In the post-trauma setting, symptoms usually develop within a few hours of the injury. The awake patient may initially complain of severe pain in the affected compartment; pain often may be refractory to opioids. The pain is due to elevated tissue pressures within a compartment. Thus the pain worsens when the muscle groups in that compartment are passively or actively stretched.

PHYSICAL EXAMINATION

This pain and the aggravation of pain by passive stretching of muscles in the compartment in question are the most sensitive (and often the only) clinical findings before the onset of ischemic dysfunction in the nerves and muscles.

When nerve conduction is affected, the patient will note numbness or dysesthesia in the sensory distribution of the nerve traversing that compartment. Motor nerve function may also be affected. Because tissue pressures do not become higher than arterial pressures, the distal pulse in the extremity will remain normal and there will not be a change in the color or warmth of the extremity. Squeezing or palpation of the muscle groups in the compartments will exacerbate pain. Firmness or fullness in the affected compartment is often detected.

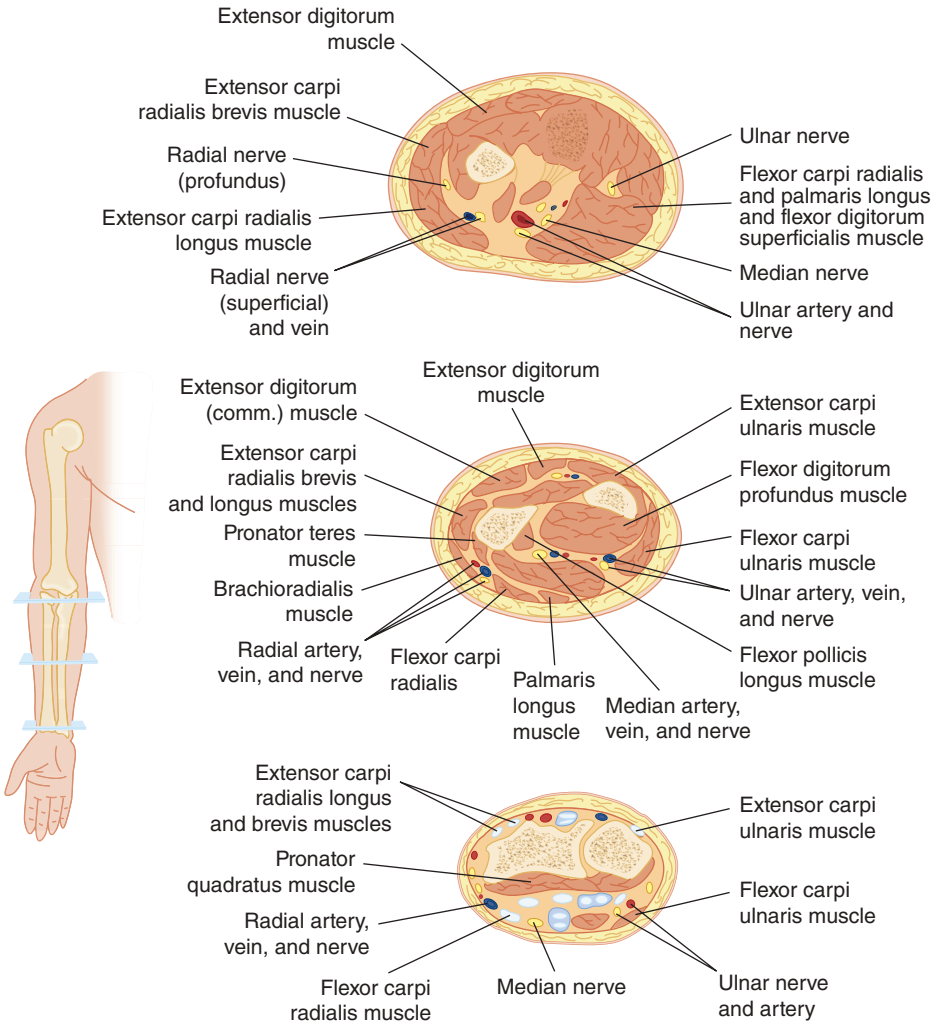

FIGURE 278-3. Forearm compartments: transverse sections through the right forearm at various levels.

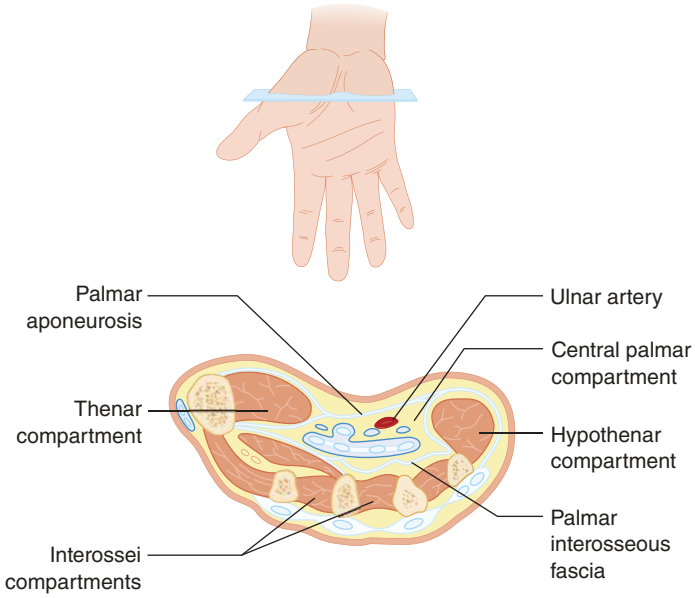

FIGURE 278-4. Hand compartments: transverse section through the right hand.

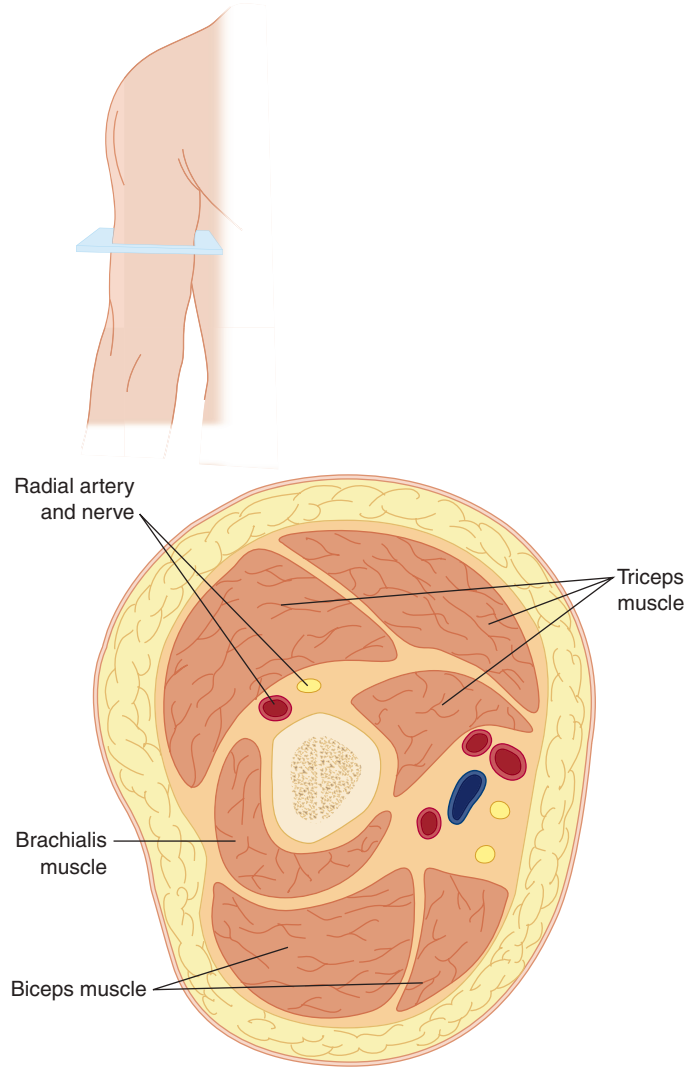

FIGURE 278-5. The biceps-brachialis (anterior) and triceps (posterior) compartments of the right arm.

TABLE 278-1 Causes of Compartment Syndrome

Orthopedic	Tibial fractures
	Forearm fractures
Vascular	Ischemic-reperfusion injury
	Hemorrhage
Iatrogenic	Vascular puncture in anticoagulated patients
	IV/intra-arterial drug injection
	Constrictive casts
Soft tissue injury	Prolonged limb compression
	Crush injury
	Burns
Hematologic	Hemophilia
	Adverse effects of anticoagulants (warfarin)

DIAGNOSIS

In the appropriate clinical setting, these exam findings alone may be sufficient to make the diagnosis and propel the patient in a timely fashion to the operating room for surgical treatment. At times, direct measurement of the tissue pressures in the compartment should be performed to help calculate the delta pressure, confirm the diagnosis, and determine patient disposition.

COMPARTMENT PRESSURE MEASUREMENT

Several commercial devices are available for measuring intracompartmental pressures. A Stryker Kit® is one such system. The kit consists of a saline-filled syringe, a manometer, and a needle with a side port. Connect the manometer between the syringe and the needle. Insert the needle into the compartment. Inject a few drops of saline to ensure that there are no air pockets and that the needle is not inserted into a tendon. The gauge gives the pressure reading in mm Hg. Check pressures twice in each compartment. Also check adjacent compartment pressures. Because pressures are highest near the injured area, obtain the measurements within 5 cm of a fracture site. Figure 278-1 demonstrates appropriate sites for pressure measurements in the lower leg, whereas **Figure 278-6** shows sites for the forearm. The hands and feet have many compartments within them, all too numerous and small to easily measure. If compartment syndrome is suspected in these sites, some specialists opt for surgical intervention without documentation of elevated pressures.

The measurement of compartment pressures may be helpful in certain settings. The patient may be obtunded, making clinical evaluation with suspected compartment syndrome difficult. Patients who are to go to the operating room for other procedures will be difficult to monitor clinically while under anesthesia.

It is not necessary to measure compartment pressures in a clinically obvious compartment syndrome.

LABORATORY TESTING

Laboratory testing is of no benefit in the setting of compartment syndrome. At times, the serum creatine phosphokinase may be elevated, as may myoglobin levels. Urinalysis may reveal myoglobinuria. Hemophiliacs or patients with clotting disorders need assay of coagulation parameters and factor levels.

TABLE 278-2 Tissue Survival of Ischemia

Muscle		Nerve	
3–4 Hours	Reversible change	2 Hours	Loss of nerve conduction
6 Hours	Variable damage	4 Hours	Neurapraxia
8 Hours	Irreversible damage	8 Hours	Irreversible damage

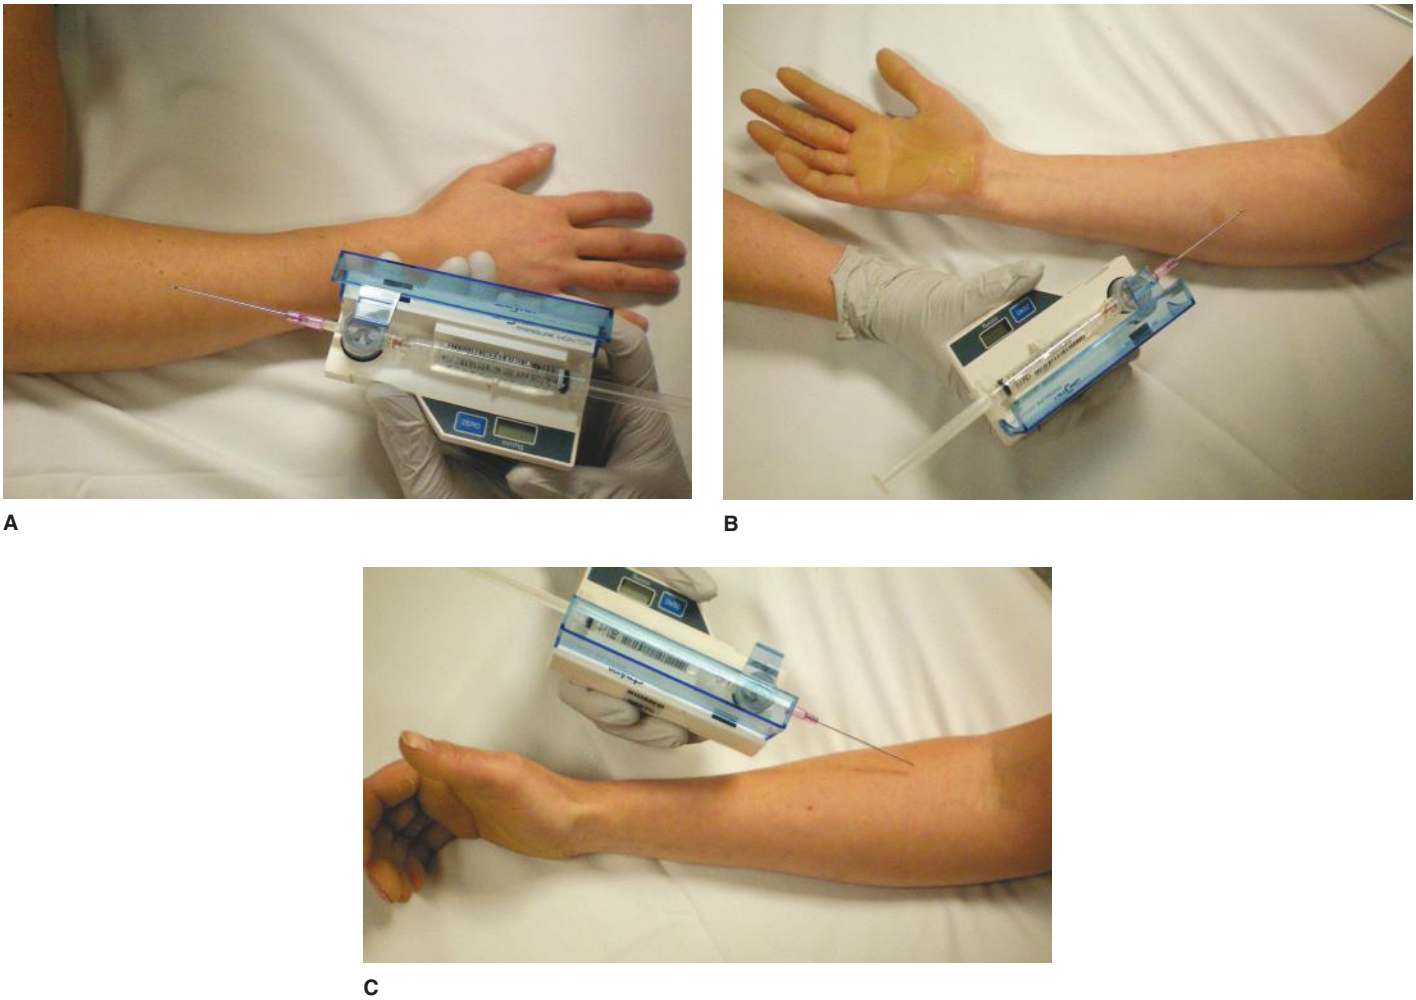

FIGURE 278-6. **A.** Forearm extensor compartment. **B.** Forearm flexor compartments. **C.** Mobile wad compartment.

TREATMENT

The initial medical management of these patients includes supplemental oxygen, if needed, and blood pressure support in the hypotensive patient. Immediately remove restrictive casts or dressings. This alone can markedly reduce tissue pressures. Place the affected limbs at the level of the heart; elevation higher than the heart increases the arteriovenous pressure gradient.

Hemophiliacs should have replacement of factor levels (see chapter 235, Hemophilias & von Willebrand Disease), and patients on anticoagulants should have reversal or factor replacement (see chapter 239, Thrombotics and Antithrombotics).

Surgical fasciotomy reduces intracompartmental pressure. Long incisions are necessary to release pressure in the affected compartment and simultaneously incise adjacent compartments. Tissue edema within the compartment will typically cause the muscle to bulge from the incision sites. The wounds should be initially left open and a second look procedure for debridement and possible closure scheduled for 48 to 72 hours after the initial intervention. Ideally, definitive wound closure is obtained within 7 to 10 days. This may require skin grafting.

A contraindication to fasciotomy is a missed timely diagnosis of compartment syndrome. Tissue pressures that have been elevated for 24 to 48 hours may have already caused permanent dysfunction and opening the compartments at this time may be futile.

DISEASE COMPLICATIONS

When fasciotomy is performed in a timely fashion, it can prevent death of the muscle within that compartment and the nerves that travel through it. When delayed, permanent neuropathy may occur, as can muscle death. Functional impairment is unlikely when compartment syndrome is diagnosed and treated within 6 hours of its onset.

DISPOSITION AND FOLLOW-UP

Admit all patients with compartment syndrome to the operating room or appropriate inpatient unit for serial observation and re-examination.

CHAPTER 279

Neck and Back Pain

David Della-Giustina
Jeffrey S. Dubin
William Frohna

EPIDEMIOLOGY

Low back pain alone accounts for approximately 3% of all ED visits in the United States.[1] Nearly one third of ED back pain patients receive x-rays, and 10% undergo CT or MRI imaging.[2] Analysis of the 2010 Global Burden of Disease study reveals a point prevalence of 5% for low back pain and 9% for neck pain. Back pain is the number one cause of disability in the United States; neck pain is number four.[3,4]

RISK FACTORS FOR SERIOUS CAUSES OF NECK AND BACK PAIN

There are many causes of neck and back pain, including trauma and biomechanical injuries, degeneration, inflammation (arthritides), infection (e.g., discitis, meningitis, and epidural abscess), infiltration (e.g., metastatic cancer and spinal cord tumors), and compression (e.g., epidural hematoma and abscess). In many cases of atraumatic neck and back pain, no specific cause can be identified. However, due to the high volume of ED patients with neck and back pain, clinicians can develop an indifference to this complaint and potentially overlook serious causes. Take care to perform a systematic evaluation based on risk factors in the history and physical examination, and let findings guide diagnostic testing and management (**Table 279-1**). Consider spinal anatomy while focusing on the presence or absence of neurologic signs to identify pathologic causes and prevent complications.

Radiculopathy and myelopathy are identified through pattern recognition of the motor and dermatome innervations and their associated spinal level (see Figure 164-1 and Tables 164-1 and 164-2 in chapter titled "Neurologic Examination").

TABLE 279-1 Risk Factors for Serious Causes of Neck and Back Pain

Risk Factors	Concern
Historical Risk Factors	
Pain >6 weeks	Tumor, infection
Age <18, >50	Congenital anomaly, tumor, infection
Major trauma	Fracture
Minor trauma in elderly or rheumatologic disease	Fracture
History of cancer	Tumor
Fever and rigors	Infection
Weight loss	Tumor, infection
Injection drug use	Infection
Immunocompromised	Infection
Night pain	Tumor, infection
Unremitting pain, even when supine	Tumor, infection
Incontinence	Epidural compression
Saddle anesthesia	Epidural compression
Severe/progressive neurologic deficit	Epidural compression
Anticoagulants and coagulopathy	Epidural compression
Physical Risk Factors	
Fever	Infection
Patient writhing in pain	Infection, vascular cause
Unexpected anal sphincter laxity	Epidural compression
Perianal/perineal sensory loss	Epidural compression
Major motor weakness/gait disturbance	Nerve root or epidural compression
Positive straight leg raise test	Herniated disk

CLINICAL FEATURES OF NECK PAIN

In general, it is helpful to classify patients with neck pain into two groups: those with uncomplicated neck pain arising mainly from the joints and associated ligaments and muscles of the neck, and those with neck pain and *radiculopathy* (signs and symptoms attributable to a single nerve root) and/or *myelopathy* (signs or symptoms due to a spinal cord lesion, stenosis, or compression).

HISTORY IN PATIENTS WITH NECK PAIN

Ask about the onset, duration, and location of the neck pain; recent or remote trauma; associated symptoms; stiffness; deformity; neurologic complaints (e.g., weakness, changes in sensation, gait, or vision); constitutional symptoms such as fever, anorexia, and weight loss; and comorbid conditions such as arthritis, cancer, and infections. See Table 279-1 for clues to serious pathology to investigate in the history. Rheumatoid arthritis, ankylosing spondylitis, and psoriatic spondyloarthropathy may involve the C1-C2 joint, damage the transverse ligament, and erode the odontoid process, yielding instability of the atlantoaxial joint. Subluxation may occur spontaneously or following a trivial injury. Morning stiffness may signify arthritic joints. Identify precipitating and palliative factors, maneuvers, or activities. Inquire about prior episodes of neck pain, past diagnostic studies, and treatment. Determine the character of pain and its distribution. Patients with radiculopathy often complain of sharp, burning, intense pain that radiates to the trapezius, periscapular area, or down the arm. Weakness or paresthesias may develop weeks after pain onset. Patients with myelopathy may have neck pain that progresses insidiously and may complain of clumsy hands, gait disturbances, and sexual or bladder dysfunction. **Table 279-2** summarizes important differences in symptoms between uncomplicated mechanical neck pain and neck pain associated with radiculopathy or myelopathy.

PHYSICAL EXAMINATION IN PATIENTS WITH NECK PAIN

Begin with a general assessment of the patient, noting evidence of weight loss, pallor, adenopathy, and abnormalities of posture, movement, and facial expression.[5] Pain may cause splinting of the head on the shoulders during position change. Assess active and passive movement, including rotation (chin to shoulder), lateral flexion (ear to shoulder), and flexion-extension (chin down, then up). Most mechanical causes of neck pain result in asymmetric lesions and asymmetrically limited or painful movements, whereas inflammatory or neoplastic disorders are typically more widespread, with pain and movement restriction being more symmetric.[5] When localized ipsilateral neck pain is felt toward the side of head movement, suspect facet (zygapophyseal) joint irritability. Examine for **Spurling's**

TABLE 279-2 Differentiating Cervical Radiculopathy from Uncomplicated Musculoskeletal Neck Pain

Factors Favoring Cervical Radiculopathy or Myelopathy*	Factors Favoring Uncomplicated Musculoskeletal Neck Pain*
Pain from the neck radiates down the arm in dermatome pattern.	Tenderness of involved muscles, examiner may find a focal point of tenderness.
Sensory changes along dermatome distribution.	Atrophy or thinning of shoulder muscles (may occur after rotator cuff injury).
Pushing down on top of head, with neck in extension (chin up) and head leaning toward symptomatic side elicits pain, typically toward or down the arm (positive **Spurling's sign**); 90% specific, 45% sensitive.	Pain increases with shoulder abduction on the side of neck pain (increased pain could derive from rotator cuff–related pain; radicular pain may decrease with this maneuver).
Pain may worsen with Valsalva, which increases intrathecal pressure.	Repetitive movement of arm or shoulder at work or play; may be new activity.
Flex neck forward until chin meets chest or pain stops movement. An electric shock sensation radiating down spine into both arms is a positive result (**Lhermitte's sign**). Occasionally, paresthesias occur.	History of recent injury or recent event of awkward position (such as neck or head position during sleep in an unfamiliar setting) or awkward standing posture to accommodate a special situation.
Depressed reflexes or, uncommonly, increased reflexes (see also Table 279-3).	Pain is accompanied by "stiffness" of involved muscle group.

*Patient in either pain category is not expected to have all, or majority, of listed signs.

sign (see Table 279-2). The **abduction relief sign**, performed by having the patient place the hand of the affected upper extremity on the top of his or her head to obtain relief, may indicate soft disk protrusion causing radicular pain. When neck pain occurs on the side away from head movement, suspect a ligamentous or muscular source.

Palpate the posterior cervical triangle, the supraclavicular fossa, carotid sheaths, and the anterior neck. C5-C6 root lesions often elicit tenderness over the brachial plexus at Erb's point, 2 to 3 cm above the clavicle, midway up the posterior border of the sternocleidomastoid muscle in the posterior triangle of the neck. A C8-T1 root lesion may cause tenderness over the ulnar nerve at the elbow.

Pathology in the lymph nodes, salivary glands, or thyroid gland may cause neck pain. A bruit over the carotid may signal cerebral insufficiency; a bruit over the subclavian arteries may be associated with thoracic outlet or vascular steal syndrome. Examine the temporal artery for tenderness, because temporal arteritis may be the cause of neck and shoulder pain (see also chapter 165, "Headache").

Sensory symptoms of pain or dysesthesias are difficult to evaluate, particularly when motor signs are absent, which is often the case in cervical spinal radiculopathies. The discrete separation of the motor and sensory roots at the cervical neural foramina can explain motor sparing despite severe sensory symptoms. For example, C7 root irritability without motor weakness can present as aching at the medial to middle scapular border; aching in the myotome distribution to the chest, axilla, or triceps; or numbness or tingling in the middle finger.

Early detection of cervical spinal myelopathies requires a complete neurologic examination. Hyperreflexia, a positive Babinski's sign, clonus, gait disturbance, sexual or bladder dysfunction, lower extremity weakness, impaired fine hand movement, and upper and lower extremity spasticity may signal myelopathy. Examine for **Lhermitte's sign** (Table 279-2), which is indicative of possible cord compression. **Hoffman's sign** indicates an upper motor neuron lesion and is performed by flicking the tip of the middle finger as the hand is relaxed in a neutral position. A positive (abnormal) response is flexion of the thumb and index finger in a pinching motion.

Table 279-3 summarizes the sensory, motor, and reflex findings in cervical radiculopathy. This information should be used to determine the level of motor and sensory involvement and to compare findings in the affected and unaffected sides. Bilateral or multilevel involvement usually implies serious pathology.

TABLE 279-3 Signs and Symptoms of Cervical Radiculopathy

Disk Space	Cervical Root	Pain Complaint	Sensory Abnormality	Motor Weakness	Altered Reflex
C1-C2	C2	Neck, scalp	Scalp		
C4-C5	C5	Neck, shoulder, upper arm	Shoulder	Infraspinatus, deltoid, biceps	Reduced biceps reflex
C5-C6	C6	Neck, shoulder, upper medial, scapular area, proximal forearm, thumb, index finger	Thumb and index finger, lateral forearm	Deltoid, biceps, pronator teres, wrist extensors	Reduced biceps and brachioradialis reflex
C6-C7	C7	Neck, posterior arm, dorsum proximal forearm, chest, medial third of scapula, middle finger	Middle finger, forearm	Triceps, pronator teres	Reduced triceps reflex
C7-T1	C8	Neck, posterior arm, ulnar side of forearm, medial inferior scapular border, medial hand, ring, and little fingers	Ring and little fingers	Triceps, flexor carpi ulnaris, hand intrinsics	Reduced triceps reflex

DIAGNOSIS OF NECK PAIN

Laboratory testing is rarely helpful, unless considering infection. See the "Epidural Compression Syndrome," "Transverse Myelitis," and "Spinal Infection" sections later in this chapter, as well as chapter 246, "Neck and Upper Airway."

The need for **imaging studies** depends on the clinical condition suspected and the duration of neck pain. Acute (days to weeks), uncomplicated, nonradicular, nonmyelopathic, atraumatic neck pain typically requires no imaging because the cause is likely benign and the treatment is conservative.[5] Obtain three-view cervical spine films in patients with chronic (weeks to months) neck pain with or without a history of trauma, those with neck pain and a prior history of malignancy or remote neck surgery,[5] and those with neck pain and preexisting spinal disorders such as rheumatoid arthritis, ankylosing spondylitis, and psoriatic spondyloarthropathy. Flexion-extension films may be useful if instability is suspected, especially in patients with rheumatoid arthritis or other inflammatory arthritides.[6] Patients with normal radiographs, patients with radiographic evidence of degenerative changes without neck instability, or patients with radiographic evidence of previous trauma *and* no neurologic signs or symptoms require no further imaging.[5] **MRI is indicated for patients with chronic neck pain with neurologic signs or symptoms regardless of the plain radiographic findings.**[5] MRI is also indicated when plain radiographs reveal bone or disk margin destruction, if there is cervical instability, and (with intravenous contrast) if epidural abscess or malignancy is suspected.[5] CT myelography is recommended when contraindications to MRI exist.

DIFFERENTIAL DIAGNOSES OF NECK PAIN

Mechanical Neck Disorders Mechanical neck disorders are also called hyperextension strain, acceleration-deceleration injury, hyperextension-hyperflexion injury, neck strain, neck sprain, and whiplash. The most common precipitating events are motor vehicle collisions, falls, sports injuries, and work-related injuries (see chapter 258, "Spine Trauma" for discussion of acute injury). Strain injury, caused by an awkward position during sleep or prolonged abnormal head-neck positions during work or recreation, is another cause.

Cervical Disk Herniations Cervical disk herniations occur as the nucleus pulposus protrudes through the posterior annulus fibrosis, producing an acute radiculopathy or, occasionally, a myelopathy. Protrusions are usually confined by the posterior longitudinal ligament but can occasionally extrude through this ligament as free fragments. Direct

posterior ruptures, although infrequent, can produce progressive myelopathy, whereas the more common posterolateral herniations can cause acute cervical radiculopathy. The levels of most frequent involvement are C5-C6 (C6 root) and C6-C7 (C7 root).

The symptoms of an acute cervical disk prolapse include neck pain, headache, pain distributed to the shoulder and along the medial scapular border, dermatome pain, and dysesthesia in the spinal root distribution to the shoulder and arm. Motor signs include fasciculations, atrophy and weakness in the dermatome distribution of the spinal root, loss of deep tendon reflexes, and, with cervical myelopathy, lower extremity hyperreflexia, Babinski's sign, and in rare cases, loss of sphincter control. Cervical hyperextension and lateral flexion to the symptomatic side (Spurling's sign; see Table 279-2) may replicate the symptoms, as can a Valsalva maneuver, whereas manual cervical distraction in flexion alleviates them. A thorough physical examination, including strength, sensory, and reflex testing, may delineate the level of root involvement (see Table 279-3). MRI is necessary for diagnosis.

Cervical Spondylosis and Stenosis Cervical spondylosis (or degenerative disk disease or osteoarthritis) is a progressive, degenerative condition resulting in a loss of cervical flexibility, neck pain, occipital neuralgia, radicular pain, or occasionally progressive myelopathy. There is progressive degeneration of the disks, ligaments, facet joints (zygapophyseal joints), and uncovertebral joints (joints of Luschka). From a radiographic standpoint, cervical spondylosis may be diagnosed if any one of three findings is present: osteophytes, disk space narrowing, or facet disease. However, there is a high prevalence of cervical spondylosis in asymptomatic individuals, and care must be taken in ascribing painful syndromes to findings on imaging. Degenerative disk disease predisposes a patient to progressive osteoarthrosis of the cervical spine, joint instability, and incongruous joint motion during neck movement. Spondylosis most commonly occurs at the C5-C6 and C6-C7 levels.

Osteophytic spurs can encroach posteriorly on the spinal canal, producing cervical myelopathy; laterally on the intervertebral foramen, producing cervical radiculopathy; and anteriorly on the esophagus, producing dysphagia. Spurious osteophytes may also produce Horner's syndrome, vertebrobasilar symptoms, severe radicular symptoms without associated neck pain, painless upper extremity myotome weakness, and chest pain mimicking angina. Neurologic findings (radiculopathy or myelopathy) may be gradual in onset unless there is a history of recent trauma.

The combination of a congenitally narrowed spinal canal, further compromised by a vertebral osteophytic bar anteriorly and a buckling ligamentum flavum posteriorly, increases the risk of myelopathy secondary to cervical spinal stenosis as the diameter of the spinal canal is reduced to less than 13 mm.

Cancer of the Cervical Spine Consider metastatic cancer in the differential diagnosis of chronic neck pain, especially unremitting night pain. Lung, breast, and prostate cancers and lymphoma and multiple myeloma may involve the cervical spine. Although most cases of epidural cord compression occur in the thoracic spine, involvement of the cervical spine and multiple levels are not unusual. Myelopathy, which is commonly caused by disk or degenerative disease, is rarely caused by metastatic tumors. Plain films have inadequate sensitivity (10% to 17% false-negative rate) in detecting spinal metastases but may reveal destruction of the vertebral bodies, lytic lesions of the pedicles, and pathologic compression fractures. MRI is the standard for the detection of spinal epidural metastatic disease and cord compression, and cancer patients with radiographic evidence of bone or disk margin destruction should undergo MRI.[5]

Cervical Myofascial Pain Syndrome Myofascial pain syndrome is a cause of chronic neck pain and is often confused with radiculopathy. Myofascial pain symptoms may present or exacerbate acutely, especially after trauma. Psychological distress and specific personality traits are risk factors. Typically, patients complain of pain in the neck, scapula, and shoulder with or without nondermatomal radiation into the upper extremity. Tender spots, "trigger points," may be evident on palpation of the head, neck, shoulder, and scapular region. Neurologic examination is normal. Because radiographic cervical spine abnormalities develop with age in the asymptomatic population, radiographic findings cannot be relied upon to verify the source of neck pain or upper extremity symptoms. Imaging reveals either nonspecific degenerative or disk changes that do not correlate with the clinically suspected site.

Other Conditions Epidural abscess, osteomyelitis, and transverse myelitis are infectious and inflammatory causes of neck pain (see related sections later in this chapter). Cervical spinal epidural hematoma often presents as neck pain followed by symptoms and signs of cord compression (see later section on epidural compression syndrome) and should be considered in the patient taking anticoagulants or in the patient with a bleeding diathesis. Pain from ischemic heart disease may radiate into the neck and shoulder. Peripheral nerve involvement, such as carpal tunnel syndrome, may present as a C6-C7 sensory radiculopathy, whereas multiple sclerosis, amyotrophic lateral sclerosis, subacute combined degeneration, and syrinx are in the differential of myelopathy.

TREATMENT AND DISPOSITION OF PATIENTS WITH NECK PAIN

Treatment issues can be divided into three categories: neck pain, neck and arm pain consistent with radiculopathy, and myelopathy. There is little evidence-based science to support many of the commonly recommended conservative treatment modalities (e.g., physiotherapy, acupuncture, electrotherapy, manipulation, traction, thermotherapy, medicinal and injection therapies, exercises).[7-11] Individual patients may indeed benefit from one or more of these therapies.

TREATMENT OF UNCOMPLICATED NECK PAIN

Most cases of neck pain without clear underlying pathology will improve with minimal intervention. The patient should be advised to "act as usual" and avoid activities that produce pain. Initial medications may include nonsteroidal anti-inflammatory drugs (NSAIDs), muscle relaxants, and for significant pain, a short course of oral opiates; no NSAID, muscle relaxant, or opiate is clearly superior to another in its class. Encourage follow-up with the primary physician to assess the need for physical or manual therapies or additional medications.

Patients with acute neck pain following an acceleration-deceleration (whiplash) injury may benefit from a similar pharmacologic regimen as that described earlier. In a Danish study of 458 patients, immobilization with a semi-rigid collar, advice to "act as usual," and active mobilization had similar effects in terms of preventing long-lasting pain and disability.[12] A soft collar reduces range of motion of the neck less than 20% and provides little immobilization or neck support.[13] If a soft collar is given, it should be used for no more than 10 days. Spinal manipulation therapy or home exercises after two 60-minute physical therapy sessions may each be more effective than medication therapy for short- and long-term pain relief.[14]

Therapy for neck pain from myofascial pain syndrome should address both muscular tension and psychobehavioral issues. See chapter 38, "Chronic Pain" for further discussion including recommendations for alternative therapies.

TREATMENT OF CERVICAL RADICULOPATHY

In the absence of myelopathy, first-line treatment is conservative activity modification to prevent symptom exacerbation or injury and oral medications. Immobilization with a soft or hard cervical collar is controversial without clear evidence for or against its use. Encourage follow-up with a primary physician for possible referral to a neurosurgical or orthopedic spine specialist, an electrodiagnostic evaluation, and additional rehabilitation interventions. Oral medications may include NSAIDs, opioid analgesics, and muscle relaxants. A 7- to 10-day course of oral steroids (e.g., methylprednisolone or prednisone) is commonly prescribed for acute radiculopathy, but steroid efficacy has been shown in only small low-quality studies of low back pain. Epidural steroid injections may be effective for chronic cervical radiculopathy when other treatments have failed. If the symptoms and signs of acute cervical root compression fail to respond to conservative treatment, or if they recur, and if imaging demonstrates concordant findings, surgery may be recommended. Indications for hospital admission include progressive upper extremity weakness, especially in the C7 distribution; acute or progressive symptoms or signs of myelopathy; and finally, in a small subset of patients, intractable radicular pain unresponsive to treatment.

TREATMENT OF CERVICAL MYELOPATHY

Treatment decisions for patients with symptoms and signs of cord compression should be made in conjunction with specialists. Cervical spondylotic myelopathy causes the greatest degree of impairment and disability in the continuum of spondylosis. Also, myelopathy is the most common cause of spastic paraparesis in patients older than 55 years of age, thus paralleling the time course of spondylosis. The patient with myelopathy should be referred to a neurosurgeon or orthopedic spine surgeon to discuss the possibility of decompressive surgery. Additional therapeutic considerations (e.g., steroids and radiation in spinal epidural metastases) will depend on the time course of symptoms and signs and etiology but should be addressed in conjunction with a neurosurgeon.

CLINICAL FEATURES OF THORACIC AND LUMBAR PAIN SYNDROMES

Back pain is categorized based on the duration of symptoms: acute back pain lasts <6 weeks, subacute pain lasts between 6 and 12 weeks, and chronic pain continues beyond 12 weeks.[15] Pain lasting >6 weeks is an indicator of more serious disease, since most episodes of nonspecific back pain (80% to 90%) resolve within 6 weeks. Risk factors for serious causes of back and neck pain are listed in Table 279-1; specific historical factors that help to identify benign verses serious causes of back pain are listed in the following sections.

HISTORICAL RISK FACTORS IN BACK PAIN

Patient Age In patients <18 years old and >50 years old, back pain is more likely to be caused by tumor or infection than in the 18- to 50-year-old age group. Patients <18 years old also have a higher incidence of congenital and bony abnormalities such as spondylolysis, spondylolisthesis, and Scheuermann's kyphosis. Patients >50 years old are more prone to fractures (age >65 years is more specific for fracture), spinal stenosis, and intra-abdominal processes such as an abdominal aortic aneurysm.

Pain Location and Radiation Pain that originates from muscular, ligamentous, vertebral, or disk disease without nerve involvement is located primarily in the back, possibly with radiation into the buttocks or thighs. *Sciatica*, radicular back pain in the distribution of a lumbar or sacral nerve root, is often accompanied by sensory or motor deficits.[15] Sciatica occurs in only 1% of patients with back pain and is associated with disk herniation or nerve root impingement below the L3 nerve root. Ninety-five percent of herniated disks occur at the L4-L5 or the L5-S1 lumbar disk spaces, impinging on the L5 or S1 nerve roots, respectively.[15]

Trauma History of major trauma is a risk factor for fracture in all patients. In the elderly, minor trauma, such as falling from standing or from sitting in a chair, may cause fracture due to associated osteoporosis. Risk factors for osteoporosis increase the incidence of compression fractures (i.e., female sex, steroid use, alcoholism).

Systemic Complaints Systemic symptoms such as fever, chills, night sweats, malaise, and an undesired weight loss suggest infection, systemic rheumatologic disease, or malignancy. These symptoms are more concerning for infection if the patient has any of the following risk factors: recent bacterial infection (including urinary tract infection, pneumonia, and especially skin abscesses), recent GU or GI procedure, immunocompromised status, injection drug use, alcoholism, renal failure, or diabetes.[16-18] Injection drug use is a substantial risk factor for spinal infection, so assume that back pain in a patient who is an injection drug user is due to spinal infection until proven otherwise.

A rupturing abdominal aortic aneurysm is the most immediately life-threatening extraspinal cause of back pain. Other potential causes of pain referred to the back include pancreatitis, a posterior lower lobe pneumonia, nephrolithiasis, and renal infarct.

Pain Features A dull, aching pain that generally worsens with movement but improves with rest and lying still is the typical description of benign back pain. Symptoms suggestive of tumor and infection include pain that occurs at night and often awakens the patient from sleep or that is unrelenting despite appropriate use of analgesics and rest.[15,19] Pain worsened by coughing, Valsalva maneuver, or sitting and that is relieved by lying in the supine position suggests herniation. Spinal stenosis is associated with bilateral sciatic pain that is worsened by activities such as walking, prolonged standing, and back extension and is relieved by rest and forward flexion. In the authors' experience, night pain and unrelenting pain are worrisome symptoms that should be specifically queried as part of the history, because these symptoms are risk factors for serious disease and such queries are often omitted in history taking.

Neurologic Deficit by History Neurologic complaints such as paresthesias, numbness, weakness, and gait disturbances must be further addressed in the history and delineated in the physical examination to determine whether the symptoms involve single or multiple nerve roots. Bowel or bladder incontinence is a serious symptom that raises concern for an epidural compression syndrome, such as spinal cord compression, cauda equina syndrome, or conus medullaris syndrome. If a patient has back pain and has a history of urinary incontinence (acute or chronic), but an otherwise completely normal history and evaluation, measure the postvoid residual volume with bedside US or by catheterization if US findings are in doubt. A large postvoid residual volume (e.g., >100 mL) indicates overflow incontinence, which, when combined with the presence of low back pain, suggests neurologic compromise and an epidural compression syndrome.[15,20]

Past Medical History History of cancer is a risk factor because back pain is the initial symptom in the majority of those with spinal metastases.[20] Malignant neoplasm is the most common systemic disease affecting the spine. Most patients with this diagnosis are >50 years old. However, only one third of patients diagnosed with spinal malignancy have a known history of cancer. Thus, symptoms such as unremitting pain, night pain, and weight loss require further diagnostic testing.

PHYSICAL EXAMINATION RISK FACTORS IN BACK PAIN

Although fever is a marker of infection, sensitivity for infection is low, varying from 27% for tuberculous osteomyelitis to 50% for pyogenic osteomyelitis, 60% to 70% for pyogenic discitis, and 66% to 83% for spinal epidural abscess.[16,19] Careful history, examination, and possibly diagnostic testing are needed for patients with back pain and fever. In patients with severe or excessive pain, consider acute spinal infection or abdominal aortic aneurysm. Examine the abdomen, listen for bruits, and palpate for masses, tenderness, and an enlarged aorta.

Examine the back for signs of erythema, warmth, skin abscesses, furuncles, and purulent drainage, which suggest an underlying spinal infection. Contusion and swelling suggest trauma. Palpate the back and percuss the vertebral bodies. Consider fracture or bacterial infection if there is point tenderness to vertebral percussion. Perform **straight leg raise testing**. With the patient lying supine, lift each leg separately to approximately 70 degrees in an attempt to produce radicular pain. A positive straight leg raise test causes a radicular pain radiating below the knee of the affected leg. This pain is worsened by ankle dorsiflexion and improved with ankle plantar flexion or decreasing leg elevation. Reproduction of the patient's back pain or pain in the gluteal or hamstring area when the leg is raised is **not** a positive result. The straight leg raise test can be easily replicated with the patient in the seated position with similar leg extension and foot dorsiflexion (**Figure 279-1**). Straight leg raise testing is a screening examination for a herniated disk. One third of those with positive straight leg raising test and a negative sitting knee extension test have an MRI-proven herniated disk.[21] **A positive straight leg raise test is 68% to 80% sensitive for a L4-L5 or L5-S1 herniated disk.**[21] Radicular pain down the affected leg when lifting the asymptomatic leg is called a positive **crossed straight leg raise test**. A positive result is highly specific but insensitive for nerve root compression by a herniated disk.

Neurologic Examination For Back Pain The neurologic examination is directed to detecting deficits in each of the specific spinal nerve roots. Sensation may be tested by using light touch initially, followed more formally by pinprick, temperature, proprioception, and vibration testing if there are any questions regarding diminished sensation. Next assess strength, with a focus on those muscle groups innervated by individual nerve roots (**Figure 279-2**). Individually test

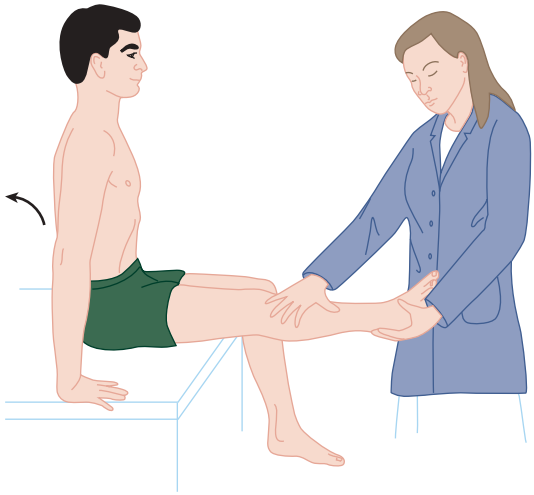

FIGURE 279-1. Sitting knee extension test. With the patient sitting on a table, both hip and knees flexed at 90 degrees, slowly extend the knee as if evaluating the patella or bottom of the foot. This maneuver stretches nerve roots as much as a moderate degree of supine straight leg raising.

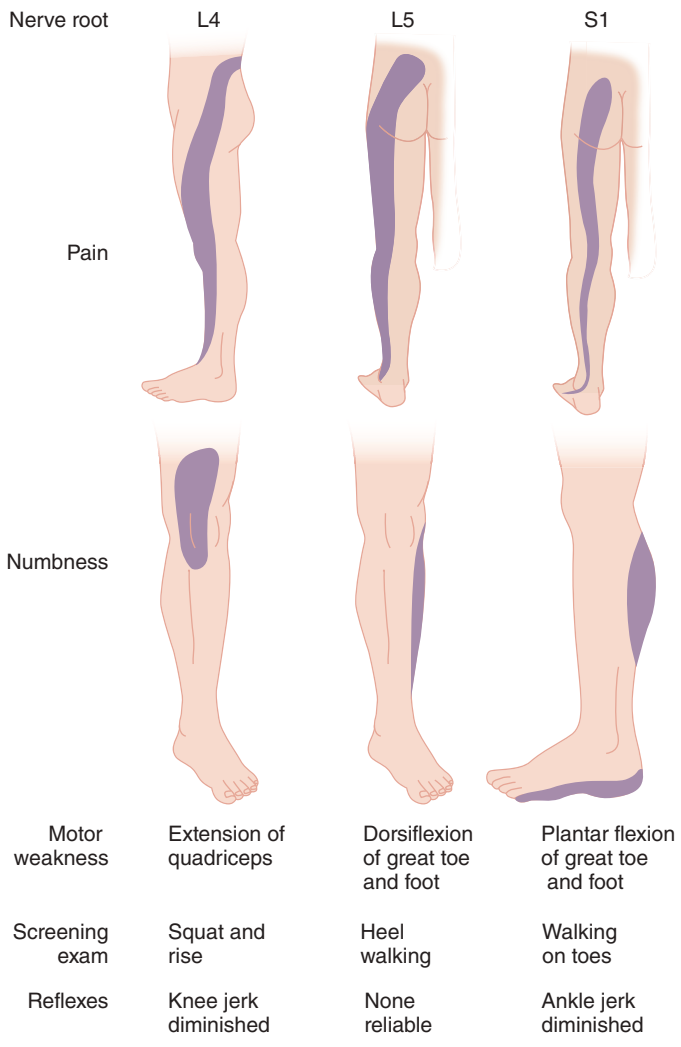

FIGURE 279-2. Testing for lumbar nerve root compromise.

the ankle dorsiflexors (L4), extensor hallucis longus (great toe dorsiflexion) (L5), and ankle plantar flexors (S1/S2). Finally, evaluate the patellar (L3-L4), Achilles (S1), and Babinski's reflexes. There is no easily obtainable reflex for the L5 nerve root.

It is not necessary to perform a digital rectal examination on all patients with back pain. However, perform rectal examination in patients with neurologic complaints or findings on physical examination and those with risk factors for serious disease. Evaluate rectal sphincter tone and perianal sensation and the presence of prostatic and rectal masses. Poor rectal tone in association with back pain and saddle anesthesia indicates an epidural compression syndrome.

DIAGNOSIS OF BACK PAIN SYNDROMES

For most patients, no testing is required. However, laboratory testing is indicated in the ED if there is concern for infection, tumor, or rheumatologic causes of the back pain. Order a CBC, erythrocyte sedimentation rate, and urinalysis. With infection, the WBC count may be normal or elevated. However, the erythrocyte sedimentation rate is typically elevated (>20 mm/h), even in immunocompromised patients, with a sensitivity of 90% to 98% for spine infection.[16,19,22] The erythrocyte sedimentation rate will also be elevated in patients with a rheumatologic or neoplastic disease of the spine.[15] The C-reactive protein will also be elevated with acute spinal infection.[15,19] Obtain a urinalysis to identify urinary tract infection or renal disease causing pain referred to the back.

IMAGING

Plain spinal radiographs can be considered when one suspects fracture, tumor, or infection, but sensitivity is only 83% for tumor and very poor for infection. Anteroposterior and lateral views are sufficient. The coned-down L5-S1 and oblique views rarely add clinically useful information while more than doubling gonadal radiation exposure and cost.

CT scanning is most useful for evaluating vertebral fractures, the facet joints, and the posterior elements of the spine. It shows good detail of the vertebral bodies but has poor resolution of the spinal canal and spinal cord in comparison with MRI. CT may be useful if MRI is unavailable or unsuitable, but CT myelography is the best substitute for conditions such as epidural abscess or cord compression when MRI is unavailable.

MRI provides the best resolution for lesions in the vertebral bodies, spinal canal, and spinal cord, and for disk disease. MRI is also the standard study in cases of suspected spinal infection, neoplasm, and epidural compression syndromes. MRI is also used to determine progression of neoplastic processes of the spine and disk disease and for continued back pain for 6 to 8 weeks.

DIFFERENTIAL DIAGNOSIS AND MANAGEMENT OF BACK PAIN SYNDROMES

ACUTE NONSPECIFIC BACK PAIN

Nonspecific back pain is a symptom complex that has countless names, including back strain/sprain, mechanical back pain, and lumbago. However, because strain and/or sprain have no histopathologic findings, a more accurate term to use is *idiopathic or nonspecific back pain*. Nonspecific back pain is the authors' choice of term, especially because most patients will never be given a more precise diagnosis.

Diagnosis is clinical. The pain is mild to moderate and is aggravated with movement and relieved with rest. Although the typical mechanism is usually minor exertion or lifting, the patient may not recall any remarkable etiology. There are no risk factors for serious disease on the history and physical examination, or if any risk factors are present, the diagnostic evaluation is normal.

Treatment focuses on restriction of activity, analgesia, manipulation, and other physical modalities. Monitor symptoms for 4 to 6 weeks before embarking on further diagnostics. In 80% to 90% of patients, symptoms will resolve on their own within this time period.[15] Watchful waiting avoids wasting time and money and eliminates exposure to unnecessary radiation. This course of action should be discussed with patients because they may expect diagnostic testing.

Patients who resume their normal activities to the furthest extent tolerable recover more rapidly than those on 2 or 7 days of bed rest or those who perform back-mobilizing exercises.[23] Thus, patients should continue daily activities using pain as the limiting factor.[15] Withhold exercise programs until the acute painful episode has resolved or improved significantly.

Medication is a combination of **acetaminophen and NSAIDs**. Acetaminophen is an excellent first-line agent, and there is little evidence that NSAIDs are more effective for symptomatic relief.[24,25] Most NSAIDs are equally efficacious for back pain. However, there are significant differences in the side effect profiles and toxicity. In one review, ibuprofen was the least toxic of the 12 NSAIDs studied, particularly with regard to upper GI bleeding. Because there is a linear relationship between dose and toxicity, the lowest dose possible should be used in patients at risk. In patients at risk for GI bleeding, the addition of a proton pump inhibitor or misoprostol can reduce the risk.[25]

We recommend using acetaminophen in combination with NSAIDs or as the sole initial agent when treating patients at higher risk for adverse effects of NSAIDs (the elderly and those with renal disease or peptic ulcers). One regimen is acetaminophen, 650 to 975 milligrams every 4 to 6 hours (do not exceed 4 grams in a 24-hour period), either alone or in conjunction with ibuprofen, 800 milligrams three times daily, or naproxen, 250 to 500 milligrams twice daily. If there is a concern for GI bleeding, then add a proton pump inhibitor such as omeprazole, 20 milligrams once daily.

Opioid analgesics should be offered to patients with moderate to severe pain, but for a limited (1 week) duration, as they are only effective in the short term.[15,24,26] When prescribing opioid analgesic combinations that include acetaminophen, warn patients not to combine them with other acetaminophen products.

Muscle relaxants are useful for treating back pain.[26] Muscle relaxants, such as diazepam, 5 to 10 milligrams every 6 to 8 hours, and methocarbamol, 1000 to 1500 milligrams four times a day, are effective. Although their efficacy appears equal to NSAIDs, there are no studies comparing muscle relaxants alone with NSAIDs in the treatment of nonspecific low back pain. Additionally, there does not appear to be any additional pain relief or synergistic benefit when these medications are used in combination.[27] Corticosteroids taken systemically or injected locally or into the epidural space have no role in the treatment of nonspecific back pain.[15,28]

Manipulative therapy, while not generally an ED treatment, is one of the more controversial treatment options for back pain. Clinical outcome of manipulation is no better than standard medical therapy according to a Cochrane review,[29] but is not harmful.[15]

Other physical modalities include traction, diathermy, cutaneous laser treatment, exercise, US treatment, and transcutaneous electrical nerve stimulation. None of these have any proven efficacy in the treatment of acute low back symptoms. The application of heat or ice may provide temporary symptomatic relief in some patients, with evidence favoring heat.[15]

CHRONIC NONSPECIFIC BACK PAIN

There is a higher concern for serious disease in patients with ongoing or intermittent symptoms for a time period of months to years. The best approach is to review the previous evaluations for completeness and to be sure that abnormalities were not overlooked. If the evaluation has been incomplete, then consider completing it in the ED at that visit, or facilitate referral for an outpatient evaluation, with urgency guided by the severity of symptoms. If the evaluation has been thorough but negative, then treat as described for nonspecific back pain. If opioid analgesics are needed, prescribe them for only a very limited time. Chronic back pain is a difficult condition to manage, and benefit of medications is small.[15,24,26,30] Further information on the management of chronic back pain can be found in chapter 38.

LOW BACK PAIN WITH SCIATICA

Although sciatica only affects a very small proportion of all patients with back pain, it is present in the vast majority of patients with a symptomatic herniated disk. Although disk herniation is the most common cause of sciatica, anything that compresses or impinges on the spinal nerve roots, cauda equina, or spinal cord can cause sciatica. Other important etiologies to consider in the ED include intraspinal tumor or infection, foraminal stenosis, extraspinal plexus compression, piriformis syndrome (see chapter 281, "Hip and Knee Pain"), and lumbar canal stenosis (spinal stenosis).

DISK HERNIATION

Diagnosis is suspected clinically and confirmed with nonurgent MRI (urgent MRI only in the setting of suspected spinal cord compression). Patients who present with sciatica due to a herniated disk generally complain more about the radicular symptoms than about back pain. Because the vast majority of disk herniations occur at the L4-L5 (L5 nerve root) or L5-S1 (S1 nerve root) level, the radicular pain extends below the knee in the dermatomal distribution of that nerve root. A small proportion (often the elderly) have disk herniation at the L2-L3 (L3 nerve root) and L3-L4 (L4 nerve root) levels. The physical examination generally demonstrates localization of pain and a neurologic deficit in a unilateral single nerve root, usually L5 or S1, and frequently includes a positive result on straight leg raise testing.

If the patient has no risk factors in the history and physical examination for serious disease other than sciatica, treat conservatively and do not perform any diagnostic tests in the ED.[15] If the patient has a demonstrable neurologic deficit, consider obtaining plain radiographs to look for other possible causes for symptoms such as tumor, fracture, spondylolisthesis, and infection. Guidelines recommend imaging (MRI preferred) in patients with severe or progressive neurologic deficits and those with serious underlying conditions suspected based on history or physical examination.[15] If the symptoms have not progressed rapidly or the symptoms are not severe, the MRI can be ordered routinely or urgently rather than emergently.

Treatment is as for nonspecific back pain. Routine daily activity is as good as 2 weeks of bed rest in terms of intensity of pain, distress associated with symptoms, and functional status.[23] Recommendations for analgesic (acetaminophen, NSAID, and opiates) and muscle relaxant therapy remain the same.[31] NSAIDs are less effective in treating the symptoms of a herniated disk than they are in treating nonspecific back pain.

Corticosteroid therapy for herniated disk has limited benefit. Specifically, epidural corticosteroid injection provides a minor reduction in leg pain and sensory deficits in comparison with placebo. However, the improvement in symptoms is not associated with any significant functional benefit, and it does not reduce the need for surgery. Although epidural steroid injection is not an ED procedure, it offers an alternative for the moderately to severely symptomatic patient in follow-up. Although oral steroids are used widely, they appear to have little measurable benefit in patients with sciatica.

Manipulation is not recommended for the routine management of symptoms from herniated disk.[29] Local application of heat or ice may provide temporary relief.

Most patients with a herniated disk may be treated and monitored by their primary care physician without specialist referral. Most patients ultimately improve with nonsurgical therapy, with over half recovering in 6 weeks. Most spine surgeons agree that surgery is appropriate only when all three of the following criteria are met: definitive evidence of herniation on imaging study; corresponding clinical picture and neurologic deficit; and conservative treatment for 4 to 6 weeks that fails to produce improvement.

Emergency decompressive surgery is required only in patients with acute epidural compression syndromes. Patients who underwent surgery had improved function and fewer symptoms at 1 and 2 years postoperatively, compared with those treated conservatively; however, by 4 and 10 years postoperatively, both groups had comparable results.[32,33]

SPINAL STENOSIS

Spinal stenosis is a narrowing of any part of the lumbar spine, including the spinal canal, nerve root canal, and intervertebral foramina, which may occur at single or multiple spinal levels. Degenerative disease causes narrowing and compression of vascular and neural structures. It is a

cause of chronic back pain, with or without associated sciatica. The symptoms, which usually begin in the sixth decade, include low back pain that is aggravated by prolonged standing and spinal extension and is relieved by rest and forward flexion. Typically, symptomatic patients present with low back and lower extremity pain while walking that is symptomatically similar to vascular claudication. This symptom is termed *neurogenic claudication* or *pseudoclaudication* to distinguish it from vascular claudication. **Neurogenic claudication is relieved with rest and forward flexing the spine and worsened by extending the spine.**[34] Physical examination findings are often absent. The diagnosis is made principally by history with confirmation by CT scan or MRI. Symptomatic treatment is the same as chronic back pain with primary care follow-up.

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis is an autoimmune arthritis that primarily affects the spine and pelvis. It is associated with human leukocyte antigen B-27, trauma, and infection. It most commonly occurs in patients <40 years old with a 3:1 male predilection. Patients complain of awakening with low back pain and stiffness that improves throughout the day with mild activity. The diagnosis is suspected by history and physical exam in individuals with symptoms longer than 3 months in duration and is confirmed by imaging and laboratory tests. Radiographic studies demonstrate sacroiliitis and squaring of the vertebral bodies, the so-called *bamboo spine*. Patients can be treated symptomatically with NSAIDs and should be referred to a rheumatologist for diagnostic confirmation and further management.

EPIDURAL COMPRESSION SYNDROME

Epidural compression syndrome is a collective term encompassing **spinal cord compression**, **cauda equina syndrome**, and **conus medullaris syndrome**.

Although the diagnosis of a complete epidural compression is obvious, the challenge is diagnosis in patients with early signs and symptoms. The initial differential diagnosis is broad and includes most conditions that cause weakness, sensory changes, or autonomic dysfunction of the lower extremities. The history and physical examination should narrow the differential diagnosis to a compressive lesion of the spinal cord or cauda equina.

Possible causes of epidural compression include spinal canal hemorrhage with hematoma, tumors of the spine or epidural space, spinal canal infections including spinal epidural abscess, and massive midline disk herniation. Transverse myelitis is a noncompressive condition that may present clinically like a compressive lesion of the spinal cord.

The history usually includes back pain with associated neurologic deficits. Specifically, it may include perianal sensory loss, fecal incontinence or urinary incontinence with or without retention, and sciatica in one or both legs. The duration of symptoms does not differentiate these syndromes from benign causes of back pain. In one small study, **urinary retention of >500 mL alone or in combination with two of the following characteristics—bilateral sciatica, subjective urinary retention, or rectal incontinence symptoms—is the most important predictor of MRI-confirmed cauda compressions.**[35] Also, a history of malignancy and a rapid progression of neurologic symptoms, especially bilateral symptoms, increase the likelihood of compression.

The physical examination findings vary depending on the level of compression and the amount and area of the spinal cord or cauda equina that is compressed. **The most common finding in cauda equina syndrome is urinary retention with or without overflow incontinence**, with a sensitivity of 90% and a specificity of about 95%.[35] Other common findings for epidural compression include weakness or stiffness in the lower extremities, paresthesias or sensory deficits, gait difficulty, and abnormal results on straight leg raise testing.[36] The most common sensory deficit occurs over the buttocks, posterosuperior thighs, and perineal regions and is commonly called *saddle anesthesia*. Anal sphincter tone is decreased in 60% to 80% of cases.

When one clinically suspects epidural compression, especially due to tumor, treat the patient with dexamethasone, 10 milligrams IV, before obtaining any confirmatory tests.[36] **After the patient has received dexamethasone, obtain an emergent MRI of the spine.** If investigating the possibility of epidural compression due to neoplasm, obtain an MRI of the **entire spine** because 10% of patients with vertebral metastases have additional silent epidural metastases that would be missed by a localized imaging study.[36] The presence of tumors remote from the symptomatic site may change patient management. Additionally, the neurologic examination may falsely localize the spinal lesion(s) and limited regional MRI may not detect the lesion. If one suspects a pure cauda equina syndrome from a herniated disk, then it is reasonable to obtain an MRI localized to the lumbosacral spine.

The functional clinical outcome for epidural compression from tumor depends on patient symptoms at presentation. Patients who cannot walk before treatment rarely walk again. Those who are too weak to walk without assistance but who are not paraplegic have a 50% chance of walking again. Those who are able to walk when treatment begins are likely to remain ambulatory.[36] Of those patients who require a catheter for urinary retention before treatment, 82% will continue to require the urinary catheter after treatment. The presence of cord compresion is an indication for urgent consultation with a spine surgeon for decompression and/or radiation therapy for a tumor mass, determined by MRI findings.[37,38]

TRANSVERSE MYELITIS

Transverse myelitis is an inflammatory disorder that involves a complete transverse section of the spinal cord. It usually presents with neck or back pain in association with neurologic complaints and findings on physical examination, depending on the level of the spinal cord that is involved. The typical clinical syndrome involves bilateral motor, sensory, and autonomic disturbances that may progress over a period of days to weeks. Fecal and urinary retention and incontinence are common.[39] Transverse myelitis may result from viral infection, after vaccination, or as part of a systemic disease such as systemic lupus erythematosus, cancer, or, more commonly, multiple sclerosis. The most important issue regarding transverse myelitis is recognition of the potential for a compressive lesion of the spinal cord and managing the patient as outlined under epidural compression syndromes. The MRI may demonstrate lesions of the spinal cord, but MRI findings may lag the clinical presentation, especially early in the disease process.[38] In those situations where the patient has definite neurologic findings that are consistent with epidural compression but has a normal MRI, transverse myelitis is one of the primary working diagnoses. In such cases, consult a neurologist for admission and consider performing a lumbar puncture to assist in the diagnosis. The spinal fluid most commonly demonstrates lymphocytosis and elevated protein.[38] Treatment includes corticosteroids and plasma exchange at the direction of a neurologist.[38]

SPINAL INFECTION

Spinal infections, such as *vertebral osteomyelitis, discitis,* and *spinal epidural abscess*, are uncommon but serious causes of back pain. Unfortunately, these infections are commonly missed on first assessment.[19,22] Risk factors for infection include the following: immunocompromised states (diabetes, HIV infection, and organ transplant recipients), alcoholism, recent invasive procedures, spinal implants and devices, injection drug use, and skin abscesses.[16,19,22]

Vertebral Osteomyelitis Patients with **vertebral osteomyelitis** usually have had prolonged symptoms, and in many cases, pain has been present for >3 months.[19,40] On physical examination, about half have fever and vertebral body tenderness to percussion.[19,40] The WBC may be normal, but the erythrocyte sedimentation rate and C-reactive protein are almost always elevated, although this is nonspecific.[16,17,19,40] Blood cultures are positive in approximately 40% of cases of vertebral osteomyelitis and should be routinely drawn as part of the management. In osteomyelitis, plain radiographs are normal until the bone demineralizes, which can take from 2 to 8 weeks. **The most common radiographic abnormalities with vertebral osteomyelitis are bony destruction, irregularity of vertebral end plates, and disk space narrowing.**[19] See the section on osteomyelitis in chapter 281 for further discussion.

Discitis In patients with discitis, >90% present with a complaint of unremitting back or neck pain, which awakens them at night and is relieved by neither rest nor analgesics.[19] Fever is present in 60% to 70% of patients, whereas the percentage of patients with neurologic deficits is highly variable, from 10% to 50%.[19] Elevation in the erythrocyte sedimentation rate occurs in >90% of patients, whereas elevated WBC count occurs in less than half of patients.[19]

Spinal Epidural Abscess The classic triad of symptoms suggesting spinal epidural abscess is severe back pain, fever, and neurologic deficits, but the triad occurs in only 8% to 13% of patients.[22] Spinal epidural abscess is commonly found in association with vertebral osteomyelitis and discitis, in 62% and 38% of cases, respectively.[16,22] Risk factors 98% sensitive for epidural abscess include injection drug use, immunocompromise, alcohol abuse, recent spine procedure, distant site of infection, diabetes, indwelling catheter, recent spine fracture, chronic renal failure, and cancer.[22] Erythrocyte sedimentation rate is elevated (>20 mm/h) in >95% of patients,[16,17,22] and the C-reactive protein is elevated in >90% of patients.[19] For all spinal infections, contrast-enhanced MRI is the gold standard imaging study. For detailed discussion, see chapter 174, "Central Nervous System and Spinal Infections."

Treatment of Spinal Infections Epidural abscess requires antibiotics and emergent evaluation and treatment by a spine surgeon. The treatment for discitis is long-term antibiotics, with surgery reserved for those with spinal cord compression or biomechanical instability. The treatment for vertebral osteomyelitis is primarily medical, consisting of 6 weeks of IV antibiotics followed by a 4- to 8-week course of oral antibiotics. For vertebral osteomyelitis, consult with a spine surgeon before antibiotic administration, because antibiotics may result in negative culture results from a bone biopsy. However, do not withhold antibiotics unless specifically directed by the spine surgeon. Empiric antibiotic therapy should be directed against *Staphylococcus aureus*. Parenteral piperacillin-tazobactam, 3.375 grams IV, and vancomycin, 1 gram IV, or similar agents with broad-spectrum coverage can be given until culture results are available.[17,18] The remainder of treatment is symptomatic.

David Hile

ANATOMY

The shoulder is designed for mobility in all directional planes, but stability is less than other joints. To meet the many demands placed on it, the shoulder uses three bones, four joints, and a specialized set of soft tissues consisting of muscles, tendons, ligaments, and bursae. The most common causes of nontraumatic shoulder pain in descending order of frequency are rotator cuff tendinopathy, acromioclavicular joint disease, adhesive capsulitis, and referred pain.[1]

BONES AND JOINTS

The humerus, clavicle, and scapula are the bones of the shoulder complex. The scapula consists of the body plus three bony extensions: the glenoid, the coracoid, and the acromion.

The four joints of the shoulder are the glenohumeral, acromioclavicular, sternoclavicular, and scapulothoracic. The glenohumeral joint is a ball-and-socket joint and is the central axis of shoulder motion. The glenohumeral joint is the most mobile and least stable joint in the body. Stability is derived from three components. The first is the glenoid labrum, which is a fibrous ring of tissue encircling the glenoid cavity. The glenoid labrum increases the surface contact area of the humeral head within the relatively shallow glenoid fossa. The second component consists of three glenohumeral ligaments, which aid stability by reinforcing the joint capsule. Finally, four specialized muscles, known as the *rotator cuff*, encompass the glenohumeral joint and provide stability during motion.

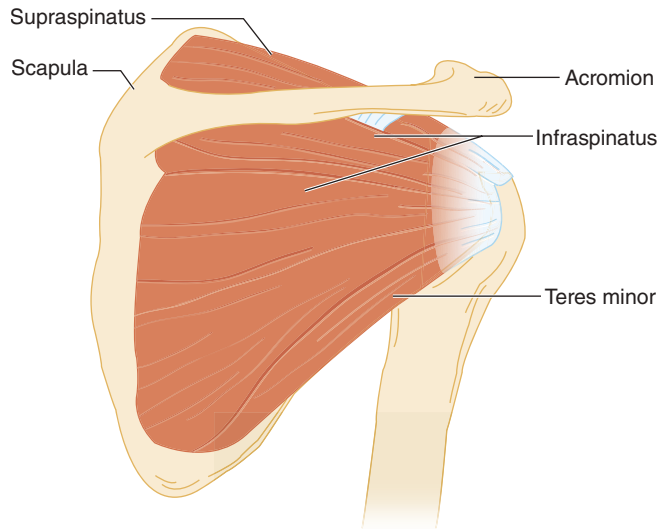

FIGURE 280-1. Posterior view of the shoulder illustrating rotator cuff muscles.

The sternoclavicular and acromioclavicular joints together contribute to glenohumeral motion, but their primary function is to suspend and stabilize the shoulder girdle. Rotation at the acromioclavicular joint and elevation at the sternoclavicular joint allow complete arm elevation. The scapulothoracic joint represents the articulation of the scapula on the posterior wall of the thorax. Scapular motion is essential for overall shoulder motion: every degree of scapulothoracic motion allows 2 degrees of glenohumeral motion.

SHOULDER MUSCLES

The deltoid, which drapes the shoulder complex and forms its contour, acts as a powerful and independent elevator of the arm. Along with the pectoralis, the deltoid is the primary source of movement of the upper extremity.

The **rotator cuff** consists of four muscles: supraspinatus, infraspinatus, teres minor, and subscapularis (**Figures 280-1 and 280-2**). All originate

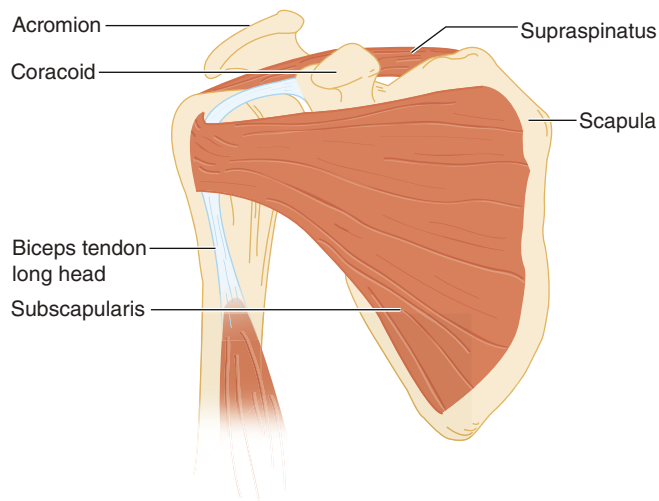

FIGURE 280-2. Anterior view of the shoulder illustrating the supraspinatus muscle and the long head of the biceps.

on the scapula, traverse the glenohumeral joint, and insert on the proximal humerus. The rotator cuff muscles also contribute to the power of the upper extremity, providing 30% to 50% of the power in abduction and 90% in external rotation.

The supraspinatus muscle originates on the posterior and superior aspect of the scapula and passes beneath the acromion, inserting onto the great tuberosity of the humeral head. It initiates arm elevation and abducts the shoulder. It also balances the power of the deltoid, keeping the humerus centered in the glenoid during deltoid contraction. The infraspinatus originates on the posterior scapula just inferior to the scapular spine. It inserts on the posterior aspect of the greater tuberosity and acts primarily as an external rotator of the arm (**Figure 280-1**). The teres minor originates on the lateral border of the scapula just inferior to the infraspinatus and inserts on the posterior aspect of the humerus. It works with the infraspinatus to provide external rotation (Figure 280-1). The subscapularis is the only rotator cuff muscle that arises from the anterior aspect of the scapula. It attaches to the lesser tuberosity of the humeral head and provides internal rotation of the arm (**Figure 280-2**).

The long head of the biceps tendon, although not part of the rotator cuff, assists in rotator cuff function. The long head of the biceps tendon courses superiorly in the bicipital groove of the humerus between the greater and lesser tuberosities, passes between the subscapularis and supraspinatus tendons, and penetrates the glenohumeral joint to insert on the labrum (Figure 280-2). During arm elevation, the tendon of the long head of the biceps depresses the humeral head, helping it remain centered in the glenoid.

BURSAE

The bursae facilitate frictionless motion between the components of the shoulder. Although there are eight bursae in the shoulder complex, only the extra-articular subacromial bursa is clinically significant. Its roof adheres to the undersurface of the deltoid, and its floor to the underlying rotator cuff. The bursa is lubricated by synovial fluid and surrounded by a layer of peribursal fat.

CORACOACROMIAL ARCH

The coracoacromial arch is formed by the coracoid posteriorly, by the acromion anteriorly, and by the coracoacromial ligament that forms the anterior roof of the arch (**Figure 280-3**). The humeral head provides the floor of the arch. This arch defines the space within which the tendons of the rotator cuff, the tendon of the long head of the biceps, and the subacromial bursa must function.

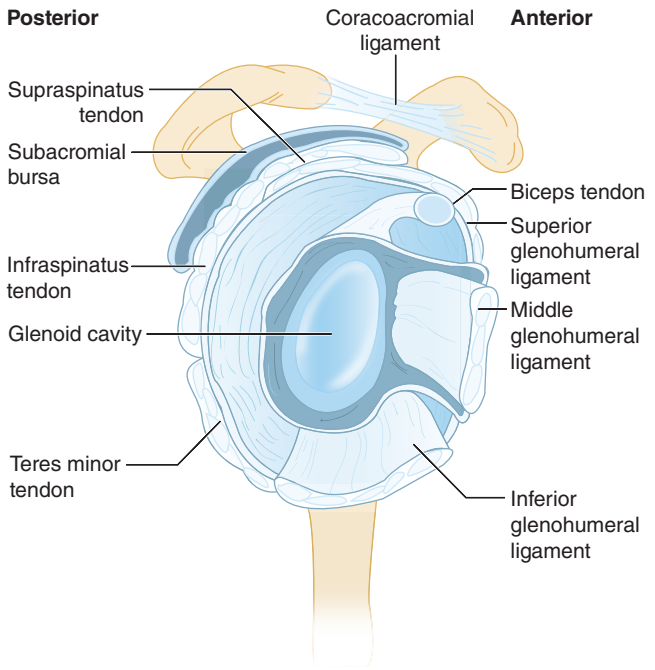

FIGURE 280-3. Lateral view of the shoulder illustrating the coracoacromial arch with the rotator cuff and subacromial bursa.

IMPINGEMENT SYNDROME (SUBACROMIAL BURSITIS, ROTATOR CUFF TENDINITIS, SUPRASPINATUS TENDINITIS, PAINFUL ARC SYNDROME)

PATHOPHYSIOLOGY

Repetitive overhead use of the arm or movement of the shoulder above the horizontal causes encroachment on the subacromial space by the humeral head (**Figure 280-4**).[2-4] Repetitive subacromial encroachment or "impingement" produces pathologic changes of the bursa, rotator cuff, and biceps tendon that result in a loss of the normal gliding mechanism between the rotator cuff and related soft tissues within the coracoacromial arch. *Impingement syndrome* is the encompassing term used for the conditions of subacromial bursitis, rotator cuff tendinitis, supraspinatus tendinitis, and painful arc syndrome.[2-5]

Repetitive impingement of the subacromial space evolves in a progressive pattern classified in three stages.[3,4] In stage 1, reversible edema and hemorrhage about the rotator cuff occur. Although possible at any age, it is classically seen in young athletes <25 years old who have excessive overhead use of the shoulder. During this stage, patients complain of a dull ache over the anterolateral shoulder that is aggravated by activity and improved by rest. The clinical course at this point is typically reversible.

Repeated mechanical trauma from the impingement can progress to stage 2, where tendinitis of the rotator cuff creates fibrosis and thickening of the tendons of the rotator cuff and bursa. This stage is typically seen in patients between the ages of 25 and 40, and the prolonged duration (weeks to months) or recurrence of symptoms is useful in making this diagnosis. During this stage, patients complain of a recurrent or chronic aching pain with daily activities, pain with vigorous activity, and night pain (caused by irritation triggered by a relaxed supporting muscle tone).

Continued overuse can lead to stage 3 with rotator cuff tears, rupture of the long head of the biceps, and subacromial spurs. Patients at this stage have progressive symptoms and disability, and they often require surgical decompression of the subacromial space.

CLINICAL FEATURES

The primary symptom with impingement syndrome is pain, developing insidiously over a period of weeks to months. The pain is located over the anterior to lateral shoulder and frequently radiates to the lateral midhumerus, but not below the elbow.[2,6] Patients usually complain of pain at night that is deep and aching and interferes with sleep. This pain occurs especially when the patient lies on that shoulder or sleeps with the arms

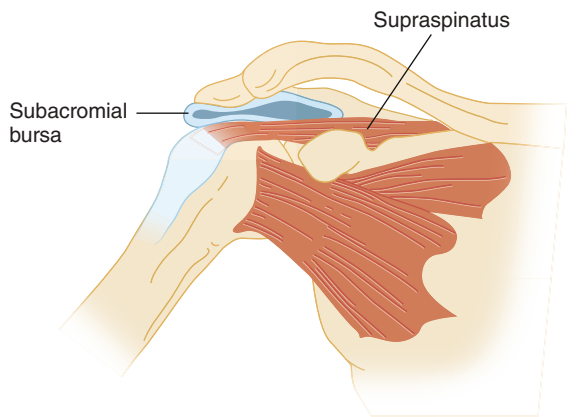

FIGURE 280-4. Impingement of the subacromial bursa and rotator cuff.

FIGURE 280-5. The "empty can" position, which isolates the supraspinatus tendon. Pain or weakness against resistance in this position suggests injury to the supraspinatus muscle.

FIGURE 280-6. Hawkins impingement test. The examiner positions the patient's shoulder at 90 degrees of abduction and 90 degrees of elbow flexion. The examiner then rotates the shoulder internally and brings the patient's arm across the front of the patient.

overhead. The pain may be exacerbated by activities that require overhead arm use, such as brushing the hair or reaching into a cupboard. Patients also note weakness and stiffness of the shoulder that is usually secondary to pain.[2,6] Once the shoulder pain has resolved, any weakness should trigger a search for a rotator cuff tear or cervical radiculopathy.

Disuse atrophy of the shoulder musculature occurs when impingement or tendinitis symptoms are chronic (stages 2 and 3). Palpation of the rotator cuff insertion at the lateral aspect of the proximal humerus usually produces pain and tenderness. During range-of-motion maneuvers, fibrosis and scarring within the tendon can cause crepitus, but the patient should have a normal and full active and passive range of motion.[6] Pain with an active arc of abduction, especially between 60 and 100 degrees, is consistent with rotator cuff pathology.[2] A sensation of catching also may be present if scar tissue is trapped beneath the acromion. Rotator cuff strength testing usually reveals mild to moderate weakness secondary to pain. The pain is usually present when resistance is applied.

The individual muscles of the rotator cuff should be isolated and tested individually, looking for pain or weakness; **to isolate the supraspinatus**, abduct the arm to 90 degrees and forward flex it 30 degrees with the thumb pointed down in the "empty can" position (**Figure 280-5**). Either symptom against resistance (continued abduction) in this position suggests inflammation or injury to the supraspinatus muscle, the most likely to be involved in the impingement syndrome.[3]

To isolate the infraspinatus and the teres minor, externally rotate the shoulder with the patient's arm against the body and the elbow bent to 90 degrees and the forearm in neutral position. Stabilize the elbow against the patient's waist and instruct the patient to rotate the arm outward.

To isolate the subscapularis, have the patient place the hand behind the back and attempt to push the examiner's hand away by moving the dorsum of the hand away from the back (lift-off test).

Specific maneuvers on physical examination test for signs of impingement by compressing the rotator cuff and bursa between the humeral head and coracoacromial arch. In the classic impingement **maneuver of Neer**, the examiner prevents scapular rotation with one hand while raising the patient's straightened arm smoothly in full forward flexion to overhead. A positive sign is pain in the arc between 70 and 120 degrees. A second test, the **Hawkins impingement test** (**Figure 280-6**), requires the examiner to position the patient's arm (shoulder) in 90 degrees of abduction and 90 degrees of elbow flexion. Rotation of the arm inwardly across the front of the patient with internal rotation of the shoulder compresses the cuff and bursa between the humeral head and coracoacromial ligament. The Neer and Hawkins tests are 75% to 89% and 91% to 92% sensitive, respectively, but specificity is much lower at 30% to 40% and 25% to 44%, respectively.[7]

DIAGNOSIS

The diagnosis is based on a history of chronic shoulder pain with a full range of motion, with possible weakness of the rotator cuff muscles and positive responses to provocative maneuvers. Radiography is used to identify other causes like fracture or degenerative joint changes. Early nonspecific radiographic signs of rotator cuff syndromes include sclerosis and subchondral cyst formation of the greater tuberosity of the humerus or sclerosis or spur formation on the anterior edge of the acromion.[8]

TREATMENT

The goals of treatment of impingement syndrome are to reduce pain and inflammation and to prevent progression of the process. Therapy starts with a conservative treatment program that should include the following:

1. *Relative rest and activity modification.* Advise the patient to avoid the aggravating activity and minimize all overhead activities. Although brief periods of support with a sling help, **avoid complete immobilization and prescribe range-of-motion exercises** (see below) three to four times daily to minimize the chance of developing adhesive capsulitis.
2. *Anti-inflammatories and analgesics.* Nonsteroidal anti-inflammatory agents for 7 to 21 days are key, with short-term opioid analgesics added for moderate to severe pain, and acetaminophen may aid in lesser pain syndromes.
3. *Cryotherapy.* Apply ice to the affected shoulder for 10 to 15 minutes three to four times daily for analgesic effects and potential reduction of inflammation and edema.
4. *Range-of-motion exercises.* Two simple exercises can help the patient maintain glenohumeral motion. Pendulum swings are done with the patient slightly bent at the waist with the arm hanging freely in front of the body. The arms should be swung in gentle arcs of motion in both a clockwise and counterclockwise direction to the level of pain tolerance for 5 to 10 minutes three to four times daily. The size of the

arcs should increase daily as symptoms allow. Also, the patient should stand sideways an arm's length from a wall and walk the fingers up the wall to the level of pain tolerance, repeating the exercise three to four times daily.

5. *Stretching and strengthening.* Stretching and strengthening exercises are best carried out under the supervision of a physical therapist.
6. *Corticosteroid injections.* Although local corticosteroid injections into the subacromial space relieve pain, adverse effects include muscular atrophy, weakness, and further tissue degeneration. Injection directly into the tendon can lead to necrosis and rupture. Injection is not an emergency procedure and is best left to the primary care physician or orthopedist.
7. *Follow-up.* Ensure reassessment within 7 to 14 days with an orthopedist and/or a rehabilitation expert.

ROTATOR CUFF TEARS

PATHOPHYSIOLOGY

Patients with rotator cuff tears present with shoulder pain after acute traumatic injury, chronic injury, or an acute extension of a chronic impingement (stage 3) of the rotator cuff. Rotator cuff tears due to chronic impingement in patients >40 years of age account for most tears. In younger patients, rotator cuff tears are seen in laborers and athletes who participate in sports that require overhead activities like tennis, swimming, and baseball.[9] In general, healthy rotator cuff tendons are resistant to acute injury, with acute rotator cuff tears accounting for only 10% of all rotator cuff tears. These acute tears usually occur as a result of trauma, such as forced or extreme hyperabduction or hyperextension from falling on an outstretched arm, lifting a heavy object, or catching a heavy object as it falls. Glenohumeral dislocation is a common cause of acute rotator cuff tears. In patients >40 years of age with a first-time dislocation, there is a 57% incidence of acute rotator cuff tear; think of a rotator cuff tear in patients with weakness >3 weeks after an acute dislocation.[9]

In addition to being categorized by the acuteness of the injury, rotator cuff tears can be full or partial thickness, with either difficult to detect on the clinical evaluation. Partial-thickness tears are twice as common as full-thickness tears, and most commonly occur on the inferior aspect of the tendon. The type and extent of the tear have significant implications for the ultimate treatment and prognosis. The supraspinatus, due to its location within the coracoacromial arch, is the most commonly affected tendon of the rotator cuff.

CLINICAL FEATURES

The clinical features of a chronic rotator cuff tear differ from those of an acute tear. Only about half of patients with chronic rotator cuff tears can recall specific trauma or an event associated with the onset of pain, often seemingly insignificant in description. Patients more commonly report a history of gradual and progressive pain; while initially described as worse at night, the pain eventually becomes persistent. The pain may be diffuse, but is commonly localized to the lateral aspect of the upper arm. Often, initial therapy with rest, anti-inflammatory agents, and glucocorticoid injections helps. If the rotator cuff weakens, the frequency, intensity, and duration of the symptoms increase and are less responsive to the usual treatments. Shoulder dysfunction progressively worsens and interferes with work, recreation, and normal daily activities. Arm elevation, external rotation, and lifting of even light objects worsen the symptoms.

With acute injuries, such as those due to falling or catching a heavy object, the patient may report a "tearing" sensation in the shoulder followed by severe pain and inability to raise the arm. An acute rotator cuff tear produces immediate profound pain and disability, with asymmetry often present due to local swelling. Active motion is limited, with inability to abduct or externally rotate the arm against even minimal resistance. On examination, disuse atrophy is often present in patients with chronic rotator cuff tears. Palpation may produce discomfort at the lateral aspect of the upper arm or in the subacromial region. Most patients with rotator cuff tears have weakness and pain on abduction, elevation, and, most commonly, external rotation. The result of the **drop arm test** is positive if the patient is unable to hold or lower a fully extended arm at 90 degrees of shoulder abduction without dropping it. Crepitus and pain are usually present on range-of-motion testing.

DIAGNOSIS

It may be very difficult to distinguish a full-thickness tear from a partial-thickness tear or a rotator cuff injury from impingement syndrome. The diagnosis is primarily clinical based on a finding of rotator cuff weakness on examination in a patient with a history of chronic shoulder pain or acute shoulder pain after significant trauma. In patients with an acute injury, it may be difficult to diagnose the tear due to excessive pain from the injury. In these cases, assume a preliminary diagnosis of acute rotator cuff tear and treat conservatively, with appropriate follow-up in 1 week.

Routine shoulder radiographs occasionally give additional diagnostic information. The most specific radiographic sign for large rotator cuff tears is a narrowing of the acromiohumeral space (<7 mm).[8] **No radiographic findings are diagnostic of an acute rotator cuff tear, and the diagnosis should rely on clinical findings.** MRI, US, and arthrography are the most sensitive modalities for detecting rotator cuff tears, although all tend to underestimate the extent of the tear.

TREATMENT

The basic goals of emergency care for suspected rotator cuff injuries are the same as with impingement (see above), with analgesia, support, and prevention of further dysfunction and disability. An arm sling can provide support and comfort until the acute symptoms subside. However, avoid prolonged immobilization and prescribe range-of-motion exercises three to four times daily to minimize the development of adhesive capsulitis.

Any evidence or suspicion of neurovascular compromise requires immediate orthopedic consultation. Refer all patients with an acute rotator cuff tear (with or without a history of chronic symptoms) and those with significant disability to an orthopedist for follow-up within a week. Complete rotator cuff tears usually require surgical repair, and functional results are better if repair is carried out early, before retraction, fibrosis, tendon degeneration, and muscular atrophy have occurred. Partial-thickness or chronic tears may respond to conservative measures.

CALCIFIC TENDINITIS

PATHOPHYSIOLOGY

Calcific tendinitis is a self-limiting disorder characterized by calcium crystal deposition within one or more tendons of the rotator cuff. In time, the calcium undergoes painful spontaneous resorption with subsequent healing of the tendon. Middle-age patients are most commonly affected, and this process is rarely seen in patients >70 years of age. Females are slightly more likely to be affected than males, and calcification is often present bilaterally. Primary tendon degeneration as a result of chronic repetitive microtrauma, age, and tissue hypoxia are causes of this disorder. The supraspinatus is by far the most commonly affected tendon, with calcium deposition usually occurring near its origin on the humerus. Any of the rotator cuff tendons or the long head of the biceps may be affected.

CLINICAL FEATURES

Because calcification occurs over a period of time, patients are generally asymptomatic or have mild pain at rest or at night. Pain with abduction or a "catching" sensation may be present on movement. During the **resorptive phase**, incapacitating pain can occur from vascular proliferation, formation of granulation tissue, and calcium crystal extravasation into the subacromial bursa. Symptoms are usually self-limited, lasting 1 to 2 weeks

in most cases. After the initially painful resorptive phase, patients can have variable levels of pain and shoulder dysfunction that may last for several months (**postcalcific period**). Adhesive capsulitis is the most common complication of calcific tendinitis and creates more chronic symptoms.

Symptomatic patients experience sudden onset of shoulder pain, usually at rest, and shoulder motion reproduces significant pain. The pain is often worse at night and interferes with sleep. During an acute attack with intense pain, the patient holds the arm across the body and often is reluctant to move it. A point of maximum tenderness may be palpated over the proximal humerus near the tendinous insertion of the rotator cuff. Both active and passive range of motion of the glenohumeral joint are usually limited to varying degrees. Flexion, extension, abduction, and internal and external rotation of this joint should be documented. Muscle atrophy and crepitus may also be present.

DIAGNOSIS

Obtain shoulder radiographs for patients with suspected calcific tendinitis to localize deposits and seek any signs of possible impingement. During the initial formative phase, calcium deposits are usually dense and well-defined if visualized. In patients who are experiencing intense pain in the resorptive phase, calcium deposits may appear hazy with poorly defined borders. The presence of visible calcifications is not necessarily specific for this disorder. US is unlikely to be helpful during the resorptive phase as the poorly defined calcifications produce little or no acoustic shadowing.[10,11]

TREATMENT

Treatment is similar to that for impingement syndrome, and nonoperative management is successful in 90% of cases. During an acute attack, nonsteroidal anti-inflammatory agents, opioid analgesics, and ice help calm the intense pain. The shoulder may be rested using a sling for brief periods of immobilization, but avoid prolonged immobilization. Instruct patients to rest the shoulder in abduction on the back of a chair as often as is tolerable. Sleeping with a pillow beneath the axilla can also help prevent restriction of motion. Local application of heat may be used once acute symptoms have diminished. Gentle and progressive range-of-motion exercises should be emphasized and encouraged. Physical therapy is indicated in patients with more chronic cases who have significantly limited range of motion of the shoulder.

Subacromial corticosteroid injection, oral steroids, platelet-rich plasma therapy, transcutaneous electrical nerve stimulation, and therapeutic US are sometimes used, but no strong supporting evidence exists for their use. Extracorporeal shockwave therapy appears to improve success rates.[12] A recent randomized controlled trial compared US-guided needle lavage with corticosteroid injection to corticosteroid injection alone, with modestly favorable clinical and radiographic results for the US group at 1 year.[13]

DISPOSITION AND FOLLOW-UP

Calcific tendinitis is a self-limited process in the vast majority of cases. For patients with new presentation of this disease, arrange follow-up with a primary care doctor within a week. For the 10% of patients in whom nonoperative methods are unsuccessful, arthroscopic or open surgery may be indicated. Refer patients who have progression of symptoms, constant pain interfering with daily activities, or absence of improvement after conservative therapy.[14]

ADHESIVE CAPSULITIS

PATHOPHYSIOLOGY

Adhesive capsulitis, commonly referred to as *frozen shoulder syndrome*, begins as painful inflammation of the glenohumeral joint, followed by eventual fibrosis of the joint capsule and restriction of shoulder motion. Primary or idiopathic adhesive capsulitis is associated with a wide variety of unrelated conditions, including diabetes, thyroid disease, postmenopausal, pulmonary neoplasm, and autoimmune disorders. Secondary adhesive capsulitis produces similar findings, but results from a known cause, such as prolonged immobilization after trauma, surgery, stroke, or a primary inflammatory condition of the shoulder such as impingement syndrome or bicipital tendinitis. The condition resolves with conservative therapy in most patients within 1 to 2 years, although some are left with residual pain or stiffness.

Four stages of this disorder exist, although patients do not necessarily follow these stages in a linear fashion. Stage 1, around the first 2 to 3 months, presents with acute synovial inflammation with limitation of shoulder movement due to pain. Stage 2 (**freezing stage**), about months 3 to 9, has decreased shoulder motion from capsular thickening and scarring, and chronic pain. Stage 3 (**frozen stage**), months 9 to 15, is characterized by less pain, but a more fibrotic and thick capsule and more limitation in range of motion. Stage 4 (**thawing stage**), usually after 15 months, has minimal pain and progressive improvement in the range of motion of the shoulder.[15]

DIAGNOSIS

Limited active and passive range of motion is the hallmark of adhesive capsulitis. Pain is typically diffuse and aching, poorly localized, accompanied by stiffness, and often extends down the upper arm. The pain is frequently worse at night and at rest, especially in earlier stages. Disuse atrophy may be present. Impingement testing is difficult due to the restriction of motion. Occasionally, posterior glenohumeral dislocation creates restricted motion of the shoulder; exam and imaging can help detect this condition. US may demonstrate increased vascular flow, thickening of rotator cuff structures, and bulging of the supraspinatus tendon. MRI or magnetic resonance angiography findings approach 70% sensitivity and 95% specificity for the condition.[15]

TREATMENT

The goals of treatment are to reduce pain and restore motion and function. Avoid shoulder immobilization; if a sling is used in patients in early stage 1 who have severe pain, limit it to days to prevent increased loss of motion due to further capsular restriction. Although physical therapy is difficult in the early, more painful stages of disease, it is key along with nonsteroidal anti-inflammatory drugs, analgesics, and ice.

Although it is not an ED procedure, intra-articular steroid injection is a potential option during follow-up to improve pain and function in the short term; the long-term effects are less clear.

Refer patients to an orthopedist if ongoing symptoms exist despite good therapy (usually after >6 months) or when the diagnosis is unsure. Closed manipulation under general anesthesia, arthroscopic capsular release, and open capsular release are surgical options.

DISORDERS OF THE BICEPS TENDON

PATHOPHYSIOLOGY

Disorders of the proximal aspect of the long head of the biceps tendon include tendinopathy, subluxation or dislocation, and partial or complete tears; these occur from inflammation, instability, or trauma.[16] The long head of the biceps tendon originates from the superior labrum and the supraglenoid tubercle on the scapula. As it exits the glenohumeral joint, it courses through the bicipital groove as it travels anterior and superior to the humeral head.[16] Approximately 50% of the long head of the biceps tendon originates from the superior labrum. Forces applied tend to pull the labrum off the glenoid rim. Due to this anatomic association, tears of the superior labrum, known as SLAP (superior labrum anterior to posterior) lesions, are frequently found in conjunction with long head of the biceps tendon pathology. Injuries of

one or the other structure may be difficult to distinguish, both clinically and operatively.

The biceps tendon may also become inflamed, may become partially displaced out of the bicipital groove, or may rupture altogether. (See chapter 271, "Shoulder and Humerus Injuries" for the approach to traumatic ruptures of the distal bicipital tendon.)

CLINICAL FEATURES

Bicipital tendinopathy may be due to inflammation (tendinitis) or collagen tears in or around the tendon (tendinosis) and may be acute or chronic. Tendinitis and tendinosis are difficult to distinguish clinically. Bicipital tendinopathy triggers intense and localized pain at the anterior aspect of the shoulder. Repetitive overhead arm motion may result in inflammation chronically or an acute SLAP lesion, particularly in athletes. Pain at rest, night pain, and pain on rotation are common. Dislocation or subluxation of the biceps tendon from the bicipital groove is painful and occurs medially or laterally, while complete dislocation is seen only medially and is associated with a subscapularis tear. Posterolateral instability is associated with a supraspinatus tear. Concurrent injury to the biceps reflection pulley is necessary for tendon dislocation in either direction.[16]

Partial or complete rupture is almost always proximal and is due to micro-tears and other age-related degenerative changes in this area of the tendon. In younger patients, mild trauma may cause complete rupture of the biceps tendon, which is heralded by an audible snap or pop followed by severe pain and deformity.

DIAGNOSIS

Palpation of the tendon within the bicipital groove reproduces the intense pain. Forearm supination, one of the main actions of the long head of the biceps, also reproduces pain, especially when resistance is applied. In assessing for instability, resisted forearm supination may cause palpable subluxation or a painful popping sensation as the tendon undergoes subluxation; these findings are classic but not common.

Because biceps tendon pathology is frequently associated with pathology of adjacent structures, clinical testing is often inconclusive and inaccurate.[16] Many provocative tests to confirm the presence of pathology of the long head of the biceps or superior labrum have been described in the literature. **Speed's test** identifies tear or tendinitis of the long head of the biceps; flex the shoulder to 90 degrees with the patient's arm (elbow) fully extended and supinated. Provide downward resistance against shoulder flexion. Pain localized to the bicipital groove indicates a positive test. The Speed's test appears to have a sensitivity of 87% and a specificity of 80% for tear of the long head of the biceps.[17]

SLAP lesions or labral tears are complex, and a recent Cochrane review concluded that physical examination alone cannot be used as the sole basis by which to diagnose a SLAP lesion. The test most likely to help diagnose a SLAP lesion is the **active compression test**. To perform, have the standing patient flex his or her shoulder to 90 degrees, and then adduct 10 to 15 degrees medially and rotate fully, with elbow extended. The examiner stands behind the patient and applies a uniform downward force to the arm. This is repeated in full lateral position. A positive response is indicated by eliciting pain on the first maneuver, which is reduced or eliminated on the second maneuver; the test is 60% to 100% sensitive and 85% to 98% specific.[17]

In biceps tendon rupture, the classic finding is described as a "Popeye" deformity caused by distal contraction of the muscle belly. Supination is weak on muscle testing, but elbow flexion remains strong because of the presence of other intact elbow flexors (short head of the biceps and brachialis muscles).

Plain radiographs are generally unhelpful in diagnosing biceps tendon or SLAP lesions. MRI is also poor in diagnosing biceps tendon and SLAP lesions; magnetic resonance arthrography is preferable. In the hands of skilled operators, US is poorly sensitive but very specific in diagnosing disorders of the long head of the biceps. Arthroscopy is considered the gold standard, although recent studies have demonstrated poor intrarater reliability of arthroscopic diagnosis.[18]

TREATMENT

Manage tendinitis and subluxation with brief use of a sling as needed for support and comfort, aided by analgesics, anti-inflammatory agents, application of ice several times daily, and elevation to reduce swelling. Prescribe early mobilization with stretching exercises and follow-up within 7 to 14 days with a primary care provider.

Although not commonly administered by emergency physicians, intra-articular injections of local anesthetic and steroid can improve symptoms. Intra-articular injections can relieve bicipital symptoms but may be ineffective if adhesions or synovitis prevent dispersal into the bicipital groove. Direct injection into the bicipital groove with US guidance may be an option for specialists if previous intra-articular injections have not worked.[18] Bicipital tendinitis usually resolves with conservative therapy.

Reserve orthopedic consultation for those with tendinopathy associated with instability, partial rupture, or high-grade SLAP lesion or those failing to respond to a conservative treatment regimen. Surgical options include debridement, tenotomy, or tenodesis.[18] Bicipital tendon rupture often requires surgical repair, so orthopedic consultation in 24 to 48 hours is best. Patients with suspected SLAP lesions or other mechanical proximal biceps injuries generally require arthroscopic or other surgical intervention when symptomatic.

OSTEOARTHRITIS

Because the glenohumeral joint is non–weight bearing, primary osteoarthritis is rare. When it does occur, presentation is similar to that of degenerative disease in other joints: the patient experiences gradual and progressive onset of pain, worse with motion and better with rest. This usually occurs concurrently with degenerative disease of the acromioclavicular joint.

Secondary osteoarthritis is more common and is usually associated with a previous fracture, recurrent dislocations, or an underlying rheumatologic, metabolic, or endocrinologic disorder. ED care of both primary and secondary arthritis relies on analgesics, anti-inflammatory agents, and gentle exercises to preserve range of motion.

OTHER CAUSES OF SHOULDER PAIN

Although disorders of the rotator cuff and other intrinsic structures of the shoulder are the most common cause of shoulder pain, extrinsic conditions outside the shoulder complex can refer pain to the shoulder. The differential diagnosis includes disorders of the cervical spine, brachial plexus injuries, axillary artery thrombosis, suprascapular nerve injury, thoracic outlet syndrome, Pancoast's tumor, and miscellaneous thoraco-abdominal disorders.

The *neck* is the most common source of pain referred to the shoulder. Degenerative disease of the cervical spine, degenerative disk disease, and herniated nucleus pulposus can all refer pain to the shoulder. A patient with a C5-C6 herniated disk may present with pain very similar to that due to rotator cuff disease. Careful and thorough examination of the cervical spine and a complete neurovascular examination should be included in the evaluation of any patient with shoulder pain. (See chapter 279, "Neck and Back Pain").

Brachial plexus injury can cause pain referred to the shoulder and can produce weakness and atrophy in the muscles of the shoulder within weeks of injury. Radiographic evaluation of the cervical spine should be included in the ED evaluation of patients with suspected brachial plexus injury or involvement. **Brachial plexus neuritis** is uncommon but can be very painful. Its etiology is unknown, although inflammatory, postimmunization, and viral origins have been proposed. Inflammation of the brachial plexus can lead to weakness and atrophy of the muscles of the shoulder complex within weeks following the onset of pain.[19] Brachial plexus neuritis is usually self-limiting. Referral to a neurologist should be arranged if this disorder is suspected.

The most serious vascular injury that can cause shoulder pain is **acute thrombosis of the axillary artery**. Repetitive mechanical trauma or

explosive stress from lifting heavy objects can compress and contuse the intimal lining of the axillary artery, predisposing the artery to thrombosis.

Compression of the suprascapular nerve can cause shoulder pain. This nerve originates from the brachial plexus distal C5-C6 nerve roots and courses posteriorly to the suprascapular notch. It can become entrapped beneath the transverse ligament at the level of the suprascapular notch. Traction injuries from explosive movements can also injure the nerve. On examination, active external rotation typically reveals infraspinatus atrophy and associated weakness. The initial treatment is conservative. Electromyography and nerve conduction velocity studies will reveal the extent and location of nerve injury. Surgery for decompression is considered if conservative measures fail.

Compression of the brachial plexus and blood vessels proximal to the shoulder, the **thoracic outlet syndrome**, can cause shoulder pain. Women in the childbearing years are affected three times more commonly than men. The medial trunk of the brachial plexus is most commonly involved, and the symptoms usually include pain that radiates through the shoulder to the medial forearm and occasionally to the small and ring fingers. Patients also complain of numbness and tingling of the fingers and a weak grip. Patients can usually identify motions that reproduce the symptoms. Plain radiographic evaluation is often nondiagnostic, although some will have evidence of a prior clavicular fracture with malunion or the presence of a cervical rib band that compress the brachial plexus. Conservative measures include activity modification, education, postural exercises, nonsteroidal anti-inflammatory drugs, and physical therapy. Referral to the primary care provider is important to allow for a thorough evaluation to differentiate between neurogenic, arterial, or venous thoracic outlet syndrome.[20,21]

Pancoast's tumor may compress the brachial plexus against the chest wall and cause shoulder pain. The patient may experience local or radicular shoulder pain or a sense of fullness in the supraclavicular fossa.

Finally, myocardial ischemia and infarction, pneumonia, pulmonary embolism, or any disorder that irritates the diaphragm can also cause referred shoulder pain. Abdominal disorders that can cause shoulder pain include biliary tract disease, splenic injury or inflammation, perforated viscus, and ruptured ectopic pregnancy.

CHAPTER 281

Hip and Knee Pain

Kelly P. O'Keefe
Tracy G. Sanson

INTRODUCTION AND EPIDEMIOLOGY

Every practicing emergency physician over his or her career will see hundreds of patients with complaints of hip or knee pain that are unrelated to major trauma or an acute fracture. Discomfort and limitations to normal use in these areas are typically related to the minor trauma that occurs on a repetitive basis from performing routine daily functions or exercising. Athletes of all varieties are especially prone to these maladies, where strenuous activity transmits forces that are equivalent to three to five times the body weight directly to these major joints. Conversely, the problem of obesity similarly contributes to joint and supporting structural stress and pain.[1]

However, be alert to the various catastrophic processes that can mimic more mundane etiologies, including ruptured abdominal aortic aneurysm, epidural abscess, and septic joint (among others). Pay close attention to historical points, specific risk factors, abnormal vital signs, and physical findings to avoid making a life- or limb-threatening misdiagnosis.

PATHOPHYSIOLOGY AND ANATOMY

The hip is a ball-and-socket joint (enarthrosis), allowing motion in all directions. The hip is similar to the shoulder in this capacity, but is much more stable and relatively resistant to dislocation. The bones of the joint (femoral head, pelvic acetabulum) are strongly reinforced with a fibrocartilaginous labrum, a joint capsule, overlying ligaments, and numerous muscles.

The knee is the largest synovial joint in the body and is relatively complicated in structure, comprising two distinct articulating groups: the tibiofemoral and patellofemoral joints. The patella floats above the main joint, attaching to the femur superiorly by the quadriceps tendon and inserting into the tibia inferiorly by the patellar ligament. The knee is stabilized internally by the anterior and posterior cruciate ligaments, and externally by the medial and lateral collateral ligaments. In addition, distal to the main joint, the fibular head attaches by ligaments to the proximal lateral tibia. The medial and lateral menisci are interposed between, and protect, the femoral and tibial condyles. Numerous muscles, tendons, bursa, and additional ligaments add to the complexity of the joint and serve as potential sources for pain and dysfunction (**Figures 281-1 and 281-2**).

NERVES OF THE UPPER LEG AND REFERRED PAIN

The femoral and sciatic nerves are the major nerves within the thigh (**Figure 281-3**). The femoral nerve is the largest branch of the lumbar plexus, and the sciatic is the longest nerve in the body, traveling posteriorly and supplying sensation to the hip joint through its articular branches. The femoral and obturator nerves also innervate the hip. The femoral nerve divides into anterior and posterior branches, with the posterior becoming the saphenous nerve and providing sensation to the lower leg. The anterior nerve supplies sensation to the anterior medial thigh by the medial and intermediate cutaneous nerves. The two major branches of the sciatic, the peroneal and tibial nerves, course through the posterior fossa of the knee, along with the popliteal artery and vein.

Pain in the area of the knee is not commonly referred to other sites, and knee pain is usually due to local pathology. However, referred pain from hip pathology is commonly felt in the buttocks, thigh, or groin; may extend to the knee; and may even travel to the foot. Pain felt in the hip and surrounding locations may be referred from pressure on the

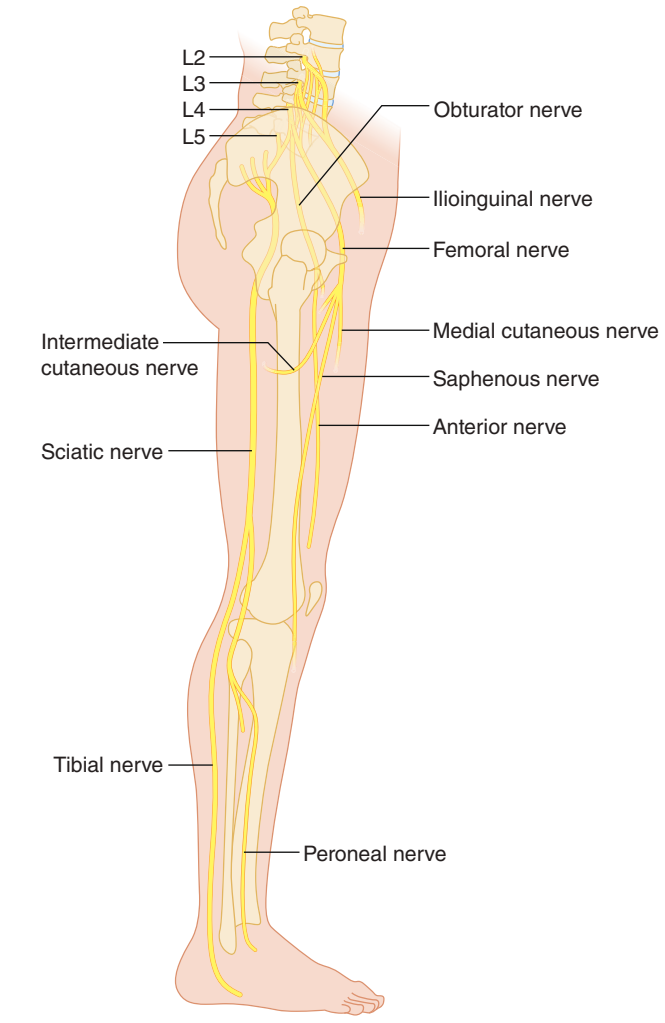

FIGURE 281-3. Nerves that innervate the thigh.

proximal nerve roots as they exit the lumbar and sacral spine. **In the patient with appropriate risk factors, consider expansion or rupture of an abdominal aortic aneurysm as the cause of hip pain that is not otherwise explained by the history or physical examination, especially when there are no preexisting joint issues.** Bedside US may exclude this life-threatening diagnosis. Other extra-articular sources of hip pain include intra-abdominal or pelvic tumors; diverticular, epidural, or psoas abscess; and the generally less worrisome diagnoses of herpes zoster or herniated lumbar disc.

DIAGNOSIS OF KNEE AND HIP DISEASES AND SYNDROMES

The majority of knee and hip problems can be diagnosed or excluded with a focused history and physical examination (**Table 281-1**).

IMAGING

A suspected diagnosis obtained via history and physical examination is confirmed or ruled out by imaging. For the majority of soft tissue injuries or overuse syndromes, radiographs are not particularly useful unless a history of significant trauma or cancer exists. More sophisticated imaging is typically not needed for evaluation in the ED but may

TABLE 281-1 Suggested Clues for the Differential Diagnosis of Hip and Knee Pain

Determine the location of the pain to narrow down the potential diagnosis.
Determine the activities that bring on the pain.
Complaints that the joint "gives out" or "buckles" generally are due to pain and reflex muscle inhibition rather than an acute neurologic emergency. This complaint may also represent patellar subluxation or ligamentous injury and joint instability.
Poor conditioning or quadriceps weakness generally causes anterior knee pain of the patellofemoral syndrome; therapy should address this weakness.
Locking of the knee suggests a meniscal injury, which may be chronic.
A popping sensation or sound at the onset of pain is reliable for a ligamentous injury.
A recurrent knee effusion after activity suggests a meniscal injury.
Pain at the joint line of the knee (palpable indentation between distal femur and proximal tibia) suggests a meniscal injury.

be indicated at follow-up or for selected ED patients on an individual basis. US can identify intra-articular or bursal effusions and soft tissue swelling and can localize muscle or tendon injuries. Normal comparison US views from the unaffected leg can be helpful. US is very helpful for the evaluation of popliteal cysts and arterial structures and will exclude deep venous thrombosis as a cause of pain and swelling.

Plain films are helpful in the evaluation of bony abnormalities such as severe arthritic changes and spurring, calcification derangements, and other inflammatory processes late in their courses. CT scan provides superior detail of osseous structures, will identify intra-articular loose bodies, and visualizes the early changes of osteonecrosis. Abnormalities of the labrum and joint capsule may also be seen. MRI, as the test of choice, precisely defines the anatomy of both the hip and knee and provides great detail for soft tissue and bony abnormalities. MRI is usually obtained on an outpatient basis. Although not frequently ordered from the ED, bone scans may be useful for the assessment of a variety of infectious and inflammatory processes, including avascular necrosis. Ultimately, arthroscopy of the knee and hip allows direct visualization of intra-articular lesions and simultaneous treatment.

SPECIFIC SYNDROMES AND DISEASES BY LOCATION

See **Table 281-2** for a summary of the most important conditions.

PSOAS ABSCESS

The psoas muscle is susceptible to the hematogenous spread of infection from distant sites because of its rich blood supply and proximity to overlying retroperitoneal lymphatic channels.[2] *Staphylococcus aureus* is the most common pathogen (80%); other less frequent pathogens include *Serratia marcescens*, *Pseudomonas aeruginosa*, *Haemophilus aphrophilus, Proteus mirabilis*, and enteric pathogens.

Symptoms include abdominal pain radiating to the hip, flank pain, fever, and limp. Presentation may be insidious. Other symptoms include nausea, weight loss, and malaise. To provoke pain, instruct the patient to perform forceful contraction of the psoas. Place your hand just proximal to the patient's ipsilateral knee, and have the patient raise his or her thigh against your hand. Confirm the diagnosis by CT scan. Treatment includes antibiotics and surgical consultation for percutaneous (most commonly) or open drainage.[2]

REGIONAL NERVE ENTRAPMENT SYNDROMES

Lateral Femoral Cutaneous Nerve Entrapment/Meralgia Paresthesia (Anterolateral Thigh Pain) *Meralgia paresthetica*, or compressive inflammation of the lateral femoral cutaneous nerve, is the best known of the lower extremity nerve entrapment syndromes. The nerve enters the thigh under the inguinal ligament near the anterior superior iliac spine and is subject to a variety of minor, reoccurring traumatic events. The syndrome can be triggered by (among other causes) wearing tight belts, heavy tool belts, car seat belts, or corsets; pregnancy; certain sitting positions (i.e., on a riding lawnmower); focal trauma, including surgical interventions such as appendectomy or hysterectomy; and obesity. It has been reported in women with muscular thighs performing activities that require repetitive flexion/extension of the leg, such as cheerleading, and in runners. Symptoms include pain to the hip area, thigh, or groin along the distribution of the nerve (proximal anterior lateral aspect of the leg; **Figure 281-4**), burning or tingling paresthesias, and hypersensitivity to light touch. Pain may be worsened or reproduced during physical examination by tapping over the area of the anterior superior iliac spine. Those affected should limit the exacerbating activity and eliminate the source of the irritation. Nonsteroidal anti-inflammatory drugs, local injections, weight loss, and (rarely) surgical excision of the nerve are other treatment options.[3,4]

Obturator Nerve Entrapment (Medial Thigh/Groin Pain) Obturator nerve entrapment is typically a sequela of pelvic fractures or abdominal/pelvic surgery. Obturator nerve inflammation is generally sensed in the groin and down the inner thigh (Figure 281-4) and aggravated by movement of the hip. Exercise-induced medial thigh pain may be the predominant symptom. The nerve is entrapped in athletes due to the presence of a fascial band at the distal obturator canal or may be compressed due to pelvic hematomas or other masses. Surgery may be required for pain relief. Imaging studies are of limited value, but needle electromyography reveals the characteristic findings of chronic denervation. Local injection of lidocaine into the area of the nerve relieves the pain and

TABLE 281-2 Selected Syndromes by Location

Diagnosis Category	Diagnosis	Pain Location
Nerve entrapment	Meralgia paresthetica	Anterolateral thigh pain or paresthesias
	Obturator nerve entrapment	Groin and inner thigh pain
	Ilioinguinal nerve entrapment	Groin pain
	Piriformis syndrome (sciatic nerve compression by piriformis muscle)	Buttocks and hamstrings pain
Hip bursitis	Trochanteric bursitis	Hip pain when lying on side or with hip abduction and adduction
	Ischiogluteal bursitis	Ischial pain
	Iliopectineal and iliopsoas bursitis	Anterior pelvis and groin, hip extension
Knee bursitis	Pes anserine bursitis	Anterior medial knee pain
	Prepatellar bursitis	Pain anterior to patella
Hip overuse syndromes	External snapping hip syndrome (coxa saltans)	Posterior lateral hip pain
	Fascia lata syndrome	Lateral thigh pain
Knee overuse syndromes	Patellofemoral syndrome (runner's knee)	Anterior knee pain, worse with prolonged knee flexion
	Medial plica syndrome	Anterior medial knee pain, knee snapping during repeated flexion/extension
	Iliotibial band syndrome or snapping knee syndrome	Pain over lateral epicondyles, or snapping when iliotibial band passes over femoral condyle
	Popliteus tendinitis	Posterior lateral knee pain, worse on downhill exercise
	Patellar tendinitis (jumper's knee)	Inferior patellar or proximal patellar tendon pain
	Quadriceps tendinitis	Proximal patellar pain
	Popliteal (Baker) cyst	Posterior knee pain

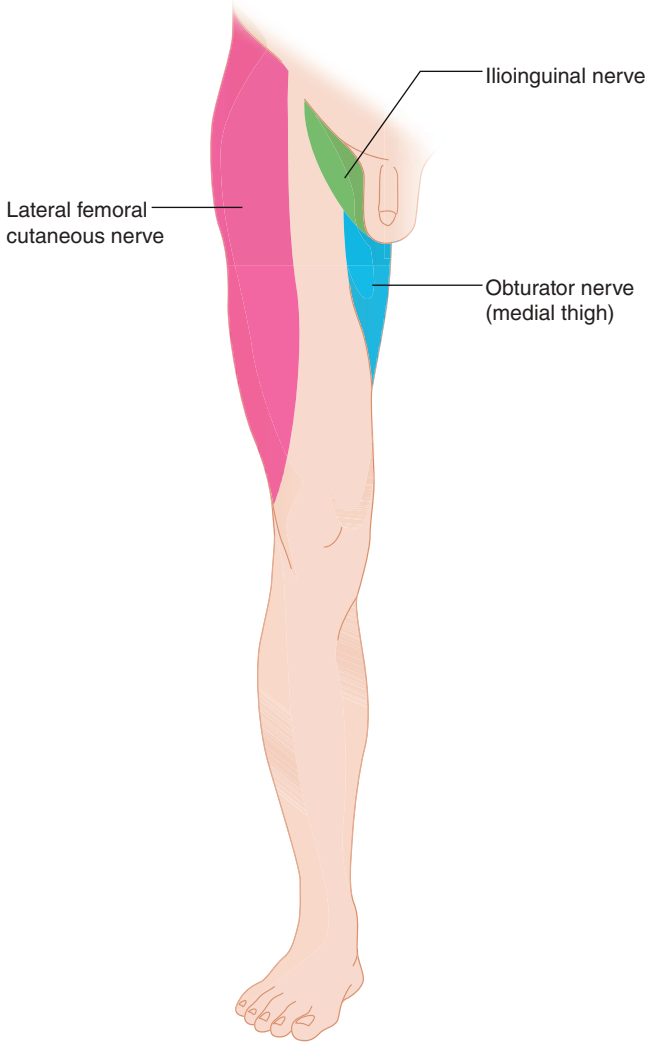

FIGURE 281-4. Local innervation and locations of pain for specific thigh and groin nerves.

associated reactive weakness and may make the diagnosis; however, the nerve block is both difficult to perform and rarely done in the ED.[5]

Ilioinguinal Nerve Entrapment (Groin Pain) The ilioinguinal nerve arises from the lumbar plexus and passes through the psoas muscle, the transverses abdominal muscle adjacent to the anterior superior iliac spine, and the abdominal oblique muscles into the inguinal canal to innervate the groin and scrotum or labrum. Entrapment occurs due to hypertrophy of the abdominal wall musculature or pregnancy. Hyperextension of the hip produces pain and hypoesthesia in the distribution of the nerve, yielding groin pain.[6]

Piriformis Syndrome (Buttock/Posterior Thigh Pain) Compression of the sciatic nerve generally produces pain in the distal extremity, but irritation of the sciatic nerve from the piriformis muscle, referred to as the piriformis syndrome, causes pain in the area of the buttocks and hamstring muscles that is worsened by sitting, climbing stairs, or squatting (**Figure 281-5**). The clinician may palpate a tender mass over the piriformis muscle and elicit pain in the region of the sacroiliac joint or gluteal musculature. Hip flexion and passive internal rotation will exacerbate the symptoms. Imaging is useful only to rule out other conditions. Treatment is conservative.

SPECIFIC BURSAL SYNDROMES OF THE HIP AREA

Bursae are self-contained flat sacs, lined with synovium, that reduce friction between tissues moving over each other in a repetitive fashion, such as ligaments, tendons, and bone. New bursae may form at any area

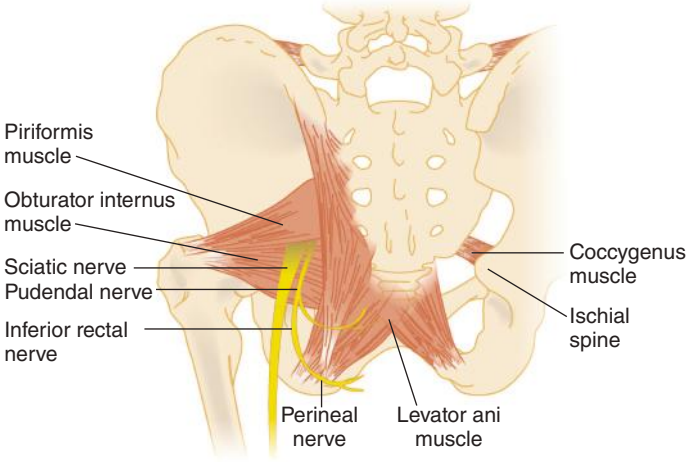

FIGURE 281-5. Proximity of the piriformis muscle and the sciatic nerve. [Reproduced with permission from Simon RR, Sherman SC, Koenigsknecht SJ: *Emergency Orthopedics: The Extremities,* 5th ed. © 2007, McGraw-Hill Inc., New York.]

that is subject to repeat irritation. Causes of bursal pain include inflammation (with repetitive minor trauma; rheumatologic disorders, such as psoriatic arthritis, rheumatoid arthritis, or ankylosing spondylitis; and crystalline disease, such as gout or pseudogout) and infection. Certain bursae are more prone than others to these insults, and these produce symptoms in specific locations that the practitioner should recognize.

Inflammation may be very difficult to distinguish from infection, because both disorders share common symptoms and signs, with a significant overlap in diagnostic cell counts when bursal fluid is aspirated. A Gram stain positive for bacteria and a culture growing pathogens are definitive for infection and septic bursitis, but infection may be present in the absence of these findings. Occasionally, with trauma or prolonged inflammation, a bursa may end up communicating with a joint. Arthrocentesis is required in these circumstances or any other when a septic joint is suspected. The development of a draining sinus tract favors septic bursitis (see chapter 284, "Joints and Bursae").

Trochanteric Bursitis (Posterolateral Hip Pain) The trochanteric bursae lie between the gluteus maximus and the posterolateral greater trochanter, with a deep and superficial component (**Figure 281-6**). Female

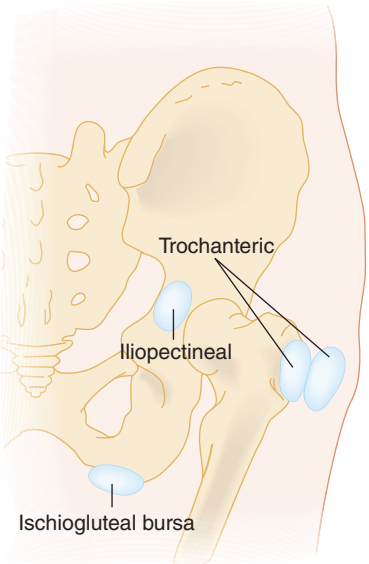

FIGURE 281-6. Selected bursae of the hip and pelvis. Proximity of the piriformis muscle and the sciatic nerve. [Reproduced with permission from Simon RR, Sherman SC, Koenigsknecht SJ: *Emergency Orthopedics: The Extremities,* 5th ed. © 2007, McGraw-Hill Inc., New York.]

runners with a broad pelvis are prone to inflammation in this location. Inflammation is commonly seen in older women and can be a complication of rheumatoid arthritis. The patient complains of pain due to direct pressure when lying on the involved side, with activities where the hip is abducted (involving the deep bursa), and when adducted for the superficial component. Simple walking and climbing stairs aggravate the pain as well. Pain is revealed by palpation over the greater trochanter and resisted abduction or adduction of the hip.[7,8]

Bursitis from abnormal calcification is uncommon, but may affect the trochanteric bursa. Calcific bursitis is identified on plain radiographs or CT as a poorly marginated line that is clearly separated from the femoral cortex. Calcification may also form around tendons.

ISCHIAL OR ISCHIOGLUTEAL BURSITIS (POSTERIOR/GLUTEAL PAIN)

Ischiogluteal bursitis presents with pain over the ischial prominence (Figure 281-5), which thus is increased in the sitting position. "Weaver's bottom" is a nickname for the inflammatory version of this bursitis, which is particularly exacerbated by sitting on a hard surface for long periods. As expected, this condition most often occurs in sedentary individuals. The bursa is also subject to focal, direct trauma. The bursa lies in close proximity to the sciatic nerve and the posterior femoral cutaneous nerve, predisposing to concomitant inflammation of these nerves and subsequent characteristic radicular pain.

Iliopectineal Bursitis (Anterior Hip, Pelvis/Groin Pain) The iliopectineal bursa is interposed between the hip joint and the iliopsoas muscle (Figure 281-6). Pain is located over the anterior pelvis and the groin on the affected side. The patient may reflexively assume a position of hip flexion and external rotation to aid in relief. On examination, extend the hip and palpate the area overlying the joint capsule to reproduce pain.[9]

Iliopsoas Bursitis (Groin Pain) The iliopsoas bursa lubricates movement of the iliopsoas tendon over the lesser trochanter and is the largest bursa in the hip region. The patient complains of pain to extension of the hip, which is reduced by hip flexion. There may be tenderness over the middle third of the inguinal ligament in the area of the femoral pulse (**Figure 281-7**). This process may be confused with iliopsoas tendinitis, hernias, femoral aneurysms, adenopathy, or psoas abscess.[10]

SPECIFIC BURSAL SYNDROMES OF THE KNEE

Pes Anserine Bursitis (Anterior Medial Knee Pain) The pes anserine (from the Latin for three-toed foot of the goose) bursa lies deep to the three tendons that insert on the medial aspect of the tibia below the knee joint—the gracilis, sartorius, and semitendinosus—and above the medial collateral ligament and medial femoral condyle (**Figure 281-8**). Pes anserine bursitis is commonly seen in obese women with osteoarthritis of the knee, in runners, and with other various overuse syndromes. The patient complains of anterior medial pain below the joint line, and focal swelling may be noted over the bursa, with increased tenderness to palpation. The symptoms are sometimes confused with the pain from a medial meniscal tear or a medial collateral ligament injury.[11]

Prepatellar Bursitis (Pain Anterior to the Patella) Also known as *housemaid's knee*, *nun's knee*, or *carpet-layer's knee*, this bursa is commonly inflamed through repetitive kneeling on hard surfaces. Pain is frequently mild, with a restricted range of motion from the swelling, presenting as an effusion over the lower pole of the patella. This swelling may be so significant that one must differentiate it from a joint effusion (**Figure 281-9**). The area is tender to palpation, and bursal margins are often palpable. The prepatellar bursa is also one of the more common sites for septic bursitis, especially in children (see chapter 284).[12,13]

Other Knee Bursae The superficial infrapatellar bursa lies between the tibial tubercle and the overlying skin (Figure 281-8). The deep infrapatellar bursa is situated between the patellar tendon and the tibia. Neither bursa is commonly inflamed or infected. Consider infection when symptoms resemble septic arthritis or osteomyelitis of the proximal tibia, with swelling and loss of full extension of the knee.[14]

The tibial collateral ligament bursa lies between the ligament and the knee capsule. Calcification may occur here, and point tenderness accompanies fibrositis of the ligament. Consider this diagnosis in the patient with medial joint line pain, especially when there is no history of knee instability. Pellegrini-Stieda disease refers to the ossification of the proximal portion of the medial collateral ligament. This results from injury and presents as a palpable, tender mass. The fibular collateral ligament has a surrounding bursa; when inflamed, it produces lateral knee pain that is increased with varus strain.

TREATMENT OF BURSITIS

Treatment is aimed at the suspected cause. For inflammatory conditions, nonsteroidal anti-inflammatory drugs, rest, heat, and time are the basis of conservative treatment. Steroids may occasionally be required, and steroid injections into the more readily accessible bursa are useful only when it is clear that no infection exists. **Do not inject steroids into tendons, because this may weaken the tendon and lead to rupture.**

For bursal pain with an unclear cause, concomitant treatment for inflammation (rest, nonsteroidal anti-inflammatory drugs) and infection (antibiotics, most commonly for *S. aureus* and *Streptococcus* species) may be reasonable while awaiting culture results. See chapter 284 for recommendations concerning bursal aspiration and diagnosis. Serial aspiration and surgical drainage or removal of the afflicted bursa are indicated for refractory, chronic conditions. If infection is suspected in an immunosuppressed patient or if any patient presents with toxicity, admit for IV antibiotics in consultation with orthopedic surgery.

When fibrosis or synovial thickening leads to the development of painful nodules, surgical excision of the bursa is indicated. Inflammation of the bursa and the surrounding ligaments and tendons frequently coexists and is difficult to separate clinically.

MYOFASCIAL SYNDROMES/OVERUSE SYNDROMES

The diagnosis of these syndromes is largely clinical. Overuse syndromes are simply the result of repetitive stresses and microtrauma outpacing the body's ability to heal.

Hip Myofascial Syndromes/Overuse Syndromes • ***External Snapping Hip Syndrome (Posterior Lateral Hip Pain)*** Also known as *coxa saltans*, a snapping sound is heard and popping sensation felt as the iliotibial band (an extension of the fascia lata) slips over the greater trochanter (**Figure 281-10**). In athletes, the syndrome is usually associated with painful inflammation of the band and the involved bursa. The iliotibial band courses from the iliac crest, sacrum, and ischium to the lateral condyles and fibular head, separating the vastus lateralis from the hamstrings, the posterior thigh muscles (semitendinosus, semimembranosus, and biceps femoris). The patient will be able to voluntarily cause the snap with hip flexion and extension. Young women are predisposed to this syndrome, which occurs with activities such as dancing or stair climbing. Occasionally, the snap may be due to an intra-articular loose body. MRI may identify intra-articular causes or demonstrate inflammation of the local bursa, the iliotibial band, or the gluteal musculature. Dynamic sonography is also an aid for the diagnosis of extra-articular causes.[15,16]

Fascia Lata Syndrome (Lateral Thigh Pain) The fascia lata syndrome is a potential cause of pain in the lateral thigh region and is associated with pain to palpation and trigger points. Unilateral enlargement of the tensor fascia lata may occur with overuse or as a protective mechanism in injury. Athletes develop pain in the anterior groin and point tenderness over the anterior iliac crest. US is a useful aid to confirm the diagnosis.

Knee Myofascial Syndromes/Overuse Syndromes • ***Patellofemoral Syndrome/Runner's Knee (Anterior Knee Pain)*** This syndrome is a major cause of anterior knee pain, with three typical causes: focal trauma (least common), overuse, and abnormal patellar tracking as it glides and rotates in the patellar groove. A major contributor to abnormal patellar tracking is weakness of the quadriceps muscle. The syndrome is more common in females due to the presence of an abnormal Q angle (>20 degrees), resulting from a broader pelvis. The Q angle is measured at the junction of a line drawn from the anterior superior iliac spine to the central patella and a second line drawn from the central patella to the tibial tubercle (**Figure 281-11**). A normal angle is approximately 15 degrees. An increased Q angle increases the risk for patellar subluxation. Because of

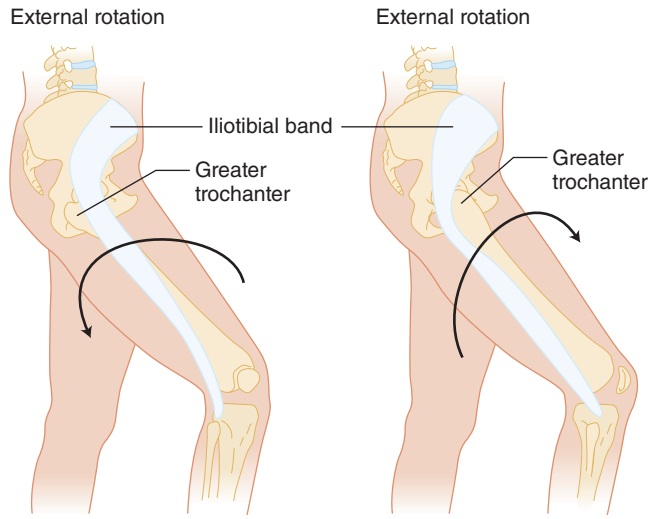

FIGURE 281-10. External snapping hip syndrome. In the snapping hip syndrome, the iliotibial band courses over the greater trochanter. [Reproduced with permission from Simon RR, Sherman SC, Koenigsknecht SJ: *Emergency Orthopedics: The Extremities,* 5th ed. © 2007, McGraw-Hill Inc., New York.]

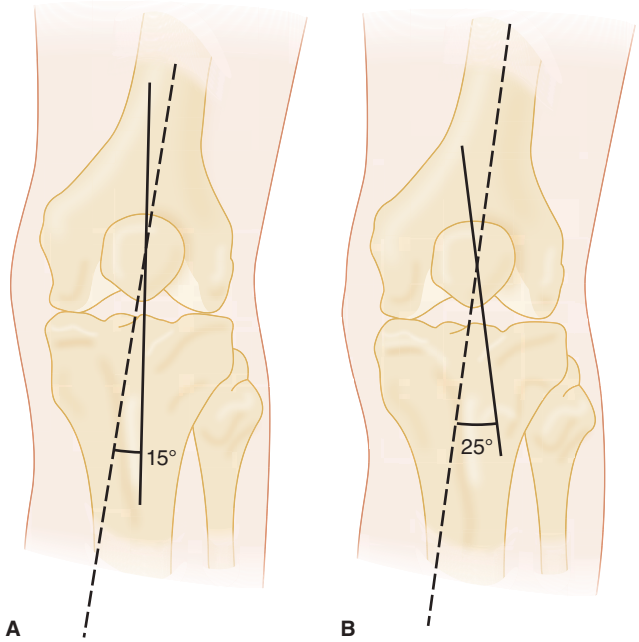

FIGURE 281-11. Measuring the Q angle. **A.** The normal Q angle is approximately 15 degrees. **B.** A Q angle of >20 degrees is considered to be abnormal. Patellar malalignment is determined clinically by measuring the *Q angle.* The Q angle is formed by a line drawn from the midpoint of the patella through the midpoint of the femoral shaft and a second line drawn from the midpoint of the patella through the tibial tuberosity. [Reproduced with permission from Simon RR, Sherman SC, Koenigsknecht SJ: *Emergency Orthopedics: The Extremities,* 5th ed. © 2007, McGraw-Hill Inc., New York.]

this relationship, females have a 50% to 100% greater incidence of knee injuries compared with males in both athletes and nonathletes.

The symptoms of anterior knee pain are gradual in onset, nonradiating, and typically unilateral. Pain is exacerbated by prolonged flexion of the knee, such as on air flights or at the movie theatre (moviegoer syndrome). Pain frequently occurs with activities of daily living, such as walking, and especially with stair climbing.

The presence of crepitus to palpation at the patella-femoral joint suggests degenerative changes but may be normal. The patellar grind test is accomplished by pressing the patella away from the femoral condyles while asking the patient to contract the quadriceps muscles. A positive test is represented by sudden patellar pain and relaxation of the muscle. The opposite test involves lifting the patella away from the knee joint while passively bending and straightening the knee. If this relieves pain, the patellofemoral joint is likely the source. Radiographic studies are of limited value but may detect arthritis of the patellofemoral joint.

Treatment involves the usual conservative measures, with an emphasis on physical therapy and strengthening. Brace support of the knee will also help correct the patellofemoral mechanism.[17,18]

Inflammatory pain to the knee may last for months to a few years following surgery or trauma and is based on a genetic predisposition to arthrofibrosis from these insults. Arthroscopy may cause the release of calcium pyrophosphate from tissue, resulting in a severe synovitis.

Chondromalacia Patellae (Anterior Knee Pain) *Chondromalacia patellae* refers to a softening of the cartilage on the posterior surface of the patella, most commonly occurring with the patellofemoral syndrome. Symptoms are pain on palpation of the patella (**Figure 281-12**).

This diagnosis is a surgical one, where the affected cartilage has a ragged appearance on arthroscopic visualization. Therefore, it is preferred that this term not be used for a new diagnosis in the ED, where the symptoms are more properly referred to simply as *anterior knee pain* or the *patellofemoral syndrome*.

Medial Plica Syndrome (Anterior Medial Knee Pain) The plica syndrome is uncommon and is difficult to distinguish from other causes of patellofemoral pain. Plicae are abnormal, redundant folds in the connective tissue of the knee, persisting from the normal embryologic septa that initially divide the knee into compartments and normally disappearing as the fetus matures. Plicae become symptomatic for unclear reasons. Reoccurring synovitis may result in a palpable, inelastic band that interferes with normal knee movement and leads to pain. This band-like structure is best palpated parallel to the medial border of the patella and produces pain in the area of the medial femoral condyle that radiates anteriorly. Pain may be brought on with activity or may occur at rest. Patients may also report a snapping sensation as the plica moves over the femoral condyle with repeated flexion and extension. Arthroscopy or MRI findings confirm the diagnosis. Treatment is conservative, with strengthening and stretching exercises; some patients require arthroscopic resection of the band.[19]

Iliotibial Band Syndrome (Lateral Knee Pain) Iliotibial band syndrome is most common in distance runners or cyclists. The iliotibial band inserts onto the lateral femoral and tibial condyles (**Figure 281-13**). The thickened fascia serves as a ligament and stabilizes the joint in extension. With overuse, the bursa underlying the band becomes irritated. Pain is reproduced consistently after reaching a certain mileage during running or other physical exertion, and on examination, there is localized tenderness to palpation over the lateral epicondyles. Treatment involves rest, decreasing the distance in training, changing shoes to reduce stress on the structures, stretching exercises, and steroid injections locally.

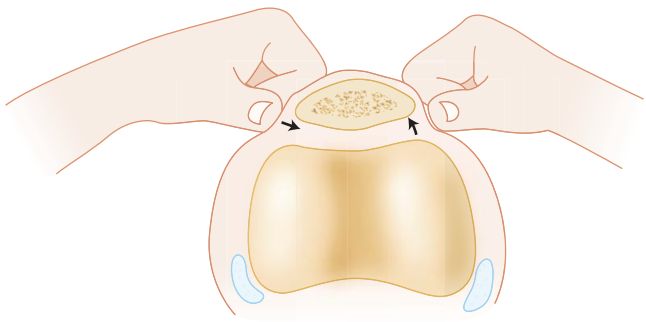

FIGURE 281-12. Patellar tenderness in chondromalacia. Palpation of the undersurface of the patella will elicit tenderness in chondromalacia of the patella. FIGURE 281-13. Iliotibial band site. **A.** The iliotibial band lies anterior to the lateral femoral epicondyle when the knee is in extension and passes posterior to it with flexion. **B.** The coursing back and forth over this bony prominence is the cause of a symptom complex referred to as the *iliotibial band syndrome*. [Reproduced with permission from Simon RR, Sherman SC, Koenigsknecht SJ: *Emergency Orthopedics: The Extremities,* 5th ed. © 2007, McGraw-Hill Inc., New York.]

Popliteus Tendinitis (Posterior Lateral Knee Pain) The small popliteus muscle passes under the lateral head of the gastrocnemius and inserts into the posterior tibia. It assists with internal rotation of the tibia, withdraws the meniscus during flexion to prevent impingement, and stabilizes the knee, preventing forward displacement. A bursa separates the tendon from the underlying structures in the area of the lateral femoral condyle. Overuse syndromes of the popliteus tendon and irritation of the bursa are associated with excessive use of the quadriceps muscle and are seen most commonly in athletes. Pain is localized over the posterior lateral aspect of the knee and is worsened by running downhill. Point tenderness may be appreciated over the insertion on the proximal posterior tibia or along the lateral joint line (palpable "soft" area between the lateral proportions of the "hard" femur and tibia). The Webb test assists in making the diagnosis: internally rotate the leg in the supine patient, flex the knee at 90 degrees, and ask the patient to force external rotation while the examiner provides resistance. A positive test produces pain with the maneuver. Treatment is rest and eventual quadriceps rehabilitation, aided by ice and nonsteroidal anti-inflammatory drugs.[20]

Patellar Tendinitis/Jumper's Knee (Anterior Superior Knee Pain) The patella tendon is subject to significant wear, with microtears and complete ruptures occurring in athletes and nonathletes alike (**Figure 281-14**). Any activity that involves jumping can result in focal pain, typically at the inferior pole of the patella or proximal portion of the tendon. Other activities that may exacerbate pain include running (especially uphill), squatting, cutting maneuvers, standing from a sitting position, or even simple walking. Symptoms may improve with activity early in the course or may progress to the point of significant discomfort at rest. Treatment involves

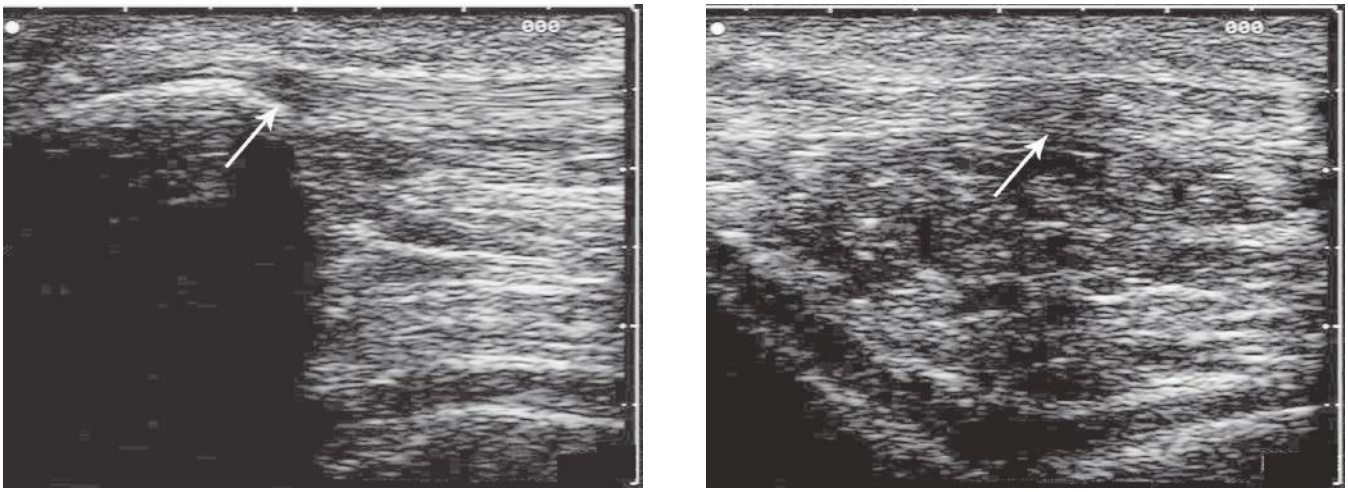

FIGURE 281-14. Patellar tendon defect. **A.** Long-axis sonogram of the proximal patellar ligament showing a hypoechoic tendon defect near the origin of the patellar tendon (*arrow*). The remainder of the tendon appears fibrillar and echogenic. A heel–toe insonating technique confirmed that a hypoechoic defect was present and that a tendinopathy ("jumper's knee") was present. **B.** Short-axis sonogram of the same patellar ligament. The ligament is seen as a somewhat echogenic horizontal structure approximately 5 mm beneath the skin surface and approximately 4 mm in width. In the central portion of the tendon, there is a focal area of hypoechogenicity that persists with careful imaging (*arrow*). This is the classic location and appearance of a "jumper's knee" or tendinopathy of the proximal patellar tendon. [Reproduced with permission from Ma OJ, Mateer JR, Blaivas M: *Emergency Ultrasound,* 2nd ed. © 2008, McGraw-Hill, New York.]

rest, nonsteroidal anti-inflammatory drugs, and cryotherapy. Steroid injections are contraindicated. Complete immobilization is not recommended, because this will reduce collagen production and stimulation of healing by loadbearing. Most recently, US-guided intratendinous injection of platelet-rich plasma has been suggested to allow rapid healing in the patellar tendon and other major tendons. However, insufficient evidence exists to support this modality definitively.[21,22] Further diagnosis and management of complete patellar tendon rupture are discussed in chapter 274, "Knee Injuries."

Infrapatellar Fat Pad Syndrome (Anterior Inferior Knee Pain) The infrapatellar fat pad location is suggested by its name: it fills the anterior part of the knee joint and is held in place by the patellar tendon, the retinaculum on both sides, and the infrapatellar synovial plica inferiorly. Due to its close anatomic relationship, the fat pad commonly becomes inflamed with patellar tendinitis.

Quadriceps Tendinitis (Anterior Superior Knee Pain) The quadriceps muscles and tendon are subject to significant forces in athletes, resulting in microtears and inflammatory changes, localized predominately at the insertion of the tendon into the proximal pole of the patella. Chronic recurrent injury or acute explosive trauma can result in complete tear of the tendon. Tendinitis is more likely to occur on a hard playing surface and with increased frequency of training. Diagnosis and management of complete quadriceps tendon rupture are discussed in chapter 274.

Semimembranosus Tendinitis (Posteromedial Knee Pain) Pain is elicited just distal to the joint line, where the tendon is easily palpated in most patients. In younger patients, the pain is associated with athletics and overuse. In older patients, it is seen secondary to degenerative changes of the knee joint, especially within the medial compartment. MRI will confirm the diagnosis if conservative therapy fails.

Snapping Knee Syndrome (Knee Pain) Snapping syndrome of the knee, similar to the same process in the hip, is a result of the iliotibial band passing over the lateral femoral condyle. The same effect may also result from the semitendinosus muscle passing over the medial condyle with the initiation of flexion and termination of extension of the knee. The snapping sensation and sound may be accompanied by pain in the location of the involved tendon. A third cause is the popliteal tendon snapping over the incisura poplitea extensoria on the lateral femoral condyle. Other causes of a snapping knee include intra-articular ganglion cysts, intra-articular loose bodies, and degenerative joint disease.[23,24]

POPLITEAL (BAKER) CYST (POSTEROINFERIOR KNEE PAIN)

A popliteal (Baker) cyst develops posteriorly and inferiorly to the knee as a distention of a local bursa, with several potential contributors existing in the areas of the hamstring tendons, the collateral ligaments of the knee, the condyles, and the heads of the gastrocnemius (**Figure 281-15**). The cyst frequently communicates with the knee (especially in adults),

TABLE 281-3 Conditions Associated with Avascular Necrosis of the Femoral Head

Traumatic
Femoral neck fracture
Hip dislocation
Occult or minor trauma
Nontraumatic
Sickle cell disease
Collagen vascular diseases
Alcohol abuse
Renal transplant
Systemic lupus erythematosus
Dysbarism
Chronic pancreatitis
Exogenous steroid administration
Cushing's disease
Caisson disease
Gaucher's disease
Renal osteodystrophy
Idiopathic

and associated intra-articular pathology is common. The cyst may develop as a herniation of the synovial membrane through the posterior joint capsule. Giant synovial cysts of the calf may develop in patients with rheumatoid arthritis and will also communicate with the knee. Popliteal venous thrombosis can be confused with the pain and swelling produced by these posterior cysts or may exist concomitantly.[25] Other potential diagnoses include aneurysms, vascular tumors, fibrosarcoma, lipoma, and other tumors.

US is useful and readily available for cyst evaluation and for the identification of other conditions (**Figure 281-16**). Arthrography or MRI is suggested for complete evaluation. Excision may eventually be required for symptom relief.[26]

PIGMENTED VILLONODULAR SYNOVITIS

Pigmented villonodular synovitis is a proliferative synovitis, also referred to as *giant cell tumor of the tendon sheath*. The articular form can be present in many joints, including the hip and knee. The synovium and synovial fluid may appear red or brown, hence the name. Radiographs show specific findings, with erosions and cysts on both sides of the articular surface, usually with normal joint space and bone density. Typically only one joint is involved. Chronic discomfort may be present, or the radiographic findings may be incidental for the asymptomatic joint.[27]

GENERALIZED ARTHROPATHY OR TENDINOPATHY RELATED TO MEDICATIONS

An important source of generalized joint pain and swelling, as well as debilitating tendinopathy/tendinitis, including frank tendon rupture, is the use of specific medications and drugs.[28] In particular, the fluoroquinolone antibiotics are well described as causing these problems. In 2008, the U.S. Food and Drug Administration issued a black box warning to this effect for the quinolones. This issue occurs with enough frequency that providers should consider alternatives to the use of these antibiotics when possible.[29] Other agents that are associated with tendinopathy include corticosteroids, oral contraceptives, and the recreational drugs marijuana and cocaine.

BONE/ARTICULAR DERANGEMENTS (DIFFUSE/VARIED JOINT PAIN)

Septic arthritis, viral arthritis, the arthritis of Lyme disease, osteoarthritis, and the other arthritides such as rheumatoid arthritis, crystalline arthritis, and seronegative spondyloarthropathy are covered in chapter 284.

Osteonecrosis Other terms used to describe osteonecrosis include *avascular necrosis, aseptic necrosis*, and *ischemic necrosis*. Osteonecrosis is the result of bone infarction caused by a lack of blood supply. Osteonecrosis may occur as an idiopathic or primary disorder, secondary to a variety of systemic conditions, or following trauma (**Table 281-3**). The trauma may be major and obvious or occult and due to repetitive injury. Major trauma leads to sudden disruption of the blood supply, as commonly occurs following dislocation or fracture in the area of the joint. When the hip is involved, pain may be present anywhere in the region of the joint, the buttocks, thigh, or even the knee. Plain radiographs are helpful in establishing the diagnosis, with findings ranging from mottled densities and lucencies to severe collapse of the femoral head (**Figure 281-17**). With the knee, the weight-bearing medial femoral condyle is more commonly affected. Early in the disease process, CT or MRI will be more helpful in establishing the diagnosis (**Figure 281-18**). Joint replacement may be required.

Osteomyelitis Osteomyelitis is an infection of the bone by bacteria or fungus, resulting in bony changes and destruction (**Figure 281-19**). It develops by spread of infection from contiguous structures (~80%) or by hematogenous spread (~20%). Hematogenous spread is more common to the long bones in children and to the spine in adults. Spinal epidural abscess is an important differential diagnosis to consider (see chapter 279, "Neck and Back Pain"). Risk factors for osteomyelitis are listed in **Table 281-4**. Pain at the site is a universal complaint and may be accompanied by warmth, swelling, and erythema. Radiographs are normal early in the course, but later will show bone demineralization, periosteal elevation, and lytic lesions. MRI is the preferred imaging modality, with approximately 95% sensitivity, but bone biopsy confirms the diagnosis with certainly. The urgency to make the diagnosis depends on the clinical situation. Osteomyelitis in diabetics is more common with skin ulcerations >2 cm, a positive probe-to-bone test result (sterile instrument reaches periosteum when probed into wound), an erythrocyte sedimentation rate >70 mm/h, or an abnormal radiograph. *S. aureus* is the most common causative agent overall. Other infectious agents and recommended therapies are listed in Table 281-4.

Blood cultures may identify the causative agent. When a blood culture is negative, bone biopsy is necessary to guide long-term antibiotic therapy. In acutely ill patients, begin presumptive treatment based on the clinical findings, with high-dose, broad-spectrum, parenteral antibiotics ensuring coverage for *S. aureus*. A 2009 Cochrane systematic

TABLE 281-4 Risk Factors, Likely Infecting Organism, and Recommended Initial Empiric Antibiotic Therapy for Osteomyelitis

Risk Factor	Likely Infecting Organism	Recommended Initial Empiric Antibiotic Therapy*
Elderly, hematogenous spread	*Staphylococcus aureus*, including MRSA, gram-negative bacteria	Vancomycin *plus* piperacillin-tazobactam, or imipenem
Sickle cell disease	*Salmonella*, gram-negative bacteria (*S. aureus* becoming more common)	Ciprofloxacin; consider vancomycin
Diabetes mellitus, or vascular insufficiency	Polymicrobial: *S. aureus, Streptococcus agalactiae,* and *Streptococcus pyogenes* plus coliforms and anaerobes	Vancomycin *plus* piperacillin-tazobactam, or imipenem
Injection drug user	*S. aureus*, including MRSA, and *Pseudomonas*	Vancomycin
Developing nations	*Mycobacterium tuberculosis*	See chapter 67, "Tuberculosis"
Newborn	*S. aureus* including MRSA, gram-negative bacteria, group B *Streptococcus*	Vancomycin *plus* ceftazidime
Children	*S. aureus* including MRSA	Vancomycin *plus* ceftazidime
Postoperative with or without retained orthopedic hardware	*S. aureus* and coagulase-negative staphylococci	Vancomycin
Human bite	Streptococci or anaerobic bacteria	Piperacillin-tazobactam or imipenem
Animal bite	*Pasteurella multocida, Eikenella corrodens*	Cefuroxime if known *P. multocida,* piperacillin-tazobactam or imipenem

Abbreviation: MRSA = methicillin-resistant *Staphylococcus aureus.*

*All patients require bone biopsy and debridement of infected/dead bone.

FIGURE 281-20. Osteochondritis dissecans (*arrow*) is shown at the lateral portion of the medial femoral condyle. [Reproduced with permission from Simon RR, Sherman SC, Koenigsknecht SJ: *Emergency Orthopedics: The Extremities,* 5th ed. © 2007, McGraw-Hill Inc., New York.]

review could not identify the optimal empiric antibiotic agent from randomized controlled trials in the literature.[30] Therefore, empiric therapy is based on the suspected organism(s) from risk factors, as listed in Table 281-4.

Osteochondritis Dissecans (Knee Pain) In osteochondritis dissecans, a portion of the joint surface cartilage separates from the underlying bone. It is rare, but seen most often in adolescents, and is of unclear origin. Occult trauma likely plays a role. The lateral portion of the medial femoral condyle is predominately involved, with unilateral occurrence. The patient experiences pain and swelling. Plain radiographs may reveal a thin rim of calcium separated from the underlying bone (**Figure 281-20**), with MRI showing much greater detail.[31] Arthroscopic repair of the lesion or removal of associated loose bodies is required if conservative therapy fails.[32]

Synovial Osteochondromatosis (Hip or Knee Pain) Synovial osteochondromatosis is characterized by idiopathic, nodular synovial membrane proliferation and subsequent calcification of the affected tissue. Eventually, multiple fragments of this growth (as large as 2 cm) break off and occupy the joint space or the area of the bursa and tendon sheaths. With time, degenerative changes and joint deterioration with secondary osteoarthritis occur. The disease is more common in males between the ages of 20 and 50 years old. Patients complain of chronic symptoms, with pain and joint swelling. There is a limitation in range of motion, and the joint may lock. The large joints are commonly involved. Radiographs will show the calcification and the intra-articular bodies and later the changes of osteoarthritis. Surgical excision of the proliferating synovium and removal of the ossified bodies from the joint space are required.[33]

Transient Osteoporosis of the Hip (Hip Pain) Transient osteoporosis of the hip occurs in middle-aged men and in pregnant women in the third trimester. The disease is uncommon, idiopathic, and characterized by sudden onset of hip pain, with the findings of osteoporosis on plain films. The disease spontaneously resolves within 6 to 12 months. Symptoms

FIGURE 281-21. Radiograph of a 73-year-old man with Paget's disease of the right proximal femur. Note the coarsening of the trabecular pattern with marked cortical thickening and narrowing of the joint space consistent with osteoarthritis secondary to pagetic deformity of the right femur. [Reproduced with permission from Fauci AS, Kasper DL, Braunwald E, et al: *Harrison's Principles of Internal Medicine,* 17th ed. © 2008, McGraw-Hill, New York.]

may abate before the associated radiographic findings have resolved. Take precautions against hip fracture while the disease remains active.[34,35]

Paget's Disease Osteitis deformans, or Paget's disease, is a chronic disorder resulting in enlarged, deformed bones from overactive breakdown and reformation. Paget's disease affects the hip joint in 50% of patients. The disease is familial and is suggested by an elevated serum alkaline phosphate level. Patients complain of pain, and radiographs reveal joint space narrowing with minimal hypertrophic changes (**Figure 281-21**). Treatment is symptomatic, and medications that slow the rate of bone turnover (calcitonin, alendronate, others) may be helpful to control the disease systemically. Surgery is required for complications of the disease, such as fracture and severe arthritis.[36,37]

Osteitis Pubis (Midline Pelvis and Groin Pain with Radiation to Hips) Osteitis pubis should be considered as a possible diagnosis in athletes with pain in the region of the pubis. It also occurs following pregnancy and after bladder and prostate surgery. In athletes, it is an inflammatory process related to overuse of the adductors and gracilis muscles. Bony changes with periostitis occur at the sites of the origins of the involved muscles. The disease is seen in runners, soccer players, weightlifters, fencers, and football players. Symptoms start off gradually and progress to severe pain with any movement of the legs. Rolling over in bed may be next to impossible due to excruciating pain, and there is a characteristic "duck waddling gait." The symptoms may resolve completely over a period of months with rest and nonsteroidal anti-inflammatory drug use. Rarely, arthrodesis of the pubic symphysis and local debridement are required.

Radiographs show symmetric bone reabsorption medially, widening of the pubic symphysis, and sclerosis along the pubic rami. These changes may take several weeks to develop. MRI more clearly details the changes, and bone scans show evidence of the inflammatory process.[38-40]

Diseases of Abnormal Calcification Myositis ossificans, or heterotrophic calcification, is the deposition of bone at a site where bone does not normally occur. The process is related to direct trauma, with the thigh and hip muscles frequently involved. Bleeding follows direct trauma to the muscle, and calcium deposits form inside the hematoma. A firm, palpable, painful mass will develop within 2 weeks and may persist for up to 1 year. Plain radiographs reveal an irregularly shaped mass around the joint or in the fascial planes (**Figure 281-22**). The appearance may be confused with a primary neoplasm, such as osteosarcoma or periosteal osteogenic sarcoma. Range of motion in the muscle

FIGURE 281-22. Myositis ossificans. This radiograph shows extraskeletal ossification of the medial proximal right thigh (immediately inferior to the head of the femur), approximately 3 weeks after a severe contusion to that area. [Reproduced with permission from Simon RR, Sherman SC, Koenigsknecht SJ: *Emergency Orthopedics: The Extremities,* 5th ed. © 2007, McGraw-Hill Inc., New York.]

TABLE 281-5 Treatment Caveats

Do not inject steroids in areas where infection is a concern, or where they may accidentally be injected into tendon sheaths and contribute to tendon rupture.
Use caution in the examination of the immunocompromised patient, because signs of infection may be subtle or altered.
Injuries in athletes should be referred to a sports medicine specialist to optimize therapy and decrease time to return to maximum activity levels.

or joint is limited due to pain or physical presence of the mass. Operative removal may be required.

Calcifying peritendinitis and bursitis are also traumatic in origin but are relatively uncommon. The trochanteric bursa of the hip is frequently affected. Radiographs reveal a thin, poorly marginated white line that is separated from the cortex of the hip.[41]

CORE TREATMENT

Treatment for the majority of inflammatory and overuse syndromes consists of nonsteroidal anti-inflammatory drugs, rest, heat, and time as the basis of conservative treatment (**Table 281-5**). "Rest" does not require full immobilization, which can lead to muscle atrophy and delayed return to normal function. Full knee immobilization, which is commonly prescribed from the ED, should therefore be used sparingly in the majority of these conditions. Appropriate rest is followed by gradual resumption of activities, physical therapy, and strengthening activities where appropriate. Steroids may occasionally be required, and steroid injections into the more readily accessible bursa are useful when it is clear that no infection exists but can be detrimental when infection is present. It is critical to avoid steroid injections into tendons, because steroids may weaken the tendon and lead to rupture. Athletes are best served by referral to a sports medicine specialist or an orthopedist.

CHAPTER 282

Systemic Rheumatic Diseases

R. Darrell Nelson

INTRODUCTION

Systemic rheumatic diseases are chronic, inflammatory, autoimmune disorders, such as rheumatoid arthritis, systemic sclerosis (scleroderma), or systemic lupus erythematosus. ED patients with systemic rheumatic diseases have complex clinical and pharmacologic histories and multi-organ system pathology. Many extra-articular manifestations of rheumatic diseases can result in serious morbidity or mortality if not recognized and properly managed. This chapter discusses rheumatologic emergencies from an organ system perspective. **Table 282-1** categorizes emergencies associated with systemic rheumatic diseases.[1]

CLINICAL FEATURES AND DIAGNOSIS

Table 282-2 reviews clinical manifestations common to many of the systemic rheumatic diseases. **Table 282-3** lists typical clinical manifestations and complications specific to rheumatic diseases. The clinical descriptors may allow suspicion for a systemic rheumatic disease in a previously undiagnosed patient. However, the diagnosis cannot be confirmed during an ED visit. The diagnostic criteria and testing sequence, which are usually completed in the outpatient setting, are beyond the scope of this chapter. The need to admit a patient with a known or suspected systemic rheumatic illness depends on the severity of the patient's presentation. Complications of systemic rheumatic disease frequently require intensive care unit admission, and in 20% of patients with systemic rheumatic disease admitted to the intensive care unit, the diagnosis is made for the first time during the intensive care unit stay.[2] Rheumatoid arthritis is the most common rheumatic disease requiring intensive care unit admission, followed in decreasing frequency by systemic lupus erythematosus and systemic sclerosis.[2-4] Infection is the leading cause for intensive care unit admission, followed by rheumatic disease flare.

AIRWAY EMERGENCIES

Critical airway obstruction may develop (**Table 282-4**) at the level of the larynx, subglottic region, or trachea.

CRICOARYTENOID JOINT ARTHRITIS

In patients with rheumatoid arthritis, systemic lupus erythematosus, and relapsing polychondritis, arthritis or edema of the cricoarytenoid joints can lead to acute upper airway obstruction.[5] In addition, secondary infections such as bacterial epiglottitis or tracheitis can quickly

TABLE 282-1 Categories of Emergencies in Patients with Systemic Rheumatic Diseases

Category	Clinical Manifestations
Disease exacerbation	Flare-up of preexisting systemic rheumatic disease
Complication	Known complication of an acute systemic rheumatic disease (i.e., pulmonary hemorrhage, pericarditis, respiratory, or renal impairment)
Infection	Infection complicated by immunosuppressive therapy
Comorbidity exacerbation	Worsening or onset of a serious illness that is not a direct manifestation of the systemic rheumatic disease
Adverse drug reaction	Reaction to a systemic rheumatic disease drug treatment

TABLE 282-2 Clinical Signs and Symptoms Associated with Systemic Rheumatic Diseases

General manifestations	**Cardiovascular manifestations**
Fatigue	Chest pain
Fever	Hypertension
Lymphadenopathy	Pericarditis and Raynaud's syndrome
Malaise	Recurrent DVT
Splenomegaly	Recurrent thrombophlebitis
Syncope	Valvular diseases
Weight loss	**Neurologic manifestations**
Joint and muscle manifestations	Dizziness and gait disturbance
Arthralgias	Headache
Arthritis	Peripheral neuropathy
Back pain	Cognitive disturbances
Myalgias	Seizures
Morning stiffness	**Eye manifestations**
Muscle weakness	Corneal ulcers
Synovitis	Eye pain
Mucocutaneous manifestations	Red eye, tearing, photophobia
Alopecia	Episcleritis and scleritis
Nasal, or oral ulcers	Uveitis
Edema	**Renal manifestations**
Erythema nodosum	Microscopic hematuria, proteinuria
Palpable purpura	Renal failure
Rash	**GI manifestations**
Recurrent sinusitis	Abdominal pain
Sclerodactyly	Acute pancreatitis
Telangiectasias	Bowel dysmotility
Respiratory manifestations	Dysphagia
Airway disturbances	Esophageal reflux
Asthma	GI bleeding
Dyspnea	Xerostomia (dry mouth)
Hemoptysis	**Urogenital manifestations**
Interstitial lung disease	Acute scrotum
Pleurisy	Urogenital ulcers
Pneumonitis	**Nonspecific laboratory abnormalities**
Pulmonary hypertension	Thrombocytopenia
Restrictive pulmonary failure	Anemia, elevated creatinine

Abbreviation: DVT = deep vein thrombosis.

compromise the airway. Signs and symptoms of cricoarytenoid arthritis are throat pain or tenderness over cartilaginous structures (aggravated by swallowing or speaking), foreign body sensation or fullness in the throat, voice changes or hoarseness, and, in more severe cases, dyspnea, cough, or stridor.[1] Pain from cricoarytenoid arthritis is sometimes referred to the ear or to the neck.

CT scanning and fiber optic laryngoscopy can evaluate the cricoarytenoid joint. Initial treatment consists of systemic high-dose corticosteroids such as methylprednisolone 250 to 500 milligrams IV.[5]

TRACHEOMALACIA

Relapsing polychondritis can cause inflammation, destruction, and collapse of tracheobronchial cartilage, resulting in airway obstruction. Regions of segmental collapse due to tracheomalacia or refractory stenosis may be resected or treated with stents. The use of noninvasive ventilation may help to prevent airway collapse. Cartilaginous destruction results in a small glottis, so, when intubation is required, use a smaller endotracheal tube than normal.

SUBGLOTTIC STENOSIS

An acute upper airway obstruction can be observed in Wegener's granulomatosis, resulting from subglottic stenosis with inability to clear tracheobronchial secretions. Subglottic stenosis can be a presenting sign of Wegener's granulomatosis. Stenosis often requires surgical intervention.

INTUBATION IN PATIENTS WITH SYSTEMIC RHEUMATIC DISEASES

Endotracheal intubation is considered "difficult" in patients with systemic rheumatic diseases because of airway-related aspects of the disease. Anticipate the need for adjunctive airway techniques. Consider fiber optic intubation and fully prepare to perform an emergency cricothyrotomy. In cases where the airway is patent but intubation is anticipated and the patient can be transferred, it may be preferable to go to the operating room for a "double setup," with preparation for a formal tracheostomy if oral intubation is unsuccessful.

Patients with rheumatoid arthritis and ankylosing spondylitis can develop temporomandibular joint dysfunction with reduced mouth opening. Patients also have a high incidence (25%) of atlantoaxial instability, C1-C2 subluxation, or dislocation. Therefore, avoid neck hyperextension in patients with rheumatoid arthritis.

Neck hyperextension and cervical manipulation are also a hazard in ankylosing spondylitis. Patients with cervical ankylosis are at high risk for cervical fractures (even after minor trauma).

In patients with scleroderma, hardening of the skin of the face and neck can be severe, decreasing the ability to open the mouth and limiting neck mobility.

PULMONARY EMERGENCIES

Lung involvement, due to the underlying disease itself or secondary to infection, is a frequent cause of major morbidity and death (Table 282-4), particularly in systemic sclerosis, rheumatoid arthritis, systemic lupus erythematosus, Wegener's granulomatosis, and polymyositis/dermatomyositis. Pulmonary complications of systemic rheumatic disease manifest primarily as interstitial lung disease and vascular disease. Due to chronic lung injury, interstitial pulmonary fibrosis, or pulmonary hypertension, even mild infection in patients with systemic rheumatic disease can cause respiratory failure.[6,7] Respiratory arrest has been reported in systemic lupus erythematosus and dermatomyositis/polymyositis patients due to phrenic nerve involvement, in rheumatoid arthritis patients due to cervicomedullary compression associated with rheumatoid atlantoaxial dislocation, and in Sjögren's syndrome patients due to hypokalemic paralysis secondary to distal renal tubular acidosis.[6]

Symptoms can develop due to chronic manifestations of the underlying disease (i.e., interstitial lung disease), or new symptoms caused by an acute complication such as pneumonia or alveolar hemorrhage. Rheumatoid arthritis patients treated with methotrexate experience increased adverse respiratory events including pneumonia.[8] Several complications outside the pulmonary parenchyma cause respiratory symptoms: involvement of the joints of the thoracic cage (in ankylosing spondylitis), pleural effusion, respiratory muscle inflammatory disease (polymyositis/dermatomyositis), cardiac involvement, and anemia. Pulmonary embolism risk is higher in systemic rheumatologic diseases.[9,10]

ALVEOLAR HEMORRHAGE

Alveolar hemorrhage is an uncommon but catastrophic pulmonary emergency.[1,3] It is a complication of systemic lupus erythematosus (where it may be the presenting manifestation), antiphospholipid syndrome, systemic

TABLE 282-3 Common Features and Complications of Systemic Rheumatic Diseases

Disorder	Common and Characteristic Clinical Features	Complications
Antiphospholipid syndrome	Multiple and recurrent venous and arterial thromboses, recurrent abortions. Secondary form is associated with systemic lupus erythematosus, rheumatoid arthritis, systemic sclerosis, and Sjögren's syndrome. Thrombophlebitis and deep vein thrombosis, thrombocytopenia, hemolytic anemia, microangiopathic hemolytic anemia, livedo reticularis, stroke, transient ischemic attack, eye vascular complications. Coronary, renal, mesenteric, and cerebral vascular occlusion.	ARDS, pulmonary embolism, ischemic complications of vascular occlusion, bleeding, severe anemia, vision loss, catastrophic antiphospholipid syndrome.
Ankylosing spondylitis	Chronic inflammatory disease of the axial skeleton, with progressive stiffness of the spine. Young adults (peak at 20 and 30 years old). Back pain (improves with exercise), buttock, hip, or shoulder pain, systemic complaints (fever, malaise, fatigue, weight loss, myalgias), uveitis, and restrictive pulmonary failure due to costovertebral rigidity, ILD, renal impairment, fracture of the ankylosed spine, asymptomatic ileal and colonic mucosal ulcerations. Secondary amyloidosis.	Acute spinal cord or nerve compression, subluxation of the atlantoaxial joint, aortic regurgitation.
Adult Still's disease	Inflammatory disorder (similar to systemic onset juvenile rheumatoid arthritis). Systemic complaints (fever, malaise, fatigue, weight loss, myalgia), arthritis, myalgia, evanescent rash, pharyngitis, lymphadenopathy, splenomegaly, anemia, thrombocytopenia. Pericarditis, myocarditis, pleurisy.	ARDS, arrhythmias, heart failure, fulminant hepatic failure, red cell aplasia, disseminated intravascular coagulation, microangiopathic hemolytic anemia.
Behçet's disease	Chronic, relapsing, inflammatory disease. Systemic vasculitis involving arteries and veins of all sizes (carotid, pulmonary, aortic, and inferior extremity vessels are most commonly involved, with aneurysm, dissection, rupture, or thrombosis). Systemic complaints (fever, malaise, fatigue, weight loss, myalgia), recurrent painful skin and mucosal lesions; asymmetric, nonde-forming arthritis of the medium and large joints; thrombophlebitis and deep vein thrombosis; ocular complications. Neuropsychiatric manifestations. Pericarditis, myocarditis.	Hypopyon, retinal vasculitis, optic neuritis, eye vas-cular complication. Dural sinus thrombosis, aseptic meningitis and encephalitis. Arrhythmias. Superior and inferior vena cava syndrome. Abdominal aorta or pulmonary artery emergencies. Bowel perforation.
Churg-Strauss syndrome	Vasculitis with a multisystemic involvement. Systemic complaints (fever, malaise, fatigue, weight loss, myalgia), myalgia, allergic rhinitis, nasal obstruction, recurrent sinusitis, asthma, and peripheral blood eosinophilia. Systemic hypertension, pericarditis, abdominal pain, peripheral symmetric neuropathy; skin lesions and rash.	Heart failure, acute myocardial infarction, acute and constrictive pericarditis, GI bleeding, bowel perforation.
Dermatomyositis/polymyositis	Idiopathic inflammatory myopathies. Muscle weakness, myalgia, and muscle tenderness. Elevated serum creatine kinase. Systemic complaints (fever, malaise, fatigue, weight loss, myalgia), Raynaud phenomenon, nonerosive inflammatory polyarthritis, esophageal dysfunction, ILD, aspiration lung infections.	ARDS. Respiratory failure and arrest due to dia-phragmatic or chest wall muscle weakness, alveolar hemorrhage, and ILD. Heart failure, arrhythmias, and conduction disturbances.
Giant cell arteritis (temporal arteritis)	Chronic vasculitis of large- and medium-sized vessels. Elderly (mean age at diagnosis: 70 years old). Associated with polymyalgia rheumatica in 50% of cases. Localized headache of new onset, tenderness of the temporal artery, and biopsy revealing a necrotizing arteritis. Temporal artery may be normal on clinical examination. Gradual onset, systemic complaints, jaw or tongue claudication, eye complaints and visual loss. Aortic regurgitation and aortic arch syndrome. Neurologic complications due to carotid and vertebrobasilar vasculitis.	Ischemic optic neuropathy, eye vessel occlusion. Aortitis (especially the thoracic tract) and aortic emergencies. Stroke.
Henoch-Schönlein purpura	Systemic vasculitis associated with immunoglobulin A deposition, generally in children. Frequently, acute presentation follows an upper respiratory infection. Palpable purpura (in patients with neither thrombocytopenia nor coagulopathy), arthritis/arthralgia, abdominal pain, and renal impairment (adult), ILD.	Respiratory failure and alveolar hemorrhage. Seizures, intracranial bleeding, GI hemorrhage, bowel ischemia or perforation, acute pancreatitis, intussusception (children). Acute scrotum.
Microscopic polyangiitis	Small-vessel systemic vasculitis, characterized by rapidly progressive glomerulonephritis and pulmonary involvement. Lung complications differentiate microscopic polyangiitis from polyarteritis nodosa. Systemic complaints (fever, malaise, fatigue, weight loss, myalgia), arthralgias, skin lesions, hemoptysis, abdominal pain, renal impairment, systemic hypertension.	Rapidly progressive glomerulonephritis, severe lung hemorrhage, GI bleeding.
Polyarteritis nodosa	Systemic necrotizing vasculitis of the medium-sized muscular arteries. Systemic complaints (fever, malaise, fatigue, weight loss, myalgia), arthralgias, skin lesions, abdominal pain, renal impairment, systemic hypertension, peripheral mononeuropathy typically with both motor and sensory deficits, eye complications, leukocytosis, and normochromic anemia.	Acute scrotum, ischemic and hemorrhagic stroke, acute coronary syndrome, heart failure, peripheral artery ischemia, mesenteric ischemia and bowel perforation, GI bleeding, acute pancreatitis, malignant hypertension.
Relapsing polychondritis	Immune-mediated condition. Ears (violaceous and erythematous auricula), nose (saddle nose deformity), and other cartilaginous structures inflammation (especially joints and respiratory tract). One-third of cases associated with other systemic rheumatic diseases. Sternoclavicular, costochondral, and manubriosternal arthritis, upper airway involvement, aortic or mitral valvular regurgitation, pericarditis, renal impairment, peripheral neuropathies, ocular complications.	Airway obstruction. Acute renal failure, aortitis and aortic emergencies, heart block, ACS, scleritis, peripheral ulcerative keratitis, and acute scrotum.
Rheumatoid arthritis	Chronic, systemic, inflammatory disorder. Symmetric and potentially destructive arthritis. Systemic symptoms (fever, malaise, fatigue, weight loss, myalgia), skin lesions, splenomegaly. Cervical spine involvement, pleuritis, ILD, pericarditis, myocarditis, and aortitis. Cricoarytenoid arthritis with potential for airway obstruction, ocular involvement. Peripheral artery disease, Sjögren's syndrome, vasculitis, and renal impairment. Abdominal pain. Anemia, leukopenia, thrombocytosis, and Felty's syndrome. Increased risk of lymphoproliferative diseases, particularly non-Hodgkin's lymphoma.	Airway obstruction, obliterative bronchiolitis, acute respiratory failure. ACS, heart failure, thoracic aorta dissection, arrhythmias and conduction disturbances, subluxation of the atlantoaxial joints, bowel ischemia and perforation. Septic arthritis. Scleritis.

(*Continued*)

TABLE 282-3 Common Features and Complications of Systemic Rheumatic Diseases (*Continued*)

Disorder	Common and Characteristic Clinical Features	Complications
Systemic lupus erythematosus	Systemic autoimmune disease, characterized by relapses and remissions, and affecting virtually every organ. Systemic complaints (fever, malaise, fatigue, weight loss, myalgia), symmetric and polyarticular arthritis (small joints of the hands, wrists, and knees), butterfly rash, mucocutaneous manifestations, oral and/or nasal ulcers, Raynaud's phenomenon. Neuropsychiatric manifestations, pleurisy, lupus pneumonitis, shrinking or vanishing lung syndrome, ILD, and pulmonary hypertension. Libman-Sacks endocarditis, pericarditis, myocarditis, endocarditis. GI unspecific complaints. Renal impairment, leukopenia, mild anemia, and thrombocytopenia. Antiphospholipid syndrome. Ocular complications.	Airway obstruction, ARDS, respiratory failure and arrest, alveolar hemorrhage, ACS, cardiac tamponade, heart failure, arrhythmias, pulmonary embolism, stroke, acute renal failure, Guillain-Barré–like syndrome, transverse myelitis, seizures. Bowel ischemia and perforation, GI bleeding, acute pancreatitis. Hemolytic anemia, thrombotic microangiopathic hemolytic anemia.
Sjögren's syndrome	Autoimmune disease. May be primary; secondary form is mostly associated with rheumatoid arthritis, systemic lupus erythematosus, polymyositis, or dermatomyositis. Xerophthalmia and xerostomia, systemic symptoms, arthralgia, skin lesions, Raynaud's phenomenon. ILD, pulmonary hypertension, pericarditis, neuropsychiatric manifestations, peripheral neuropathy, hepatic abnormalities, renal impairment, increased risk of non-Hodgkin's lymphoma.	Hypokalemic respiratory arrest. Heart block, pulmonary embolism, ischemic stroke, transverse myelitis, optic neuritis, renal tubular acidosis, acute pancreatitis.
Systemic sclerosis (scleroderma)	Inappropriate and excessive accumulation of collagen and matrix in a variety of tissue; widespread vascular lesions with endothelial dysfunction, vascular spasm, thickening of the vascular wall and narrowing of the vascular lumen. Systemic complaints (fever, malaise, fatigue, weight loss, myalgia), skin lesions (fingers, hands, and face), carpal tunnel syndrome, Raynaud's phenomenon. ILD, renal impairment, GI dysmotility, gastroesophageal reflux (aspiration pneumonitis), chronic esophagitis and stricture formation. Vascular ectasia in the stomach ("watermelon stomach").	Scleroderma renal crisis. Respiratory failure, ARDS, aspiration pneumonitis, pulmonary hypertension, alveolar hemorrhage, heart failure, arrhythmias, and conduction disturbances.
Takayasu's arteritis	Chronic vasculitis, young women, predominantly Asians. Systemic complaints (fever, malaise, fatigue, weight loss, myalgia), arthralgias, skin lesions, abdominal pain and diarrhea. Aorta and its primary branches, and pulmonary artery involvement. Neurologic manifestations, syncope, subclavian steal syndrome, extremities ischemia. Renovascular hypertension. Normochromic normocytic anemia.	ACS, bowel ischemia and perforation, GI bleeding, stroke.
Wegener's (granulomatosis with polyangiitis)	Multiple organ system vasculitis and necrotizing granulomas. Respiratory tract manifestations in approximately of 100% cases, with nose, oral cavity, upper trachea, external and middle ear, and orbit inflammations. Upper airway and pulmonary manifestations. Constitutional symptoms, arthralgias, glomerulonephritis and small vessel vasculitis (scleritis and episcleritis, palpable purpura or cutaneous nodules, peripheral neuropathy, deafness). Systemic hypertension. Pericarditis, myocarditis. Renal impairment. Anemia, leukocytosis, and thrombocytosis.	Airway obstruction, subglottic stenosis, bronchiolitis obliterans organizing pneumonia, and alveolar hemorrhage. ACS, arrhythmias. Rapidly progressive glomerulonephritis.

Abbreviations: ACS = acute coronary syndrome; ARDS = adult respiratory distress syndrome; ILD = interstitial lung disease.

TABLE 282-4 Airway and Pulmonary Emergencies in Patients with Systemic Rheumatic Diseases

		Ankylosing Spondylitis	Adult Still's Disease	Antiphospholipid Syndrome	Behçet's Disease	Churg-Strauss Syndrome	Dermatomyositis/Polymyositis	Giant Cell (Temporal) Arteritis	Henoch-Schönlein Purpura	Microscopic Polyangiitis	Polyarteritis Nodosa	Rheumatoid Arthritis	Relapsing Polychondritis	Systemic Lupus Erythematosus	Sjögren's Syndrome	Systemic Sclerosis	Takayasu's Arteritis	Wegener's Granulomatosis

vasculitis, Wegener's granulomatosis, dermatomyositis/polymyositis, microscopic polyangiitis, and systemic sclerosis. Early recognition and aggressive management are critical for improved outcome.[3,11] Delay in treatment, age >60 years old, end-stage renal failure, and cardiovascular comorbidity worsen prognosis.[11] Patients with alveolar hemorrhage complain of acute shortness of breath, fever, and cough. Symptom onset is usually abrupt, with a progression to respiratory failure requiring mechanical ventilation in more than half of cases.

The classical triad of hemoptysis, pulmonary infiltrates on chest x-ray, and rapid fall in hemoglobin level supports the diagnosis, but the triad is not always present.[12,13] New lung infiltrates (83% to 100%) and anemia (75% to 100%) are more sensitive signs of alveolar hemorrhage; the most common initial diagnosis is "atypical" pneumonia.[12] If symptoms are accompanied by high fever, it is difficult to distinguish between alveolar hemorrhage, acute lupus pneumonia, and infectious pneumonia. The distinction is of utmost importance, because the therapeutic options are exactly the opposite (immunosuppressant vs antibiotics). Emergency bronchoscopy with bronchoalveolar lavage can confirm the diagnosis but is done after admission. Treatment is directed to the underlying condition and includes high-dose glucocorticosteroids, cyclophosphamide, local vessel embolization, or plasma exchange. [12]

INTERSTITIAL LUNG DISEASE

Interstitial lung disease is characterized by infiltration of the pulmonary interstitium by inflammatory cells and matrix, leading to fibrosis, pulmonary hypertension, and respiratory insufficiency. Rheumatoid arthritis, systemic sclerosis, polymyositis/dermatomyositis, and Henoch-Schönlein purpura are commonly associated with interstitial lung disease. Interstitial lung disease may be asymptomatic, may produce slowly progressive symptoms (cough and dyspnea), or, rarely, can cause acute respiratory failure. Treatment in the ED is ventilatory support, with oxygen, noninvasive ventilation, and intubation as needed.[14]

PULMONARY HYPERTENSION

Pulmonary arterial hypertension can be a complication of any rheumatic disease with associated pulmonary fibrosis and interstitial lung disease, but is especially common in systemic sclerosis and systemic lupus erythematosus. Pulmonary vasculitis and pulmonary thromboembolism (i.e., in antiphospholipid syndrome patients) may also lead to pulmonary arterial hypertension. Clinical symptoms reported by patients with pulmonary arterial hypertension range from cough or mild shortness of breath, to severe dyspnea, cardiac arrhythmias, chest pain, and right ventricular failure. For further discussion, see chapters 57 and 58, "Systemic Hypertension" and "Pulmonary Hypertension," respectively.

CARDIOVASCULAR EMERGENCIES

Heart disease develops through several pathophysiologic mechanisms, accounting for different manifestations: inflammation, fibrosis, infiltration, vasculitis, thromboembolism, and accelerated coronary atherosclerosis.[15] Pulmonary hypertension can lead to right heart failure. Coronary atherosclerosis can be due to an imbalance between the inflammatory and anti-inflammatory activity and the use of specific drugs, such as corticosteroids. **Table 282-5** provides a review of cardiac disorders in patients with systemic rheumatic diseases.[15-20]

ACUTE CORONARY SYNDROMES

Based on epidemiologic, clinical, laboratory, and experimental data, systemic lupus erythematosus, antiphospholipid syndrome, rheumatoid arthritis, and a few other rheumatic diseases promote accelerated coronary atherosclerosis and have an increased rate of cardiovascular morbidity and mortality.[15-17] The relative risks for atherosclerosis vary from about 1.6 in ankylosing spondylitis and psoriatic arthritis to 3.0 in rheumatoid arthritis (with a threefold increased adjusted risk of myocardial infarction) and 6.0 in systemic lupus erythematosus.[17] The risk of cardiovascular disease equals that of type 2 diabetes with coronary artery disease more prominent in rheumatoid arthritis and peripheral arterial disease more prevalent in type 2 diabetes.[21]

From a clinical point of view, it is useful to consider systemic rheumatic disease a "new" risk factor for coronary atherosclerosis. Patients with rheumatoid arthritis are less likely to undergo invasive evaluation and treatment.[19] Contributing factors may be low incidence of typical angina symptoms and attribution of chest pain to arthritis.

Coronary atherosclerosis is a major cause of cardiac mortality in young patients with systemic lupus erythematosus.[16] The risk of myocardial infarction in premenopausal women is more than twofold compared with women without lupus.[16] Medical management of acute coronary syndrome is the same as in the normal population. Coronary arteritis, fibrosis, and coronary artery vasospasm may occur in systemic sclerosis and vasculitis.

ACUTE HEART FAILURE

Acute heart failure may develop as a consequence of a myocardial disease (ischemia, cardiomyopathy, myocarditis, fibrosis), pericardial disease (tamponade or constrictive), valvular diseases (acute regurgitation), and/or conduction or rhythm disturbance.[15,16] Acute management of decompensated heart failure does not differ from the normal population, except when a flare of the underlying disease is responsible. In systemic sclerosis, diastolic dysfunction, malignant hypertension during a sclerodermal renal crisis, and decompensated pulmonary hypertension are important causes of acute heart failure.

CARDIAC ARRHYTHMIAS

Rhythm and conduction disturbances are common, especially in rheumatoid arthritis, systemic sclerosis, systemic lupus erythematosus, and polymyositis/dermatomyositis. The physiopathologic basis for these disorders is complex, involving reentry pathways, fibrosis, altered automaticity, conduction system injury, primary and/or secondary myocardial injury, and side effects of treatment. Population studies demonstrate a 40% higher risk for atrial fibrillation in patients with rheumatoid arthritis.[22] Arrhythmias and sudden cardiac death in systemic rheumatic disease have a higher incidence compared with the normal population.[19,20] Ventricular arrhythmias are a risk for sudden cardiac death, especially in patients with systemic sclerosis.[20]

MALIGNANT HYPERTENSION

Systemic hypertension may be a clinical manifestation of renal injuries or an adverse effect of disease treatment. Severe malignant hypertension is a complication of systemic sclerosis (usually observed during a "renal crisis"), but it can be also observed in catastrophic antiphospholipid syndrome, polyarteritis nodosa, and a few other rheumatic diseases.

VASCULAR AND VALVULAR DISEASE

Valvular heart disease is an extra-articular manifestation of spondyloarthropathies, particularly ankylosing spondylitis. Fibrotic changes of the aortic valve cusps lead to valvular insufficiency of the aortic and/or mitral valves. Arterial lesions can be aneurysmal (frequently complicated by fatal rupture) or, less commonly, occlusive. Aortitis may lead to aortic aneurysms in patients with giant cell arteritis (temporal arteritis), Takayasu's arteritis, and Behçet's disease, and aneurysms may rupture or dissect. In giant cell arteritis, great vessel involvement due to arteritis can result in aortic valve incompetence and aortic rupture as a late complication of the disease.

Any part of the arterial tree can be affected in Behçet's disease, but the abdominal aorta is the most frequently involved site. Pulmonary artery inflammation can be complicated by hemoptysis, aneurysm, thrombosis, hemorrhage, and pulmonary infarction. In Takayasu's arteritis, arterial narrowing and/or aortitis can produce neurologic symptoms or

TABLE 282-5 Cardiovascular Emergencies in Patients with Systemic Rheumatic Diseases

syncope related to the subclavian steal syndrome. Acute coronary syndrome, mesenteric artery ischemia, and peripheral arterial ischemia are other complications of Takayasu's arteritis.

THROMBOEMBOLISM

Superficial thrombophlebitis and deep vein thrombosis are common in Behçet's disease. After the veins of the lower extremities, other affected veins are the inferior and superior vena cavae, veins of the upper extremities, and hepatic and portal veins. Thrombosis is related to vascular inflammation and is not usually complicated by peripheral embolism. Deep venous thrombosis and pulmonary vasculitis can coexist. Hemoptysis, a sign of pulmonary artery inflammation, may mimic signs of pulmonary embolism. Treatment with anticoagulant or fibrinolytic may increase the risk of fatal hemorrhage.

Thromboembolic disease may also be observed in antiphospholipid syndrome and systemic lupus erythematosus. Vessel thrombosis can be venous and/or arterial, affect any vessel, and be recurrent and bilateral. Peripheral gangrene, acute coronary syndrome, renal artery thrombosis, sagittal sinus thrombosis, transient ischemic attack, and Budd-Chiari syndrome due to hepatic vein thrombosis are some examples of thromboembolism resulting from antiphospholipid syndrome and systemic lupus erythematosus.

CATASTROPHIC ANTIPHOSPHOLIPID SYNDROME

This uncommon vaso-occlusive process leads to multiorgan failure and is usually associated with systemic lupus erythematosus, but it may be observed in rheumatoid arthritis, systemic sclerosis, dermatomyositis, and other systemic rheumatic diseases.[23] Multiple simultaneous venous and/or arterial occlusive thromboses (involving mainly small vessels) and multiorgan failure develop suddenly and progress rapidly. In half of the cases, a precipitating factor may be identified (i.e., infection, surgery, trauma, cancer, drugs such as oral contraceptives). The kidney is the primary organ involved (acute renal failure), followed by the lungs (adult respiratory distress syndrome, embolism), CNS (stroke, seizures, venous occlusion), the heart (acute myocardial infarction and heart failure), and skin (necrosis). *Livedo reticularis* (lacelike purplish discoloration of the lower extremities due to vein engorgement) and thrombocytopenia are important diagnostic findings (a decrease in platelet count is observed in 60%), and occasionally, laboratory features of disseminated intravascular coagulation may be present.[23] This dramatic clinical scenario is frequently fatal, with a reported mortality rate approaching 50% despite therapy. Treatment is IV heparin and high-dose glucocorticosteroids with or without plasma exchange and IV immunoglobulins.[23]

NEUROLOGIC EMERGENCIES

Neurologic disease can result from accelerated atherosclerosis, direct involvement by the primary disease, vasculitis, arterial aneurysm, rupture or dissection, embolism, or infection[24] (**Table 282-6**). Libman-Sacks valvular endocarditis of lupus can result in embolism of valve vegetations. Vasculitis of the cerebral vessels, with vessel rupture or occlusion, may lead to ischemic or hemorrhagic stroke. Giant cell arteritis affects the extracranial vasculature, causing transient ischemic attacks, especially

TABLE 282-6 Neurologic and Ocular Emergencies in Patients with Systemic Rheumatic Diseases

involving the vertebrobasilar circulation, with signs and symptoms of vertigo, hearing loss, gait disturbance, and other focal neurologic deficits involving the brainstem.

Neurologic disease can also manifest as a consequence of therapy for systemic rheumatic diseases. Medications such as infliximab and adalimumab, which block tumor necrosis factor-α, increase the risk for herpes zoster outbreaks, especially multidermatomal and zoster ophthalmicus.[25] Lupus and rheumatoid arthritis are independent risk factors for herpes zoster outbreaks.[26]

SPINAL CORD COMPRESSION AND SPINAL FRACTURES

Degenerative disease of the cervical spine may result in acute spinal cord compression, vertebral artery compression syndrome (with diplopia and dysphasia), gait abnormalities, paresthesias, or obstructive hydrocephalus in patients with rheumatoid arthritis and ankylosing spondylitis. Rigidity and osteoporosis of the spine in ankylosing spondylitis increase the risk for fracture and spinal cord injury. Occult fracture of the ankylosed spine may occur, even in the absence of trauma, and may result in acute radiculopathy, paraparesis, or tetraparesis. The most common symptom is severe and progressive pain. Cauda equina syndrome is a rare complication.

INSTABILITY OF THE CERVICAL SPINE

The atlantoaxial joint is a preferred target of rheumatoid arthritis. Instability of the cervical spine and spontaneous atlantoaxial subluxation can result in acute cervical myelopathy, even after minor trauma. The signs and symptoms that raise suspicion of an unstable cervical spine are severe neck pain with occipital radiation and paresthesias or motor weakness involving the upper extremities. Instability may produce vertigo or other signs of vertebral insufficiency. The patient may complain of an electric shock sensation radiating down the back during neck flexion, a change in bladder function, or progressive quadriparesis.

Atlantoaxial instability can be clinically silent, so avoid neck flexion in the patient with rheumatoid arthritis. After even mild trauma, or if neurologic symptoms as described above develop, keep the cervical spine stabilized. CT of the cervical spine will detect fracture, but MRI is needed to assess spinal cord integrity. Neurosurgical (or orthopedic spine specialist) consultation is needed for management.

TRANSVERSE MYELITIS

Transverse myelitis is a rare, devastating acute inflammatory process affecting a focal area of the spinal cord that may lead to rapid onset of irreversible paraplegia. It is clinically manifested with acute or subacute progressive symptoms and signs of neurologic dysfunction of the spinal cord. The clinical picture may be insidious at the beginning, with weakness, back or limb pain, urinary retention, and autonomic and sensory deficits.[27]

Transverse myelitis occurs more commonly in patients with Sjögren's syndrome and patients with systemic lupus erythematosus, in whom acute transverse myelitis may be the initial manifestation. The clinical

picture of transverse myelitis may also be caused by vasculitis, arterial thrombosis, embolism, or artery dissection. An anterior spinal artery syndrome may be observed in other rheumatic diseases and is caused by the blood supply impairment secondary to dissection of the aorta, vasculitis, or embolism involving the anterior spinal artery. The clinical picture is indistinguishable from transverse myelitis.

OCULAR EMERGENCIES

The eye is a sensitive barometer for onset or flare of rheumatic diseases.[28] Ocular pain or discomfort, vision disturbances, red eye, tearing, photophobia, diplopia, or reduced visual acuity should lead to careful evaluation (Table 282-6). Optic neuritis and keratitis are complications of systemic rheumatic diseases and are discussed in brief in chapter 241, "Eye Emergencies."

Sudden and permanent blindness is also a concern in temporal or giant cell arteritis, a systemic disease that may lead to vasculitis and ischemia and that affects middle-aged to elderly individuals. The patient may report amaurosis fugax and complain of new headache, tender scalp, visual disturbance, or jaw, tongue, or upper extremity claudication. Frequently, vision loss is the presenting feature of giant cell arteritis. To prevent permanent vision loss, high-dose steroids are administered based on the clinical diagnosis, even before biopsy of the temporal artery (see chapter 241).

RENAL EMERGENCIES

The kidney is almost always involved in systemic rheumatic disease and is a major factor leading to morbidity and mortality (**Table 282-7**).

A decline in renal function should prompt careful observation and follow-up in any rheumatic disease patient. Kidney impairment may be related to the rheumatic disease itself, the results of therapy, or both. Acute nephritic syndrome, renal thrombotic events, renal artery lesions, and rhabdomyolysis are other possible causes of acute renal failure. In polyarteritis nodosa, rupture of arterial aneurysms can cause a perirenal hematoma.

Renal disease is the most common cause of death in systemic sclerosis, and a sudden catastrophic form of renal involvement, named *scleroderma renal crisis*, may be the cause. Scleroderma renal crisis typically develops early in the course of systemic sclerosis, and 75% of cases occur during the first 4 years after the onset of disease.[29] Scleroderma renal crisis presents with abrupt and rapid deterioration in renal function and is heralded by severe headache, visual disturbance, and hypertensive encephalopathy. Microangiopathic anemia with mild thrombocytopenia is another important but nonspecific diagnostic finding in scleroderma renal crisis.

The mainstay of therapy in scleroderma renal crisis is effective and prompt blood pressure control with angiotensin-converting enzyme inhibitors.[29] Start captopril, 6.25 to 12.5 milligrams PO three times daily, and increase as tolerated (during admission or follow-up).[29] Enalaprilat can be used if PO therapy is not possible. Consult nephrology for dialysis recommendations; dialysis is required in 50% of patients.[30] Avoid diuretics as they can exacerbate renal failure. For further discussion, see chapters 57 and 58.

Distal renal tubular acidosis occurs in 30% of patients with primary Sjögren's syndrome. This condition is characterized by hyperchloremic metabolic acidosis with low bicarbonate levels and hypokalemia. Consider hypokalemia as a cause of progressive weakness in patients with Sjögren's syndrome. Hypokalemia is corrected with standard treatment (see chapter 17, "Fluids and Electrolytes").

GI EMERGENCIES

GI emergencies are outlined in Table 282-7. GI complications include ischemia (primarily due to vasculitis), infarction, perforation, vascular rupture, infection (i.e., cholecystitis, diverticulitis), and hemorrhage. Vasculitis is the most common GI manifestation and may affect large vessels (giant cell arteritis), medium-sized vessels (polyarteritis nodosa), or small vessels (systemic lupus erythematosus). Lupus mesenteric

vasculitis is one of the most serious complications of systemic lupus erythematosus, with mortality of 13%.[31] Leukopenia, hypoalbuminemia, and elevated serum amylase are associated with poor outcome.[31] Bowel ischemia can be the result of the same pathophysiologic process that leads to acute coronary syndrome or the result of ischemic stroke or mesenteric artery vasculitis, as in lupus and other systemic rheumatic diseases. The patient may complain of symptoms consistent with "abdominal angina" prior to bowel infarction. Due to chronic or recurrent ischemia, the bowel may develop wall edema, strictures, and stenosis. These changes may account for colicky abdominal pain, diverticular disease, intestinal obstruction, or episodes of paralytic ileus. Acute pancreatitis is common in several systemic rheumatic diseases.

INFECTIOUS EMERGENCIES

Rheumatic diseases predispose to infection in several ways. The disease itself results in immunocompromise; treatment results in further immunosuppression (see "Adverse Drug Reaction" section below for infections associated with specific drugs used to manage systemic rheumatic diseases); the disease can result in anatomic changes that predispose to infection (see "Pulmonary Emergencies" above). Empiric antibiotics are indicated until infection can be clearly excluded. Using an elevated procalcitonin of 0.5 nanogram/mL is 90% specific for sepsis in patients with autoimmune diseases but is only 75% sensitive.[32] Isolated organisms may not differ from the normal population, but chronic immunosuppressive therapy may predispose patients with systemic rheumatic disease to opportunistic infections (i.e., *Candida*, *Pneumocystis jiroveci*, *Legionella*, *Mycobacterium tuberculosis*).

The prevalence of septic arthritis is doubled in patients with rheumatoid arthritis who are treated with glucocorticoids or tumor necrosis factor-α blockers.[33] The physical findings of severe pain and limited range of motion may be absent in cases of septic arthritis in patients with systemic rheumatic disease or may mimic a typical exacerbation of inflammatory arthritis.[34] Procalcitonin can help to differentiate septic from nonseptic arthritis, but using the standard cutoff of 0.5 nanogram/mL yields a sensitivity of only 46% to 67% with a specificity of 91%.[34] Using a lower cutoff of 0.25 nanogram/mL yields a sensitivity of 93% and a specificity of 75%.[34] Patients suspected of having septic arthritis should have arthrocentesis. See chapter 284, "Joints and Bursae" for further discussion of diagnosis and treatment.

OTHER EMERGENCIES

Several hematologic complications and other emergencies are encountered in patients with rheumatic diseases (**Table 282-8**).

Anemia, thrombocytopenia, leukopenia, and coagulation abnormalities are some of the important hematologic emergencies. Severe hemolytic anemia may develop in systemic lupus erythematosus (autoimmune) and in systemic sclerosis during renal crisis (microangiopathic). Thrombocytopenia is also observed in antiphospholipid syndrome patients and may present as thrombotic thrombocytopenic purpura. A low WBC count may also occur as a part of underlying disease or secondary to drug use. Pancytopenia can be observed when autoimmune rheumatic disorder affects all the cellular lines, in acute hemophagocytic syndrome, and in medullar suppression secondary to cytotoxic drugs. In autoimmune hematologic emergencies, transfusion of blood product may carry some risk of transfusion reaction.

Raynaud's phenomenon, digital ulcers, spontaneous finger ischemia, rash, and cellulitis are some examples of skin manifestations. In systemic lupus erythematosus, toxic epidermal necrolysis can be triggered by medication.

Patients with steroid-dependent rheumatic diseases are at risk for acute adrenal insufficiency either from unexpected stressors or from abrupt cessation of prescribed steroid medication.

Orchitis is one of the most characteristic manifestations of polyarteritis nodosa, and reports of scrotal involvement in boys with Henoch-Schönlein purpura range from 2% to 38%. Clinical findings include pain, tenderness, and swelling of the involved testicle and/or scrotum. The presentation may mimic testicular torsion. Ultrasonography confirms the correct diagnosis.

ADVERSE DRUG REACTIONS

Table 282-9 lists the more common clinical manifestations of adverse reactions associated with drugs used to manage systemic rheumatic diseases. When patients with systemic rheumatic diseases develop new

alarming and unexplained symptoms, a drug reference guide or similar resource should be consulted for a listing of rare adverse drug reactions.

IMMUNOSUPPRESSION

IMMUNOSUPPRESSION CAUSED BY DRUGS USED TO MANAGE SYSTEMIC RHEUMATIC DISEASES

Immunosuppressants and disease-modifying antirheumatic drugs are used to treat multiple types of systemic rheumatologic diseases with the aim to induce or maintain remission, to reduce exacerbations or relapse, and/or to allow tapering of glucocorticoids. These drugs have a variety of actions that are not completely understood but that modify critical pathways in the inflammatory process. They may cause immunosuppression primarily or as a side effect and lead to secondary diseases, infections, and reactivation of latent diseases or malignancies[35-43] (**Table 282-10**).

Risk factors for infection during immunosuppression include the drug, dose, duration of use, concomitant use of immunomodulators, the nature of the disease process, the functional status of the patient, healthcare facility exposure, and older age.[44]

Glucocorticoids impact both the innate and acquired immune system through a variety of inhibitory mechanisms. Immediate effects on the innate immune system include decreased phagocyte migration, eosinophil apoptosis, decreased macrophage production and function, decreased degranulation of mast cells, decreased inflammatory cytokine production, and decreased proinflammatory mediators. Neutrophils are affected by decreased ability to bind to and exit the endothelium, increased release from bone marrow, and decreased apoptosis resulting in increased overall leukocytosis but decreased effectiveness.

Acquired immunity is also affected by a decrease in dendritic cells, rapid depletion of T cells, increased apoptosis of CD4 and CD8 cells, B-cell reduction (although to a lesser extent than T cells), and in chronic use, a decrease in immunoglobulin G and immunoglobulin A.[45] Glucocorticoid therapies are associated with a dose-dependent increase in risk of infection. In trials, infection occurs more often with steroid therapy (relative risk, 1.6). Infection rates increase in therapy doses greater than 10 milligrams/d or cumulative doses greater than 700 milligrams.

TABLE 282-10 Categories of Drugs Used to Treat Rheumatic Diseases and Common Infections Associated With Their Respective Use

	Biologic Agents	Conventional Agents	Cytoxic Agents	Other Agents	Common Infections Associated with Agent
Abatacept	x				Pneumonia, bronchitis, cellulitis, and UTI. Pharyngitis. Overall infection risk 54% in adults and 36% in children.
Adalimumab	x				URI. Sinusitis.
Anakinra	x				Nasopharyngitis. Cellulitis. Overall serious infection risk 2%–3%.
Azathioprine			x		Various due to leukopenia. Reactivation of latent viruses, bacteremia, interstitial pneumonia.
Belimumab	x				Viral gastroenteritis. UTI. Influenza. Bronchitis. URI. Sinusitis. Reactivation of polyoma viruses.
Canakinumab	x				URI. Pharyngitis. Bronchitis. Sinusitis. Influenza. Overall infection risk in children 30%–55%.
Certolizumab pegol	x		x		Pharyngitis. Sinusitis. Bronchitis. TB. UTI. Overall infection risk 38%. Serious infection risk 3%.
Chlorambucil			x		Interstitial pneumonia. Sterile cystitis.
Cyclophosphamide			x		Reactivation of latent viruses, sepsis (*Salmonella, Staphylococcus, Meningococcus*), URI, pneumonia, opportunistic infections.
Cyclosporine				x	Viral infections, CMV, bacterial pneumonia, fungal infection/sepsis. Reactivation of polyoma viruses. Hemorrhagic cystitis. Squamous cell cancer.
Etanercept	x				URI. Rhinitis. Pharyngitis. Overall infection risk 50%–81% in adults and 62% in children. Viral infections 4%.
Glucocorticoid					
Gold				x	Interstitial pneumonitis. Enterocolitis (rare with mortality rate of 50%).
Golimumab	x				URI. Pharyngitis. Sinusitis. Bronchitis. Overall infection risk 27%.
Hydroxychloroquine		x			Overall infection is low.
Infliximab	x				Overall infection risk 36%. URI. Pharyngitis. Sinusitis. Bronchitis.
Leflunomide				x	URI. Bronchitis. Pharyngitis. Pneumonia. Sinusitis. Skin abscess.
Methotrexate			x		Viral infections, CMV, EBV, reactivation of latent viruses. Reactivation of polyoma viruses.
Mycophenolate				x	Viral infections, CMV, reactivation of polyoma viruses.
NSAID				x	None
Rituximab	x				Pneumonia. Cerebral toxoplasmosis. Reactivation of latent viruses. Progressive multifocal leukoencephalopathy due to JC virus reactivation.
Sirolimus				x	Viral/bacterial pneumonias. Reactivation of polyoma viruses.
Sulfasalazine		x			Overall serious infection risk is low but increased in the setting of neutropenia.
Tacrolimus				X	Viral/bacterial pneumonias, fungal infection/sepsis. Squamous cell cancer.
Thalidomide			x		Pharyngitis. Rhinitis. Sinusitis. Overall infection risk 6%–8%.
Tocilizumab	x				Pharyngitis. Rhinitis. Sinusitis. Conjunctivitis. HSV.
Zileuton				X	URI. Sinusitis. Pharyngitis.

Abbreviations: CMV = cytomegalovirus; EBV = Epstein-Barr virus; HSV = herpes zoster virus; JC = John Cunningham; TB = tuberculosis; URI = upper respiratory infection; UTI = urinary tract infection.

CHAPTER 283

Nontraumatic Disorders of the Hand

Carl A. Germann

HAND INFECTIONS

PATHOPHYSIOLOGY

The most common pathogens causing hand infection are *Staphylococcus aureus, Streptococcus* species, and gram-negative species.[1] Polymicrobial infections are common, especially with inoculation of mouth flora. In most U.S. cities, community-associated methicillin-resistant *Staphylococcus aureus* is the most common pathogen cultured from patients with skin and soft tissue infections in EDs,[2] including 47% to 78% of hand infections.[3-8]

Injection drug users typically present with abscesses or deep space infections secondary to *S. aureus* and gram-negative organisms.[9] These infections are most commonly caused by direct introduction, but hematogenous spread from bacterial endocarditis is a possibility (see chapter 296, "Injection Drug Users").

Hand infections are also discussed in chapter 46, "Puncture Wounds and Bites."

Paronychia and felons are caused by minor trauma like chewing fingernails or exposing minor injuries to saliva. Most of these infections are polymicrobial including anaerobic bacteria.

Infections caused by animal bites reflect the oral flora of the involved species. Bites introduce a broad range of bacteria, including gram-positive, anaerobic, and gram-negative organisms. Common pathogens include streptococci, staphylococci, *Haemophilus*, *Eikenella*, *Fusobacterium*, peptostreptococci, *Prevotella*, and *Porphyromonas* species.[10] Cat and dog bites harbor *Pasteurella multocida*, which typically produces an aggressive, rapidly spreading cellulitis that becomes suppurative. (See chapter 46.)

Patients with diabetes or acquired immunodeficiency syndrome have common bacterial infection or develop atypical infections, including those caused by *Mycobacterium* or *Candida albicans*. Those who are immunocompromised or asplenic are at risk for rapid progression and require prompt source control and antibiotics.

PRINCIPLES OF EVALUATION AND MANAGEMENT

Hand infections are most commonly introduced by an injury to the dermis. The infection initially may remain superficial and broader, termed *cellulitis*, or be localized as seen in a paronychia or felon. Left untreated, infections may spread along anatomic planes or to adjacent compartments in the hand. Deeper injuries may directly seed underlying structures, creating rapidly spreading infections such as those seen with closed fist injuries or cat bites.

Obtain a directed history to delineate a likely cause of the infection. The physical examination should note the anatomic limits of the infection. Look for skin, subcutaneous tissue, fascial space, tendon, joint, or bone involvement. If deep structures of the hand are involved, emergently consult a hand specialist because treatment likely will involve inpatient care and operative drainage.

With the exception of superficial cellulitis, hand infections are managed using basic principles. **First**, incise and drain any collection of pus. Superficial and discrete infections, such as paronychia and felons, can be drained in the ED. Deep infections are better treated in the operating room by a hand surgeon. **Second**, immobilize and elevate the extremity. This will rest the hand, reduce inflammation, avoid secondary injury, and limit extension of the infection. Immobilize by applying a bulky hand dressing and splinting the hand in a position of function: the wrist at 15 to 30 degrees of extension, the metacarpophalangeal joints at 50 to 90 degrees of flexion, and the interphalangeal joints at 5 to 15 degrees of flexion (**Figure 283-1**). Elevate the hand on pillows or suspended using stockinet. **Third**, use broad-spectrum antibiotics initially targeting possible common and serious bacteria, altering only based on response and culture results (**Table 283-1**). **Fourth**, if the patient is not admitted to the hospital, ensure reexamination within 48 hours.

Empiric treatment for these infections is based on local antibiotic resistance patterns, using trimethoprim-sulfamethoxazole, doxycycline or minocycline (outpatient), or vancomycin or linezolid (inpatient) for methicillin-resistant *S. aureus* infections.[11] In some communities, clindamycin is effective,[11] whereas in other communities, fluoroquinolones are effective.[6]

CELLULITIS

Cellulitis is the most superficial of hand infections and is treated with oral antibiotics absent widespread or systemic signs. Diagnosis is made by documenting erythema, warmth, and edema in the affected portion of the hand without any involvement of deeper structures in the hand. Specifically, range of motion of the digits, hand, or wrist should not be painful, and palpation of the deeper structures of the hand should not produce any tenderness.

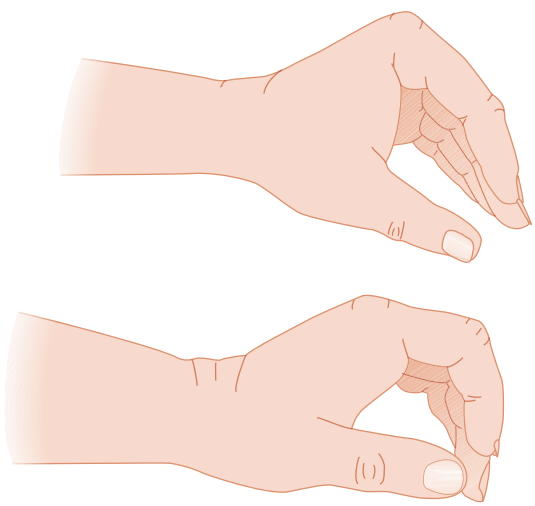

FIGURE 283-1. Positioning the hand during immobilization. Top position is used when splints are applied in fractures or severe sprains. Bottom position is the position of function used when applying a soft bulky dressing.

The most common offending organisms are *S. aureus* **(predominately methicillin-resistant)**[1-8] and *Streptococcus pyogenes*. Initial treatment is in Table 283-1. Methicillin-resistant *S. aureus* infections are more common in patients with diabetes mellitus, immunocompromised patients, intravenous drug users, prisoners, and the homeless.[3,4] Given the increasing rates of methicillin-resistant *S. aureus* and difficulty distinguishing among the types of *S. aureus* cellulitis, routine empiric treatment of methicillin-resistant *S. aureus* should be considered. In addition, choose an agent active against streptococci.[10] Empiric monotherapy with trimethoprim-sulfamethoxazole or other methicillin-resistant *S. aureus*–targeted antibiotic is not recommended given the limited published efficacy data and concerns about effectiveness against streptococci.[10,12] For more extensive involvement, start parenteral antibiotics, admit, and consult a hand surgeon. Consider admission for the immunocompromised, those with clinical toxicity, and those with rapidly spreading infections.

Hand infections following **injuries from handling fish** require different antibiotics and admission to the hospital. Infecting organisms include *Vibrio vulnificus*, *Klebsiella pneumoniae*, *Streptococcus* group A, *S. aureus*, and *Enterobacter* species.[13] Antibiotic coverage with ceftazidime and doxycycline was successful in a large case series of patients.[13]

For all cases of cellulitis, immobilize the hand in a position of function, and make sure the patient keeps the hand elevated as much as possible. Remove digit rings and give tetanus prophylaxis as needed. Finally, for those discharged, arrange reexamination within 48 hours.

FLEXOR TENOSYNOVITIS

Flexor tenosynovitis is a surgical emergency. Failure to accurately diagnose and manage flexor tenosynovitis may result in adhesions, tendon vascular compromise and necrosis, or extension into adjoining deep spaces. This can lead to loss of function of the digit and eventually loss of function of the entire hand. The diagnosis is supported by the presence of the classic clinical signs described by Kanavel[1]; however, all four signs may not be present early in the course of infection (**Table 283-2**).

The infection usually is associated with penetrating trauma of the affected area, although the patient may be unaware of injury. *Staphylococcus* is the most common bacterium isolated; however, infections often harbor anaerobes or are polymicrobial. Suspect disseminated *Neisseria gonorrhoeae* in a patient with a recent history consistent with a sexually transmitted infection (see chapter 149, "Sexually Transmitted Infections").

Initiate treatment with parenteral antibiotics because the infection can spread rapidly through deep fascial spaces (Table 283-1). The use of vancomycin is recommended because of the high prevalence of methicillin-resistant *S. aureus* in most communities. Send any spontaneous exudate for Gram stain and culture with sensitivities.

Immobilize and elevate the hand, and consult the hand surgeon in the ED. If the infection is identified early in its course, nonoperative therapy with parenteral antibiotics, immobilization, elevation, and reevaluation is a common path.

DEEP SPACE INFECTIONS

The hand has compartments where infections may propagate and migrate. Infection of the spaces also occurs by direct inoculation or spread from surrounding structures. These areas include the thenar space, midpalmar space, radial bursa, and ulna bursa (see Figures 268-3 and 268-8 in chapter titled "Injuries to the Hand and Digits").

The volar aspect of the hand is covered by the tough and fixed tissues. The veins and lymphatics course through the softer tissues on the dorsum of the hand. Therefore, the dorsum of the hand often swells whenever there is an inflammatory or infectious process. For this reason, a deep space infection initially may be misdiagnosed as a cellulitis over the dorsum of the hand. An ideal **examination includes palpation of the volar surface of the hand to elicit tenderness, induration, or fluctuance.**

TABLE 283-1 Initial Antibiotic Coverage for Common Hand Infections

Infection	Initial Antimicrobial Agent(s)	Likely Organisms	Comments
Cellulitis	*For mild to moderate cellulitis*: TMP-SMX double strength, 1–2 tablets twice per day PO for 7–10 d.* *Plus/minus* cephalexin, 500 milligrams PO four times per day for 7–10 d, *or* dicloxacillin, 500 milligrams PO four times daily for 7–10 d. *For severe cellulitis:* Vancomycin, 1 gram IV every 12 h.	*Staphylococcus aureus* (MRSA) *Streptococcus pyogenes*	Clindamycin is an option, but increasing MRSA resistance to clindamycin has been reported. Consider vancomycin for injection drug abusers.
Felon/paronychia	TMP-SMX double strength, 1–2 tablets twice per day PO for 7–10 d.* *Plus/minus* cephalexin, 500 milligrams PO four times per day for 7–10 d,* *or* dicloxacillin, 500 milligrams PO four times daily for 7–10 d.* *Consider* addition of clindamycin or amoxicillin-clavulanate to TMP-SMX (rather than cephalexin) if anaerobic bacteria are suspected.	*S. aureus* (MRSA), *S. pyogenes*, anaerobes, polymicrobial	Antibiotics indicated for infections with associated localized cellulitis, otherwise drainage alone may be sufficient, culture recommended by hand surgeons.[4-7]
Flexor tenosynovitis	Ampicillin-sulbactam, 1.5 grams IV every 6 h, *or* cefoxitin, 2 grams IV every 8 h, *or* piperacillin-tazobactam, 3.375 grams IV every 6 h. *Plus:* vancomycin, 1 gram IV every 12 h, if MRSA is prevalent in community.	*S. aureus,* streptococci, anaerobes, gram negatives	Parenteral antibiotics are indicated; consider ceftriaxone for suspected *Neisseria gonorrhoeae*.
Deep space infection	Ampicillin-sulbactam, 1.5 grams IV every 6 h, *or* cefoxitin, 2 grams IV every 8 h, *or* piperacillin-tazobactam, 3.375 grams IV every 6 h. *Plus:* vancomycin, 1 gram IV every 12 h, if MRSA is prevalent in community.	*S. aureus,* streptococci, anaerobes, gram negatives	Inpatient management.
Animal bites (including human)	If no visible signs of infection: amoxicillin/clavulanate, 875/125 milligrams PO twice daily for 5 d. For signs of infection: ampicillin-sulbactam, 1.5 grams IV every 6 h, *or* cefoxitin, 2 grams IV every 8 h, *or* piperacillin-tazobactam, 3.375 grams every 6 h. For penicillin allergy, use clindamycin plus moxifloxacin or TMP-SMX and metronidazole.	*S. aureus,* streptococci, *Eikenella corrodens* (human), *Pasteurella multocida* (cat), anaerobes, and gram-negative bacteria	All animal bite wounds should receive prophylactic oral antibiotics.
Herpetic whitlow	Acyclovir, 400 milligrams PO three times daily for 10 d.	Herpes simplex	No surgical drainage is indicated.

Abbreviations: MRSA = methicillin-resistant *Staphylococcus aureus*; TMP-SMX = trimethoprim-sulfamethoxazole.

*While many sources recommend 7-10 days of therapy, the Infectious Disease Society of America recommends 5 days of therapy if symptoms resolve, continue therapy if symptoms persist.

Range of motion of the digits often produces marked pain for the patients with deep space infection.

Occasionally, infections will arise in the web space. These "collar button" abscesses present with pain and swelling of the web space causing separation of the affected digits. Examination reveals induration or fluctuance in the dorsal and/or volar web space, along with erythema, warmth, and tenderness.

Deep space infections arise from penetrating inoculation, contiguous spread, and rare, hematogenous seeding.[1] *S. aureus* and *Streptococcus* species are the most common organisms isolated.[1]

Give parenteral antibiotics (Table 283-1) and opioid analgesia, and immobilize and elevate the hand. Operative draining is often needed, requiring emergent hand surgeon consultation.

INFECTIONS FROM CLOSED FIST INJURIES

The most common human bite infection of the hand is the result of striking another individual's teeth with a clenched fist (**Figure 283-2**). Often termed "fight bite infections," these injuries usually occur over the dorsal aspects of the third, fourth, and fifth metacarpophalangeal joints. Although these injuries may at first appear innocuous, morbidity can result from late presentation or inadequate initial management

TABLE 283-2 Kanavel's Four Cardinal Signs of Flexor Tenosynovitis

Percussion tenderness	Tenderness over the entire length of the flexor tendon sheath
Uniform swelling	Symmetric finger swelling along the length of the tendon sheath
Intense pain	Intense pain with passive extension
Flexion posture	Flexed posture of the involved digit at rest to minimize pain

Because of the force and the penetrating nature of the human incisor, closed fist infections tend to occur in multiple planes and spread rapidly to adjacent compartments. Skin, extensor tendons, joint space, bone, and surrounding deep spaces often are involved because the inoculum may traverse all these structures.

FIGURE 283-2. Clenched fist injury. The lacerations in this photograph were sustained from teeth during a fight. Note the subtle black ink stamp across the proximal metacarpals possibly revealing a clue about the wound's etiology. [Photo contributor: Lawrence B. Stack, MD. Reproduced with permission from Knoop KJ, Stack LB, Storrow AB, Thurman RJ (eds): *The Atlas of Emergency Medicine*, 3rd ed. New York: McGraw-Hill; 2010, Fig 11-30.]

On examination, document the extent of the infection. Plain radiographs will detect fractures or foreign material including tooth fragments. The most common organisms reflect the natural flora of the mouth and include *Streptococcus* species, *S. aureus, Eikenella corrodens, Fusobacterium, Peptostreptococcus,* and *Candida* species; polymicrobial sources are common. If you suspect any deep space, palmar space, joint, or tendon infection, give broad antibiotics and consult a hand surgeon for open debridement and irrigation in the operating room. Treat all infections with hand elevation and splinting in the position of function. Unless very superficial, use prophylactic antibiotics for wounds caused by a clenched fist (Table 283-1).

PARONYCHIA

Paronychia is an infection of the lateral nail fold or perionychium, occasionally extending to the cuticle or eponychium. It is usually caused by minor trauma such as nail-biting, manicures, or embedded lateral nails ("hangnails"). The infection often starts as a small area of induration that progresses to eponychial swelling, tenderness, erythema, and drainage. Most paronychia contains both aerobic and anaerobic bacteria, with *S. aureus* and *Streptococcus* species the most common aerobic bacteria cultured. Chronic paronychia occurs, particularly in patients who are immunocompromised, and may include usual pathogens or atypical bacteria and fungi such as with *C. albicans*.[14]

Absent fluctuance, treat the paronychia with warm soaks, elevation, and antibiotics (Table 283-1). Suppuration leads to either fluctuance or identifiable pus requiring drainage. Minor infections can be treated with elevation of the perionychium or eponychium with a flat probe to encourage drainage (**Figure 283-3**). If drainage is successful, use warm soaks for days after care. In general, only nonviable tissue can be incised without provoking pain.

More extensive infections that do not communicate directly with the nail fold require digital block and incision directly into the area of greatest fluctuance. Severe infections with pus beneath the nail require removal of a portion of the lateral or proximal nail to ensure adequate drainage. Rarely, a free-floating nail will be encountered on a bed of pus, necessitating removal of the entire nail.

Following incision and drainage, keep the hand elevated and immobilized. Warm soaks may be initiated to keep the wound open and clean. Routine antibiotics are not needed unless cellulitis, immunocompromise, or vascular insufficiency exists; when used, a 7-day course is common or until resolution of the infection.[13] In complicated or drained cases, reassess the wound within 48 hours.

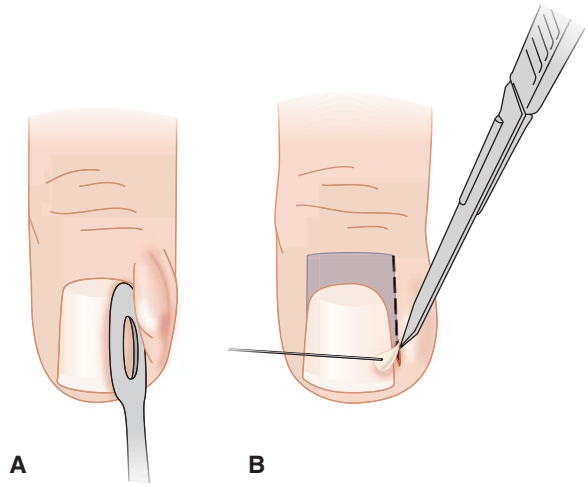

FIGURE 283-3. Paronychia. **A.** The eponychial fold is elevated using a flat probe or a #11 blade to allow the wound to drain. **B.** Alternatively, for more extensive infections, a #11 blade may be used to incise the area of greatest fluctuance directly into the eponychium. The wound may then be gently probed with a small clamp to ensure drainage.

FELON

A felon is a subcutaneous pyogenic infection of the pulp space of the distal finger or thumb. The septa of the finger pad produce multiple individual compartments and confine the infection under pressure. This results in a red, tense, and markedly painful distal pulp space. Infection typically begins with minor trauma to the dermis overlying the finger pad. The infection can start and spread between septae, forming multiple compartmentalized abscesses. Left untreated, the infection may spread to the flexor tendon sheath, causing flexor tenosynovitis, or to the underlying periosteum, resulting in osteomyelitis.

S. aureus is the most common organism (primarily methicillin-resistant *S. aureus*),[3] but *Streptococcus* species, anaerobes, and gram-negative organisms are frequent. If possible, obtain a Gram stain and culture since these infections may be difficult to eradicate, and chronic infections may be caused by atypical organisms. If osteomyelitis occurs, identification of the offending organism guides long-term antibiotic therapy.

Drain the infection if the finger pad is swollen and tense or if there is any palpable fluctuance. A digital block using a long-acting anesthetic is ideal for comfort (see chapter 36, "Local and Regional Anesthesia"). A unilateral longitudinal approach spares the sensate volar pad and achieves adequate drainage (**Figure 283-4A**). Do not incise the distal end of the finger pad because this can cause instability and loss of sensation to the fingertip. Dissect the septa using a small clamp to ensure complete drainage. A small wick encourages continued drainage.

If the felon is pointing toward the volar fat pad, an option is a longitudinal volar approach, depicted in **Figure 283-4B**. Avoid extending the incision to the flexor crease of the distal interphalangeal joint. **More extensive incisions such as the "fishmouth," "hockey stick," and through-and-through incisions are not indicated** as these can alter sensation to the fingertip or compromise pulp vascularity.

Following drainage, irrigate the wound and place a dry, sterile dressing; ask the patient to keep the extremity elevated. Reevaluate the wound within 48 hours, and use warm soaks to keep the wound clean and promote continued drainage.

Most felons have associated cellulitis that should be treated with oral antibiotics (Table 283-1). Refer chronic felons or felons not responding to the above treatments to a hand specialist for more definitive management and long-term follow-up.

HERPETIC WHITLOW

Herpetic whitlow is a viral infection of the distal finger caused by the herpes simplex virus, usually from contact with oral herpetic infections. Herpetic whitlow in children tends to be associated with gingivostomatitis and herpes simplex virus type 1, whereas adults most commonly harbor herpes simplex virus type 2. Healthcare workers, often nurses and respiratory and dental technicians, are at increased risk of this infection given their exposure to orotracheal secretions.

The patient develops a burning, pruritic sensation similar to all herpes simplex infections. On examination, the lesion is erythematous and tender, with vesicular bullae (**Figure 283-5**). The infection occurs 2 to 14 days after contact, usually maturing in 14 days.[1] The finger may be indurated, but is not tense, as is seen in a felon. **Do not mistake herpetic whitlow for a felon because incision and drainage may result in a secondary bacterial infection and prolonged failure to heal.** If there is any question concerning the diagnosis of herpetic whitlow, a vesicle may be unroofed, and the drainage fluid may be used for a Tzanck smear to confirm the diagnosis.

Herpetic whitlow usually resolves without treatment within 3 weeks.[15] Treatment consists of immobilization, elevation, and pain medication. Antiviral agents such as acyclovir or valacyclovir may abort recurrent infections and decrease the course of protracted cases[1] (Table 283-1). The finger should be kept in a clean dressing to prevent autoinoculation or spread of the herpes infection to other individuals.

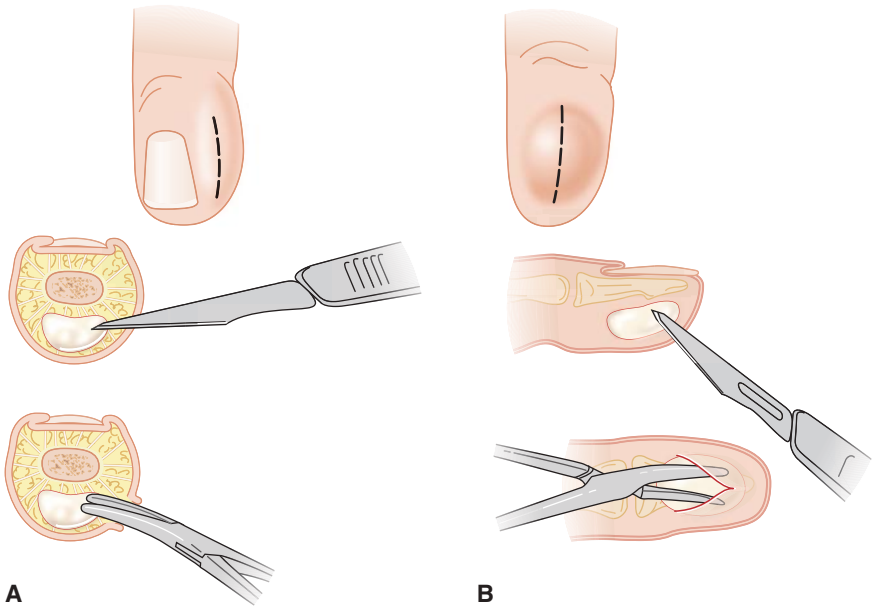

FIGURE 283-4. Felon. **A.** The unilateral longitudinal approach is the most frequently used method for draining felons. This approach minimizes interference with sensate areas of the finger pad. **B.** If the felon is pointing toward the volar surface of the finger pad, the longitudinal volar approach may be used.

NONINFECTIOUS INFLAMMATORY STATES OF THE HAND

Noninfectious inflammatory states of the hand often present as an acute exacerbation of symptoms related to recent overuse. Inflammatory states of joints and tendons are painful and difficult to distinguish from acute septic arthritis or suppurative tenosynovitis. If the diagnosis is in doubt, treat for infection, and consult a hand specialist.

FIGURE 283-5. Herpetic whitlow. Note the cluster of vesicles on an erythematous base located at the distal finger. Tzanck smear is positive. [Photo contributor: Lawrence B. Stack, MD. Reproduced with permission from Knoop K, Stack L, Storrow A, Thurman RJ: *Atlas of Emergency Medicine,* 3rd ed. New York, NY: McGraw-Hill; 2010.]

If an inflammatory state is diagnosed, treat with rest, immobilization, elevation, and anti-inflammatory agents.

TENDINITIS AND TENOSYNOVITIS

Inflammatory tendinitis may involve the flexor or extensor tendons of the hand. Most often, the patient is able to recount a history of repetitive motion directly affecting the inflamed tendon. Palpation of the tendon produces tenderness. Active or passive movement of the tendon produces significant pain.

Treatment is splinting in the position of function with elevation of the affected area and prescribing nonsteroidal anti-inflammatory drugs, with referral for care from the primary care physician or a hand surgeon. Remind patients to return to the ED for worsening pain, increased swelling, or any signs of infection, including fever and erythema.

TRIGGER FINGER

Tenosynovitis can develop in the flexor sheaths of the fingers and thumb as a result of repetitive use. Scarring or inflammation may cause the tendon to become nodular, which results in friction and catching between the tendon and its sheath, usually in the vicinity of the A1 pulley at the volar crease at the base of each digit. The A1 pulley is the proximal portion of the tendon sheath. This is referred to as *stenosing tenosynovitis* or "*trigger finger*." The patient experiences binding of the tendon, usually as the finger extends, relieved by a painful "snap" as the tendon clears the obstruction. Occasionally, this condition may progress to the point that the finger locks, usually in flexion. Conservative treatment includes rest, anti-inflammatory medications, and immobilization (buddy tape or finger split) to reduce inflammation and swelling of the flexor tendon sheath. Early stages of trigger finger have been treated successfully with corticosteroid injection into the tendon sheath,[16] although recurrence occurs in over half of patients.[17] Surgical release of the A1 pulley is curative.

DE QUERVAIN'S STENOSING TENOSYNOVITIS

De Quervain's tenosynovitis is a common condition that occurs in patients who have experienced excessive use of the thumb or wrist. Often, no plausible cause is found. This is a tenosynovitis of the extensor

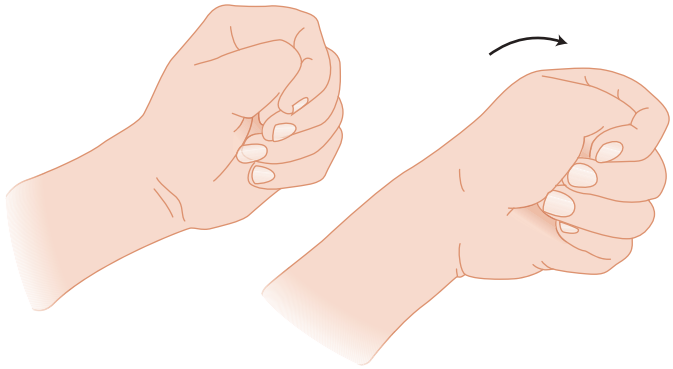

FIGURE 283-6. The Finkelstein test. The thumb is cupped in the closed fist, and ulnar deviation reproduces pain along the extensor pollicis and abductor pollicis.

FIGURE 283-7. Dupuytren's contracture. This chronic problem is seen at the most common site: the ring finger. [Photo contributor: Alan B. Storrow, MD. Reproduced with permission from Knoop KJ, Stack LB, Storrow AB, & Thurman RJ (eds): *The Atlas of Emergency Medicine*, 3rd ed. New York: McGraw-Hill; 2010, Fig. 12-36.]

pollicis brevis and abductor pollicis tendons, where the tendons lie in the groove of the radial styloid.

The patient presents with pain along the radial aspect of the wrist that may radiate to the thumb or extend into the forearm. The diagnosis of De Quervain's tenosynovitis is supported by a history of pain in this location along with a painful range of motion of the thumb and local tenderness over the distal portion of the radial styloid. Further confirmation of the diagnosis may be provided by a positive Finkelstein test (**Figure 283-6**), in which the patient grasps the thumb in the palm of the hand and the examiner ulnar deviates the thumb and hand. This stretches the tendons over the radial styloid and produces sharp pain along the involved tendons.

Immobilize the thumb and wrist with a splint. Instruct the patient to remove the splint briefly each day and perform range-of-motion exercises to prevent joint stiffness. Also, start an anti-inflammatory medication for 10 to 14 days. Recurrence of this condition is common, particularly when related to occupational stress. Persistent cases may benefit from local corticosteroid injection or surgical decompression.[17]

CARPAL TUNNEL SYNDROME

Carpal tunnel syndrome is a peripheral mononeuropathy involving entrapment of the median nerve in the carpal canal or tunnel, which is covered by the tense transverse carpal ligament. Whenever a condition causes swelling in the carpal tunnel, the median nerve is compressed, causing paresthesias extending into the index and long fingers, the radial aspect of the ring finger, and along the palmar aspect of the thumb. Pain may also radiate proximally into the forearm or shoulder. The patient often complains of awakening at night with burning pain and tingling in the hand, or numbness when driving a car or maintaining the wrist in prolonged flexion.

Carpal tunnel syndrome may develop from traumatic, hematologic, rheumatologic, anatomic, and infectious causes. A common scenario is overuse, in which the patient recounts a history of repeated flexion and extension of the wrist. Also, edematous conditions such as pregnancy and congestive heart failure may acutely exacerbate symptoms in patients with a predisposition for carpal tunnel syndrome. The final common pathway consists of a space-occupying lesion that increases intracanal pressures. As the pressure increases, perfusion of the epineurium decreases, causing ischemia and nerve conduction block.

Pain or paresthesia in the median nerve distribution suggests carpal tunnel syndrome and may be confirmed by electrodiagnostic testing. The median nerve sensory distribution is illustrated in chapter 36. Two-point discrimination in this distribution is described as one of the most useful physical examination maneuvers for diagnosing carpal tunnel syndrome.[18] In addition, Tinel's sign supports the diagnosis and involves tapping the volar aspect of the wrist over the median nerve. A positive sign produces paresthesias that extend into the index and long finger. Phalen's sign is more sensitive and specific, and involves flexing the wrist maximally and holding it in this position for at least 1 minute. A positive test occurs when the patient complains of tingling and numbness along the median nerve distribution. Both tests are subject to false-positive and false-negative results.

The presence of median nerve motor deficit requires emergency hand consultation. Otherwise, initial treatment is a volar splint to maintain the wrist in neutral position coupled with anti-inflammatory medications for 10 to 14 days. Refer those with persistent symptoms to a hand surgeon for surgical decompression. Most patients have complete resolution of their symptoms following surgical decompression, with around 5% requiring revision.[19]

DUPUYTREN'S CONTRACTURE

Dupuytren's contracture is a relatively common yet poorly understood disorder characterized by fibroplastic changes of the subcutaneous tissues of the palm and volar aspect of the fingers. The fourth and fifth fingers are affected earliest. The condition is found most commonly in men of northern European descent. Dupuytren's contracture is seen in those with tobacco use, alcoholism, diabetes mellitus, and repetitive handling or overuse.[20]

This progressive fibrosis eventually may lead to tethering and joint contracture (**Figure 283-7**). Firm longitudinal thickening and nodularity of the superficial tissues over the distal tendon sheath of the palm are usually readily appreciated as the scarring process advances. The diagnosis is made by identifying a nodule in the palm, usually at the distal palmar crease of the ring or small finger, which is held in the classic flexion contracture. Refer to a hand specialist for excision.[21]

GANGLION CYSTS

A ganglion or synovial cyst is a cystic collection of synovial fluid within a joint or tendon sheath (**Figure 283-8**). It is common, often following an injury. Ganglion cysts arise from a herniation of synovial tissue from a joint capsule or tendon sheath. The patient presents with a tender cystic swelling over or near a tendon sheath. Common locations are the dorsal and volar wrist, flexor surface of the metacarpophalangeal joint, or the base of the nail. Involvement of the thumb may appear as generalized thumb pain, pain with movement, and edema. Treatment is pain control and anti-inflammatory medications. About one third of cysts resolve spontaneously, with referral to a hand surgeon for those with persistent or recurrent pain or cosmetic deformity. Treatment options include cyst aspiration, corticosteroid injection, or surgical excision. Surgery is generally effective; however, ganglion cysts may recur in up to 39% of patients.[22]

CHAPTER 284

Joints and Bursae

John H. Burton
Timothy J. Fortuna

INTRODUCTION

Many mechanisms provoke acute joint symptoms: degradation and degeneration of articular cartilage (osteoarthritis), deposition of immune complexes or immune system–related phenomena (rheumatoid arthritis, rheumatic fever and possibly, a component of gonococcal arthritis), crystal-induced inflammation (gout and pseudogout), seronegative spondyloarthropathies (ankylosing spondylitis [see chapter 282, "Systemic Rheumatic Diseases"] and reactive arthritis [postinfectious with HLA-B27 susceptibility]), and bacterial invasion (gonococcal and nongonococcal septic arthritis, including Lyme arthritis) or viral invasion (viral arthritis). These processes impact joint capsules and surfaces, resulting in a cascade of reactive and inflammatory events. *Septic arthritis* is invasion of a joint by an infectious agent with organism proliferation and associated inflammation; bacterial arthritis is a subset of septic arthritis. Under ideal conditions, the infectious agent is recoverable from the joint fluid in septic arthritis, but in clinical practice, this is often not the case. This chapter reviews the common causes and treatments of acute nontraumatic joint pain. Joint injuries are discussed in section 22, "Injuries to Bones and Joints," and disorders due to repetitive use syndromes are discussed in section 23, "Musculoskeletal Disorders," by anatomic site.

CLINICAL APPROACH TO ACUTE JOINT PAIN

Septic arthritis is the most important consideration in the evaluation of a swollen, warm, and painful joint. Urgent treatment may prevent both joint destruction and mortality (11% with treatment).[1,2] The diagnosis of septic arthritis is clinical and is supported by diagnostic tests.[1,2] **No single diagnostic parameter is sufficiently sensitive to screen patients for septic arthritis including synovial WBC counts.**[3]

TABLE 284-1 Risk Factors for Nongonococcal and Gonococcal Septic Arthritis

Nongonococcal	Gonococcal
Injection drug use*	HIV infection*
Diabetes mellitus*	Injection drug use*
Rheumatoid arthritis*	Pregnancy
Prosthetic joint, knee,* or hip*	Menses
Immunosuppression, HIV*	Systemic lupus erythematosus
Age: >80 y old*	Complement deficiency
Skin ulceration and/or infection*	
Hemophilia	
Hypogammaglobulinemia	
Malignancy	
Hemodialysis	
Liver disease	
Alcoholism	
Steroid therapy	

Abbreviation: HIV = human immunodeficiency virus.
*Risk factors supported by epidemiologic study.

CLINICAL FEATURES AND RISK FACTORS

Risk factors (**Table 284-1**),[3,4] the number of joints involved (**Table 284-2**), and the migratory pattern (**Table 284-3**), if one exists, aid in the differential diagnosis. Approximately 85% of patients with nongonococcal septic arthritis present with a single joint infected; *Staphylococcus aureus* and *Streptococcus pneumoniae* are more likely to infect two or more joints simultaniously.[5-8] Septic arthritis involving more than one joint can occur in rheumatoid arthritis (50%), immunocompromise, gout, diabetes, and/or renal disease; the morality rate is significantly higher in patients with polyarticular septic arthritis (11% vs 30%).[5,7] Recent joint surgery and cellulitis overlying a prosthetic hip or knee are the only

TABLE 284-2 Differential Diagnosis of Arthritis by Number of Affected Joints

Number of Joints	Differential Considerations for Typical Presentations
1 = Monoarthritis	85% of nongonococcal septic arthritis*
	Crystal-induced (gout, pseudogout)
	Gonococcal septic arthritis
	Trauma-induced arthritis
	Osteoarthritis (acute)
	Lyme disease
	Avascular necrosis
	Tumor
2–3 = Oligoarthritis†	15% of nongonococcal septic arthritis, more common with *Staphylococcus aureus* and *Streptococcus pneumoniae*
	Lyme disease
	Reactive arthritis (Reiter's syndrome)
	Gonococcal arthritis
	Rheumatic fever
>3 = Polyarthritis†	Rheumatoid arthritis
	Systemic lupus erythematosus
	Viral arthritis
	Osteoarthritis (chronic)
	Serum sickness
	Serum sickness–like reactions

*Involvement of more than one joint does not rule out septic arthritis.
†The distinction between oligoarthritis and polyarthritis varies in the literature with a cut point of either three or four joints.

TABLE 284-3 Common Joint Disorders with a Migratory Distribution Pattern

Gonococcal arthritis
Acute rheumatic fever
Lyme disease
Viral arthritis
Systemic lupus erythematosus

findings on history or physical examination that significantly alter (both increase) the probability of nongonococcal septic arthritis.[3]

SYNOVIAL FLUID ANALYSIS

When septic arthritis is suspected, aspirate joint fluid, and obtain analysis and culture of the aspirate to direct treatment.[1,2] Table 284-4 provides diagnostic guidance based on synovial fluid results in the context of different patient characteristics.[1-12]

Analyze joint fluid for Gram stain, leukocyte count with differential, and a wet preparation for crystals.[4,6] Glucose, protein, and lactate dehydrogenase levels do not direct treatment decisions.[4] Synovial lactate levels may prove an aide in identifying septic arthritis if future studies confirm preliminary reports.[3] Culture for gonococci and anaerobes, in addition to typical gram-positive and -negative organisms.[1,2,4]

SERUM LABORATORY STUDIES

Serum erythrocyte sedimentation rate and C-reactive protein levels are commonly elevated in several acute inflammatory and reactive arthritides (gonococcal and nongonococcal septic arthritis, crystal-induced, spondyloarthropathies, and rheumatoid and Lyme arthritis) but are not helpful for establishing a specific diagnosis in adults. However, erythrocyte

TABLE 284-4 Septic Arthritis: Joint Aspiration Results in Different Patient Groups*

Key Factor	Patient Status	Joint Aspiration	Diagnostic Considerations/Management
Positive Gram stain	Acute joint pain and swelling	Gram stain positive for bacteria	Initiate empiric IV antibiotics, admit to the hospital, monitor culture and patient course (positive Gram stain is found in <50% of patients with septic arthritis).
Classic synovial WBC count	Acute joint pain and swelling	>50,000 WBC/mm^3 or >90% PMNs	Synovial fluid with >50,000 WBC/mm^3 is 56% sensitive and 90% specific for septic arthritis. Initiate empiric IV antibiotics and hospital admission.
Increased sensitivity of lower synovial WBC counts	Acute joint pain and swelling in a patient with risk factors for septic arthritis or systemic signs of infection	>25,000 WBC/mm^3 or >90% PMNs	Synovial fluid with >25,000 WBC/mm^3 is 73% sensitive and 77% specific for septic arthritis. Consider empiric IV antibiotics and admission to the hospital for monitoring of patient course and cultures.
Acute gout with coexisting septic arthritis	Acute joint pain and swelling; patient with acute gout or history of gout with systemic signs of infection	Crystals, >2000 WBC/mm^3, or >90% PMNs	Crystal-induced arthritis may coexist with septic arthritis; cell counts are <6000 WBC/mm^3 in 10% of infected joints; more than one joint is involved in 10%–45%. Look for infected tophi. Consider empiric IV antibiotics and admission to the hospital for monitoring of patient course and cultures.
Prosthetic joint	Acute pain and swelling in patient with prosthetic joint	>10,000 WBC/mm^3, >90% PMNs	Consult operating orthopedic surgeon before aspiration if possible. AAOS definition for acute periprosthetic infection is 3 of the following: (1) CRP elevated above 100 milligrams/L *and* ESR elevated above local norm, (2) synovial WBC >10,000/mm^3, (3) synovial PMNs >90%, (4) positive culture, and (5) positive histologic analysis of periprosthetic tissue.
Immunocompromise	Joint swelling in an immunocompromised patient or systemic signs of infection in a patient with immunocompromise	>200 WBC/mm^3, >25% PMNs	Immunocompromised patients sustain septic arthritis with diminished immune response; cell counts and percent PMNs are frequently lower than in immunocompetent patients with similar infections. Consider empiric IV antibiotics and admission to the hospital for monitoring of patient course and cultures.
Gonococcal arthritis	Monoarticular or polyarticular joint pain in a patient with history of unprotected sex (primarily in young patients)	10,000–80,000 WBC/mm^3	Positive culture in <50% of infected joints; collect urogenital cultures plus pharynx and rectum cultures as determined by history. Consider empiric IV antibiotics and admission to the hospital for monitoring of patient course and cultures.
Rheumatoid arthritis with coexisting septic arthritis	Joint pain and/or swelling in a patient with rheumatoid arthritis	2000–120,000 WBC/mm^3	Severe pain and limited range of motion may be absent in patients on immunosuppression. Look for infected rheumatoid nodules or ulcerated foot calluses; source in 76% of cases. Consider empiric IV antibiotics and admission to the hospital for monitoring of patient course and cultures.
Lyme disease	Acute joint pain in a patient living in a Lyme disease–endemic area or with a history of rash or tick bite	200–300,000 WBC/mm^3	Consider empiric antibiotics and close follow-up to monitor culture and patient course; admit if clinical picture is indistinguishable from septic arthritis. Arthralgia appears months after initial symptoms. Joint effusion (moderate to large) may be out of proportion to the patient's pain (mild to moderate). Knee is the most common affected joint.
Post trauma	Joint trauma several days prior, initial swelling, now increasing pain	0–2000 WBC/mm^3, <25% PMNs, 0–500 RBC/mm^3	Posttraumatic effusions may become infected in patients with skin infections or bacteremia. Aspiration of the joint reduces pain for approximately 1 week, but has no effect on long-term disability.
Dry tap	Patient with acute joint pain and suspected swelling, with or without other symptoms or signs to suggest septic arthritis	"Dry tap"	Major causes of dry tap are mistaken physical diagnosis of effusion; blockage of the needle by plica, fat, or debris; or synovial fluid with high viscosity or true lipoma arborescens (benign replacement of subsynovial tissue by fat cells). Use US to determine true effusion and direct needle to largest collection of fluid.
Normal synovial cell counts	Patient with sufficient joint pain and swelling to warrant arthrocentesis, no comorbidities, absent signs and symptoms of sepsis	<200 WBC/mm^3, <25% PMNs	Normal WBC cell counts and differential percentages make the diagnosis of septic arthritis unlikely in a patient without comorbidities or objective signs of infection. A mechanism should be in place for timely follow-up of culture results if they turn positive.

Abbreviations: AAOS = American Academy of Orthopedic Surgeons; CRP = C-reactive protein; ESR = erythrocyte sedimentation rate; PMNs = polymorphonuclear leukocytes.

*All patients who received joint aspiration for suspected septic arthritis should have cultures of synovial fluid, blood, and any nonjoint source clinically suspected of infection (e.g., skin, urine).

sedimentation rate and C-reactive protein are recommended as an aid to monitor response to therapy by the British Society of Rheumatology Guidelines,[2] and the American Academy of Orthopedic Surgeons guidelines include erythrocyte sedimentation rate and C-reactive protein as part of their minor criteria for the diagnosis of acute periprosthetic joint infection (Table 284-4).[11] The American Academy of Orthopedic Surgeons also recommends that an elevation of either erythrocyte sedimentation rate or C-reactive protein be used as criterion to aspirate a painful prosthetic joint with increased warmth.[11] The sensitivity of the serum WBC count in adults for the diagnosis of nongonococcal bacterial septic arthritis is approximately 60%.[3] Blood cultures should be obtained before antibiotic therapy for presumptive or possible septic arthritis. However, the sensitivity for identifying the causative organism in adults and children with nongonococcal bacterial septic arthritis is 23% to 36%.[3] Elevated procalcitonin levels provide 90% specificity to help rule in the diagnosis of septic arthritis but are only 67% sensitive in screening for the diagnosis.[3,13]

Laboratory studies can aid in the diagnosis at follow-up. Possible studies include Lyme titer, rheumatoid factor, antinuclear antibodies, antineutrophil cytoplasmic antibodies, HLA-B27 tissue typing, lupus anticoagulant, and repeat synovial fluid analysis.

IMAGING

Bedside US is useful to identify joint effusion and aids successful joint aspiration.[14,15] Obtain radiographs of an inflamed joint if trauma, tumor, avascular necrosis, and osteomyelitis are diagnostic considerations. Radioisotope scanning is not usually required for ED diagnosis but can be useful to detect osteomyelitis, occult fracture, avascular necrosis, or tumor. MRI is not recommended for routing assessment of septic arthritis but may be helpful for difficult diagnostic cases. MRI is more sensitive to identify joint effusion than specific for the diagnosis of septic arthritis.[16]

ARTHROCENTESIS

Prepare the site to avoid bacterial contamination. The skin overlying the affected joint should be free of cellulitis or impetigo to avoid contamination of the joint space during arthrocentesis. Orthopedics should be consulted before aspiration of a prosthetic joint for direction in diagnostic workup and interpretation of results.[11] Other relative contraindications to joint aspiration are coagulopathy, including hemarthrosis in hemophiliac patients before factor replacement.[17]

Cleanse a large area overlying and adjacent to the affected joint with povidone-iodine solution. After air drying, clean the skin with an alcohol wipe to remove the povidone-iodine solution from the skin surface. Removal of the overlying povidone-iodine prevents the introduction of the povidone-iodine antiseptic into the joint, which can result in chemical irritation or sterilization of the aspiration sample. Next place sterile drapes over the site and maintain sterile technique throughout the procedure.

Anesthetize the skin and soft tissues overlying the joint with a 25- to 30-gauge needle. Avoid intra-articular injection of anesthetic because the anesthetic can inhibit bacterial growth and may result in a spuriously negative culture in an early septic joint.

Use a large-bore needle (18 or 19 gauge) for aspiration of fluid from large joints. Use smaller-bore needles for small joints (no smaller than 22 gauge). Choose a syringe large enough to accommodate the anticipated volume of fluid within the joint space. Remove as much synovial fluid as possible to obtain a good diagnostic sample and to relieve pain from joint capsule distention. Promptly send aspirated fluid to the laboratory for culture, Gram stain, leukocyte count with differential, and crystal analysis. US should be used in the event of a dry tap (see Table 284-4).

SHOULDER JOINT ASPIRATION

US can facilitate shoulder aspiration. The anterior or posterior approach can be used.

Anterior Approach Have the patient sit upright, facing you, and externally rotate the humerus. Insert the needle just lateral to the coracoid process, between the coracoid process and the humeral head (**Figure 284-1A**). Direct the needle posteriorly. If it is difficult to locate

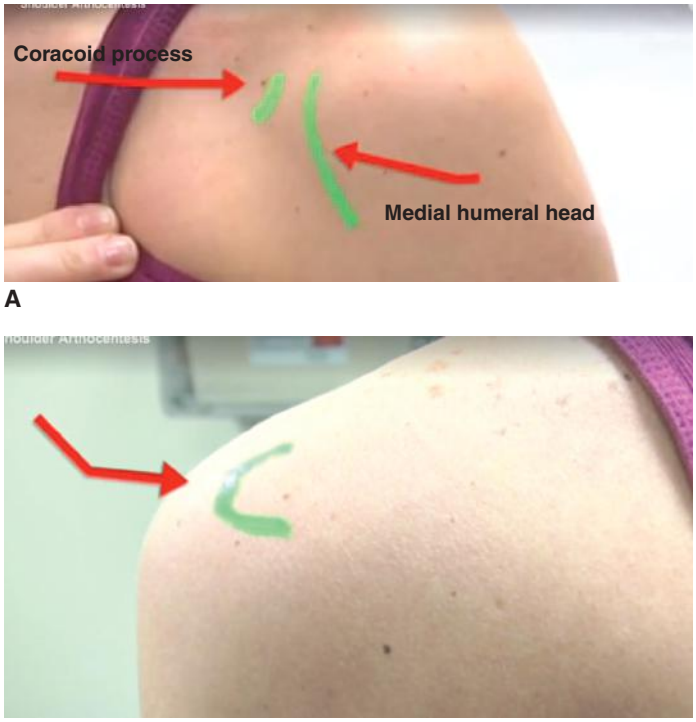

FIGURE 284-1. Shoulder arthrocentesis. **A.** anterior approach. **B.** Shoulder Arthrocentesis posterior approach.

the coracoid process, the posterior approach to the glenohumeral joint may be easier.

Posterior Approach Sit the patient upright with the back facing you. Palpate the spine of the scapula to its lateral limit: the acromion. Identify the posterolateral corner of the acromion. Use a 1.5-inch needle. The point for needle insertion is 1 cm inferior and 1 cm medial to the posterolateral corner of the acromion (**Figures 284-1B and 284-2**). Direct the needle anterior and medial toward the presumed position of the coracoid process. The glenohumeral joint is located at a depth of approximately 1.0 to 1.5 inches.

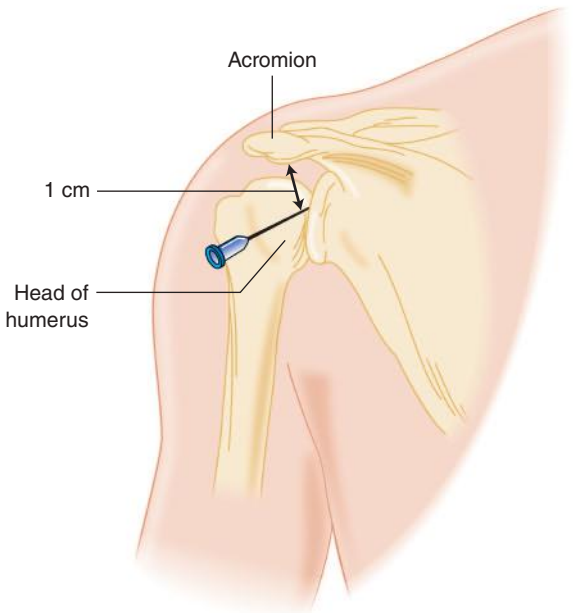

FIGURE 284-2. Shoulder arthrocentesis, posterior approach.

FIGURE 284-3. Arthrocentesis of the elbow.

ELBOW JOINT ASPIRATION

Use a lateral or posterior approach to the elbow joint. Do not use a medial approach to avoid neurovascular structures. Place the elbow in 90-degree flexion, resting on a table, with the hand prone to widen the joint space. Locate the radial head, lateral epicondyle of the distal humerus, and the lateral aspect of the olecranon tip. These three landmarks form the anconeus triangle. The center of this triangle is the site for needle entry into the skin. Using the tip of the gloved index finger of the nondominant hand, palpate a sulcus just proximal to the radial head. The sulcus is the needle entry point. Direct the needle medial and perpendicular to the radius toward the distal end of the antecubital fossa (**Figure 284-3**).

WRIST JOINT ASPIRATION

Landmarks for wrist arthrocentesis are palpable with the wrist in a neutral position. The landmarks are the radial tubercle of the distal radius, the anatomic snuffbox, the extensor pollicis longus tendon, and the common extensor tendon of the index finger (**Figure 284-4**). Insert the needle perpendicular to the skin, ulnar to the radial tubercle and the anatomic snuffbox, between the extensor pollicis longus (just ulnar to the extensor pollicis longus) and the common extensor tendons.

HIP JOINT ASPIRATION

Hip arthrocentesis may be performed by an anterior or medial approach. If local practice dictates open surgical assessment and drainage, an orthopedic consultant will often perform this procedure. US-guided arthrocentesis by an emergency physician or radiologist is also acceptable if local practices and training are in place to support this approach (**Figure 284-5**). Controversy exists regarding the utility of US or MRI as a screening test before open surgical evaluation.[15,18] Immediate consultation with an orthopedic surgeon is therefore desirable when a diagnosis of septic hip arthritis is considered.

KNEE JOINT ASPIRATION

The knee joint can be entered either medial or lateral to the patella. With the patient supine, fully extend the knee and make sure the quadriceps muscle is relaxed. Identify the midpoint of the patella. The insertion point of the needle is located approximately 1 cm inferior to the patellar edge, either lateral (**Figure 284-6**) or medial (**Figure 284-7**) to the middle of the patella. Direct the needle posterior to the patella and horizontally toward the joint space. Compression or "milking" applied to both sides (proximal and distal) of the joint space by an assistant who is using sterile technique may facilitate aspiration of small amounts of fluid. In patients with obese or large knees, it may be necessary to use a needle longer than 1.5 inches to enter the joint space. **Figure 284-8** demonstrates the use of US to visualize a knee joint effusion.

ANKLE JOINT ASPIRATION

Ankle arthrocentesis may be performed at either the tibiotalar joint (medial approach) (**Figure 284-9**) or the subtalar joint (lateral approach) (**Figure 284-10**). The medial approach is generally preferred.

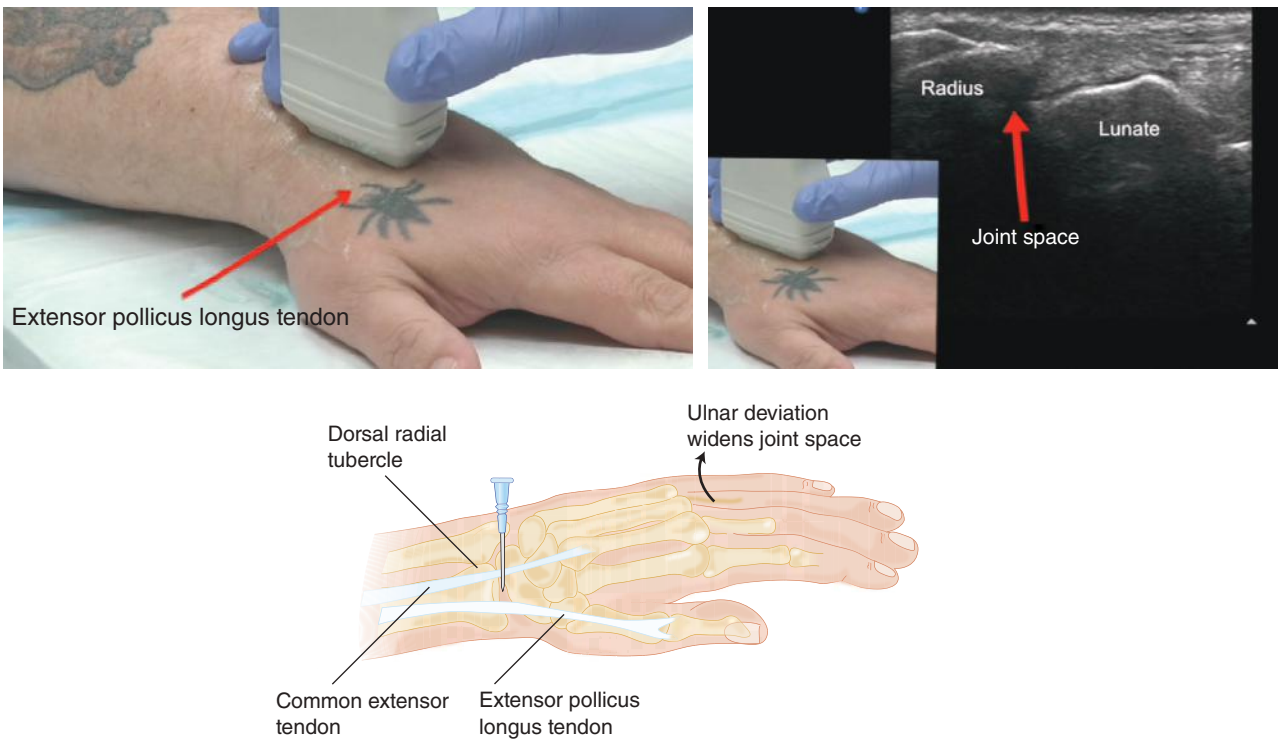

FIGURE 284-4. Arthrocentesis of the wrist. [Images used with permission of Sandra Werner.]

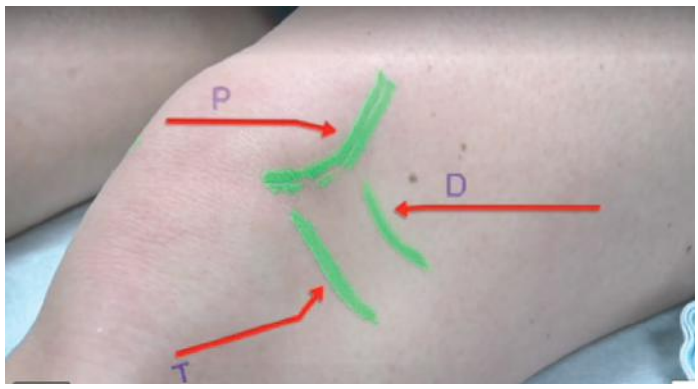
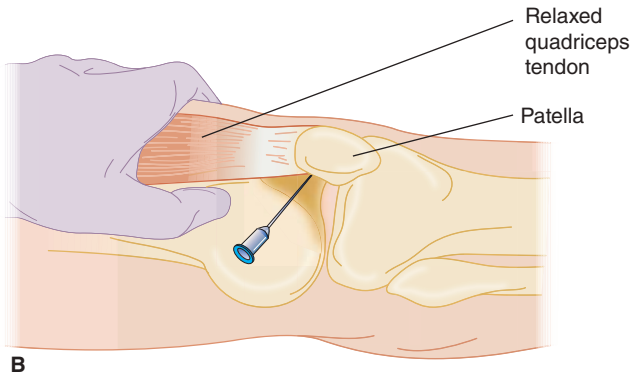
FIGURE 284-5. Demonstration of US-guided hip arthrocentesis with transducer orientation marker angled superomedially and drape and probe cover omitted for purpose of demonstration. [Reproduced with permission from Freeman K, Dewitz A, Baker WE: Ultrasound-guided hip arthrocentesis in the ED. *Am J Emerg Med 25: 80, 2007*. Copyright Elsevier.]

Medial (Tibiotalar) Approach Have the patient supine with the foot initially perpendicular to the leg. This position facilitates the location of a sulcus lateral to the medial malleolus and medial to the tibialis anterior and extensor hallucis longus tendons (Figures 284-9 and **284-11A and B**). Then plantar flex the foot with the needle entering the skin overlying the sulcus. Angle the needle slightly cephalad as it passes between the medial malleolus and the tibialis anterior tendon.



A



B

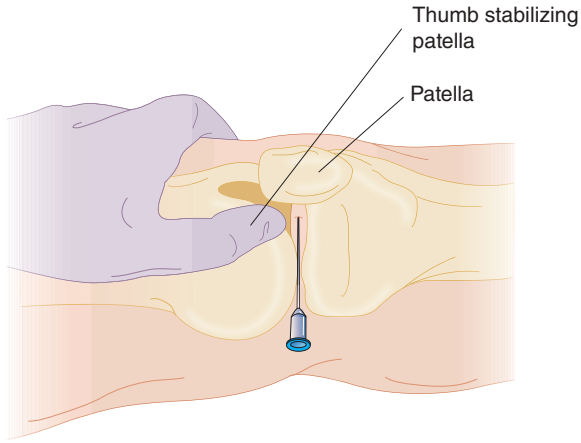

FIGURE 284-7. Arthrocentesis of the knee, medial approach.

Lateral (Subtalar) Approach Keep the patient's foot perpendicular to the leg. Enter the subtalar joint just below the tip of the lateral malleolus (Figure 284-10). Direct the needle medially toward the joint space.

SEPTIC ARTHRITIS

An acute hot, swollen, and tender joint (or joints) with restriction of movement is bacterial nongonococcal septic arthritis until proven otherwise.[1] Clinical features, risk factors, and treatment differ for bacterial, nongonococcal septic arthritis and gonococcal arthritis (Tables 284-1 through 284-4). For management of septic arthritis in infants and children, see chapter 140, "Musculoskeletal Disorders in Children." In young adults, sexual activity increases the prevalence of gonococcal arthritis and reactive arthritis (formerly known as Reiter's syndrome) associated with chlamydial urethritis.

BACTERIAL NONGONOCOCCAL SEPTIC ARTHRITIS

Although no clinical pattern is diagnostic of bacterial nongonococcal septic arthritis, certain general observations are helpful. Joint pain (85%), a history of joint swelling (78%), and fever (57%) are the only findings that occur in >50% of patients with bacterial nongonococcal septic arthritis.[4] Sweats (27%) and rigors (19%) are less common findings.[4]

The involved joint can become exquisitely painful over a few hours. The patient may splint the affected joint to relieve pain with movement. Joint effusion may be small or large. Resistance to passive and active movement and limitation of full joint movement are notable findings but are common with gout without infection and may be absent in immunosuppressed patients. Although joint aspiration and analysis are essential to the diagnosis, the sensitivity of any one finding for the diagnosis of nongonococcal septic arthritis is only moderate. For example, the sensitivity of joint fluid WBC to make the diagnosis of nongonococcal septic arthritis using the commonly quoted cutoff of 50,000 cells/mm^3 is only 56%.[3] The sensitivity of erythrocyte sedimentation rate for nongonococcal septic arthritis using a cutoff of 30 mm/h ranges between 76% and 96%,[3] but this test is nonspecific.

If a septic arthritis diagnosis cannot be reliably excluded after clinical evaluation, including arthrocentesis, admit the patient for parenteral antibiotics and pain control until synovial fluid culture results are available. Antibiotic coverage is directed at staphylococcal and streptococcal species including methicillin-resistant *S. aureus*. Vancomycin plus a third-generation cephalosporin is the preferred therapy (**Table 284-5**).[1,2,19]

Consult orthopedic surgery for possible joint irrigation in the operating room if the joint aspiration is positive for infection. Repeat closed-needle aspiration, arthroscopic irrigation, or less commonly, open surgical drainage may be required, depending on a number of factors, including consultant preference, patient age, affected joint,

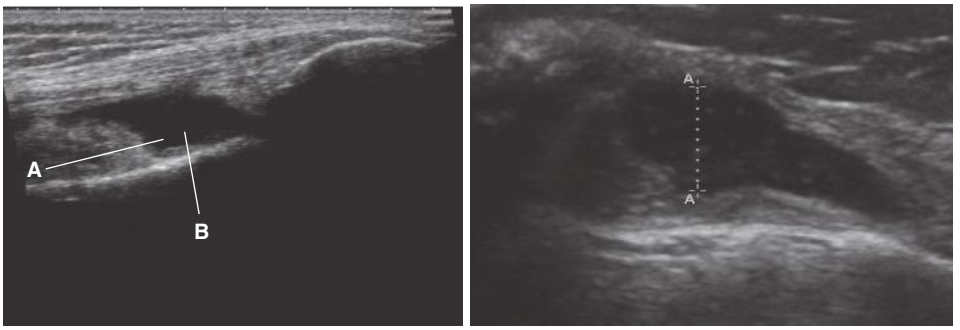

FIGURE 284-8. Bedside US of the knee in long axis (**A**) and short axis (**B**) demonstrating joint effusion.

comorbid illnesses, and likelihood of septic source.[1,20] Consultation with infectious disease may be required to determine ideal antibiotic choice in select patients.[2]

GONOCOCCAL SEPTIC ARTHRITIS

Gonococcal arthritis is the most common cause of septic arthritis in young sexually active adults.[21,22] Joint infection will typically have a prodromal phase in which migratory arthritis and tenosynovitis predominate before pain and swelling settle on one or more septic joints. Vesiculopustular lesions, especially on the fingers, may be found (see Figure 149-33 in chapter titled "Sexually Transmitted Infections").

Synovial fluid cultures are often negative in gonococcal arthritis, with only 25% to 50% of cases yielding positive identification of the organism.[4] Cultures of the posterior pharynx, urethra, cervix, and rectum (as directed by history of sexual contact) before antibiotic treatment

TABLE 284-5 Commonly Encountered Organisms in Septic Arthritis in Adolescents and Adults*

Patient/Condition	Expected Organisms	Antibiotic Considerations
Young healthy adults, or patients with risk factors for *Neisseria gonorrhoeae*	*Staphylococcus, N. gonorrhoeae, Streptococcus*, gram-negative bacteria	Vancomycin, 15 milligrams/kg IV load, if Gram stain reveals gram-positive organisms in clusters. Ceftriaxone, 1 gram IV, or imipenem, 500 milligrams IV, should be used/added if either gram-negative organisms are present or no organisms are present on Gram stain and *N. gonorrhoeae* is suspected (also culture urethra, cervix, or anal canal as indicated).
Adults with comorbid disease (rheumatoid arthritis, human immunodeficiency virus, cancer) or injection drug users	*Staphylococcus*, gram-negative bacilli	Vancomycin, 15 milligrams/kg IV load, plus cefepime, 2 grams IV, or imipenem, 500 milligrams IV. Meropenem 1 gram IV may be used as an alternative agent.
Sickle cell patients	*Salmonella* (increasingly *Staphylococcus*)	Vancomycin, 15 milligrams/kg IV load, plus ciprofloxacin, 400 milligrams IV. Imipenem, 500 milligrams IV, may be used as an alternative agent.

*Recommendations differ from the 2006 British Society of Rheumatology treatment guidelines due to the rising incidence of methicillin-resistant *Staphylococcus aureus* septic arthritis.

increase the culture yield.[21,23] Cases of gonococcal arthritis suspected clinically should be treated despite negative initial results while waiting for all culture results to return.

Treatment for gonococcal arthritis follows the same general principles as treatment for nongonococcal septic arthritis (see Table 284-5 for details). However, gonococcal arthritis does not yield joint destruction with the frequency of nongonococcal arthritis, and therefore, surgical intervention is rarely needed.[23,24] Daily joint aspiration is routinely done until there is clinical improvement.[21,23,24] *Neisseria gonorrhoeae*, in the setting of arthritis, remains sensitive to third-generation cephalosporin therapy (see chapter 149).

CRYSTAL-INDUCED SYNOVITIS (GOUT AND PSEUDOGOUT)

Crystal-induced synovitis is primarily an illness of middle-aged and elderly adults. Uric acid (gout) and calcium pyrophosphate (calcium pyrophosphate deposition, or pseudogout) are the two most common crystalline agents, with gout representing the most common form of inflammatory joint disease in men >40 years old.[25,26] The classic description of gout is monoarthritis involving the great toe or knee joint in a man >40 years old.[25] Gout is less common in women during their reproductive years but may occur in association with periods of increased insulin resistance such as gestational diabetes.[27]

CLINICAL FEATURES

Joint pain develops over hours. An acute gout or pseudogout attack often follows trauma, surgery, a significant illness, or change in medication. Gout results from precipitation of urine acid crystals in the joint, and pseudogout results from calcium pyrophosphate crystals. Crystalline involvement of joints has a predilection for the foot and knee. Although the first metatarsophalangeal joint is a classic focus for acute gout, no joint is the exclusive site of involvement for either crystal.

DIAGNOSIS

The diagnosis of a crystal-induced synovitis is by joint aspiration and identification of crystals through a polarizing microscope. Uric acid crystals (gout) appear needle shaped and blue when the source of light is perpendicular to the crystal (negative birefringence). Calcium pyrophosphate (pseudogout) is yellow in this alignment (positive birefringence), with a rhomboid shape. Crystals are located within phagocytes from aspirates of synovial fluid, or within inflamed tissues adjacent to the affected joint.

Serum uric acid levels are not generally useful for diagnosis, as up to 30% of patients will have normal uric acid levels during an acute gout attack.[25] There is no elevation of serum uric acid, calcium, or phosphate in pseudogout. The joint aspirate WBC can be elevated with gout and pseudogout.[25,26] However, the presence of crystals, the absence of bacteria on Gram stain or culture, and frequently, the dramatic response to nonsteroidal anti-inflammatory drugs (NSAIDs) clarify the diagnosis. When the diagnosis of a septic joint cannot be excluded, hospital admission until cultures and/or clinical response clarify the diagnosis is the safest course of action.[1,2]

TREATMENT

When the diagnosis of gout or pseudogout is established, treatment is an NSAID for 5 to 7 days. First-line treatment is indomethacin (or naproxen).[25,26] **Do not give NSAIDs to patients with renal insufficiency.** For patients with normal renal function, the initial dose of indomethacin is 50 milligrams. Therapy is continued three times a day for 3 to 7 days as needed. Substantial pain relief typically occurs within 2 hours of NSAID administration.[25,26] **Colchicine** is an alternative agent to treat acute gout and pseudogout in patients with normal renal and hepatic function. Oral colchicine is typically administered at a dose of 0.6 milligram/h until intolerable side effects (vomiting or diarrhea) or efficacy ensues. IV administration of colchicine can be associated with serious side effects, with risks such as bone marrow suppression, neuropathy, myopathy, and death.[25] For patients with renal insufficiency, narcotic analgesics are needed for pain relief because NSAIDs and colchicine are generally avoided. **Prednisone** is a first-line treatment option provided the patient is not diabetic.[25,26]

Discharge is typical unless pain is not controlled or if septic arthritis is a consideration. Once acute symptoms have resolved, long-term control may be achieved with reduction or elimination of gout-inducing agents (diuretics, aspirin, or cyclosporine) and treatment with prophylactic drugs, such as allopurinol or probenecid. There is no effective prophylaxis for pseudogout.

VIRAL ARTHRITIS

The most common causes of viral arthritis in the United States are parvovirus B19, rubella, and hepatitis B (**Table 284-6**).

PARVOVIRUS ARTHRITIS

Parvovirus B19 causes **erythema infectiosum** in children. In adults, this rash occurs in less than half of patients. Joint involvement is more common in adults, with morning stiffness, swelling, erythema, and a presentation similar to acute presentations of rheumatoid arthritis.[28,29]

HEPATITIS VIRUS ARTHRITIS

The most commonly involved joint with hepatitis B is the knee. Signs and symptoms are fever and lymphadenopathy, followed by joint pain, and then jaundice. Immune complexes in the synovium are responsible for synovial inflammatory changes. Hepatitis C causes a polyarticular arthritis, which may become chronic.[29]

RUBELLA ARTHRITIS

The arthritis of rubella is uncommon in children and adult males, but occurs in 50% of adult females with acute rubella, appearing soon after the emergence of the classic rash. The arthritis is polyarticular, most frequently involving the wrist, hand, knee, ankle, and elbow.

TABLE 284-6 Common Causes of Viral Arthritis

Virus	Prevalence of Arthritis	Findings	Duration	Additional Features
Parvovirus B19	Children 10% Adults 50%–70%	Polyarticular Symmetric	2–8 wk or chronic	Causes erythema infectiosum in children, rarely causes aplastic crisis
Rubella	Adults 50%	Polyarticular	5–7 d	Relapse
Epstein-Barr virus	1%–5%	Poly- or monoarticular	1–12 wk	Autoantibodies
Hepatitis B	10%–25%	Migratory	1–3 wk	Vasculitis
Hepatitis C	10%	Polyarticular	Chronic	Vasculitis
HIV	10%–50%	Mono- or oligoarticular	Chronic	Viral load >10,000 copies of HIV RNA, CD4 count <350 cells
Alphaviruses*	>50%	Oligoarticular	1–4 wk	More common in Asia, Africa; fever, myalgias

Abbreviation: HIV = human immunodeficiency virus.
*Alphaviruses include: Sindbis virus, Mayaro virus, Ross River virus, Semliki Forest virus, O'nyong-nyong virus, Chikungunya virus, and Barmah Forest virus.

ALPHAVIRUS AND HUMAN IMMUNODEFICIENCY VIRUS ARTHRITIS

Alphaviruses are common causes of arthritis in Africa, Asia, Australia, the West Pacific, and South America. Human immunodeficiency virus may cause an associated arthralgia/arthritis, a reactive arthritis, or psoriatic arthritis. In human immunodeficiency virus, CD4 counts below 350 cells/mm^3 increase the likelihood of bacterial arthritis. Counts below 200 cells/mm^3 are associated with an opportunistic cause of arthritis.[29] Overall management is discussed in chapter 154, "Human Immunodeficiency Virus Infection."

LYME DISEASE

The arthritic manifestations of Lyme disease occur weeks, months, or years after primary, stage I infection. Symptoms include monoarticular or oligoarticular asymmetric joint involvement. Large joints are most often affected, particularly the knee.[30] A migratory pattern of oligoarthritis may be noted in addition to brief attacks of bursitis and tendonitis.

The diagnosis of Lyme arthritis is initially suspected in patients residing in, or with a recent visit to, an endemic area. A history of tick bite or erythema chronicum migrans rash (see Figure 160-1 in chapter titled "Zoonotic Infections") is helpful but often absent. Arthrocentesis yields an inflammatory synovial fluid, usually with negative cultures. For detailed discussion of the diagnosis and treatment of Lyme disease, see chapter 160. Given the difficulty of making a definitive diagnosis in many patients, treatment of suspected Lyme arthritis is often initiated on the grounds of high clinical suspicion. Treatment is administered for 4 weeks, with a number of antibiotics recognized as effective, including ceftriaxone, 1 gram IV twice daily, switching to PO after clinical improvement; doxycycline, 100 milligrams PO twice daily; amoxicillin, 500 milligrams three times daily; or cefuroxime, 500 milligrams twice daily.[30]

HEMARTHROSIS

TRAUMATIC HEMARTHROSIS

Traumatic hemarthrosis has a high association with ligamentous injury or an intra-articular fracture. Effusions following trauma may range from small minor effusions to large painful fluid collections that impede range of motion. Aspiration of very large traumatic effusions will provide pain relief for approximately 1 week and increase range of motion but has no effect on long-term outcome.[12] Treatment of traumatic hemarthrosis consists of immobilization, ice, and elevation of the affected joint. In the absence of a fracture or significantly unstable joint requiring immediate orthopedic evaluation, follow-up is needed for possible ligamentous and articular injuries.

SPONTANEOUS HEMARTHROSIS

Spontaneous hemarthrosis usually indicates underlying systemic illness and should prompt consideration for primary or secondary coagulopathies. Hemophiliacs should receive specific clotting factor replacement for hemarthrosis (see chapter 235, "Hemophilias and von Willebrand's Disease"). Joint aspiration for acute hemarthrosis in hemophilia is controversial but recommended by some for a large hemarthrosis that can be aspirated during the first 12 hours of symptoms. **Joint aspiration should only be performed after factor replacement.**[17] Follow-up and/or consultation should be provided with hematology and orthopedics.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis is typically a progressive disease, with polyarticular involvement of symmetric joints and sparing of the distal interphalangeal joints. Women are affected more commonly than men. Patients describe stiffness of the joints occurring after prolonged periods of inactivity (morning stiffness). A "boggy," slightly edematous synovium may be palpated. Arthrocentesis of synovial fluid is typically noted for an inflammatory profile. For further discussion of systemic clinical features of rheumatoid arthritis, see chapter 282.

Salicylates or other NSAIDs are the cornerstone of treatment for an acute exacerbation. Corticosteroids may be used for brief periods, with long-term therapy using agents such as methotrexate, leflunomide, sulfasalazine, and other nonbiologic and biologic disease-modifying antirheumatic drugs.[31] Consider septic arthritis in patients with an acute episode of arthritis who are also receiving immunosuppressives.

OSTEOARTHRITIS

Osteoarthritis is distinguished from rheumatoid arthritis by a lack of constitutional symptoms and/or multisystem involvement. Destruction of joints in osteoarthritis may involve the distal interphalangeal joints, with less dramatic symmetric, polyarticular exacerbations. Although osteoarthritis is a chronic, polyarticular disease, patients may present with an acute monoarthritis exacerbation, typically of the knee. Effusions are small and difficult to aspirate. If fluid is aspirated, it is noninflammatory.

Radiographs demonstrate characteristic joint space narrowing due to destruction of articular cartilage. Treatment is joint rest and NSAIDs or acetaminophen in the setting of GI complications.[32] Systemic corticosteroids are not indicated, although intra-articular corticosteroids may be administered by a primary care physician or orthopedist.

REACTIVE ARTHRITIS

Reactive arthritis (formerly known as *Reiter's syndrome*) is a seronegative spondyloarthropathy characterized by an acute, asymmetric oligoarthritis occurring 2 to 6 weeks after an infectious illness.[33-35] **The classic triad of Reiter's syndrome is arthritis, urethritis, and conjunctivitis. A history of all three components is not necessary for diagnosis.** *Chlamydia* or *Ureaplasma* are common inciting infectious agents (postvenereal reactive arthritis). Enteric infections may precipitate a reactive arthritis (postdysentery reactive arthritis). Implicated agents of postdysentery reactive arthritis are *Salmonella*, *Shigella*, *Yersinia*, and *Campylobacter*, and possible agents include *Escherichia coli* and *Clostridium difficile*.[33,34]

Conjunctivitis occurs in one third of postvenereal and >50% of post-dysentery forms of reactive arthritis.[34]

Joint involvement in reactive arthritis typically involves the lower extremities, including the feet. Back and buttock pain may occur. A diffuse swelling of an entire digit (sausage digit) may be found as well but is not specific to reactive arthritis.[33,34] Synovial fluid aspirates demonstrate an inflammatory profile. Treatment has traditionally been supportive, with emphasis on pain control with NSAID therapy. Antibiotics were previously thought to be of no benefit, but now long-term combination antibiotic therapy is being used for *Chlamydia*-induced reactive arthritis, using rifampicin combined with either doxycycline or azithromycin.[35] Arthroscopic synovectomy may also provide benefit.[36] Suspected cases should be referred to rheumatology for confirmation of diagnosis and management.

BURSITIS

NONSEPTIC BURSITIS

Bursitis is an inflammatory process involving one of the >150 bursae in the body, but most commonly the bursa overlying the elbow or the knee (see also chapter 281, "Hip and Knee Pain").[37] Bursitis can be caused by repetitive trauma or can be associated with gout, pseudogout, or rheumatoid arthritis. Repetitive activities that can precipitate bursitis are identified by the typical names given: "carpet layer's or housemaid's knee" (prepatellar bursitis) or "student's elbow" (olecranon bursitis). The affected bursa is easily palpated but is not tender and not erythematous. Bursal enlargement is usually chronic or progressive but not acute. If bursitis is acute, consider septic bursitis (see "Septic Bursitis" below). In nonseptic bursitis, there is no limitation of, or pain upon, joint movement. The skin over the bursa may be thickened and calloused, indicating chronic repetitive trauma or pressure. Treatment is NSAIDs and elimination of activities that produce symptoms. Aspiration and drainage of bursal fluid is controversial (if infection is not suspected), because bursal fluid often reaccumulates after aspiration.

SEPTIC BURSITIS

Unlike septic arthritis, septic bursitis is more likely secondary to bacterial spread from a skin lesion or local cellulitis to an injured or inflamed bursa. Therefore, cultures more closely reflect skin flora.[37] Septic bursitis is characterized by acute pain, tenderness, erythema of the affected bursa, and overlying warmth when compared with the unaffected side.[37,38] The most common sites for septic bursitis are the prepatellar bursa (50% to 53%) and the olecranon bursa (40% to 45%).[38-40]

Fever occurs in <50% of patients with septic bursitis.[38] Pain can occasionally be mild (10%) but is usually moderate or severe.[39] Associated cellulitis of the surrounding skin may be evident.

Most authors recommend the aspiration of bursal fluid if septic bursitis is considered.[37,39] Bursal aspiration can be diagnostic and therapeutic. Bursal fluid demonstrates characteristic findings in infection (**Table 284-7**).[37] Culture is the definitive test for presence or absence of infection. Diagnosis is presumed by one of the following criteria based on bursal fluid results: positive Gram stain, >3000 WBC/mm^3, >50% polymorphonuclear cells, glucose <31 milligrams/dL, or bursal to serum glucose ratio of <50%.[37]

S. aureus accounts for the majority of infections, but *Staphylococcus epidermidis* and *Streptococcus* species are also encountered.[37-39] Septic bursitis generally responds well to oral antibiotics, with emphasis on coverage of *Staphylococcus* and *Streptococcus* species. With the high prevalence of methicillin-resistant *S. aureus,* adjust antibiotic choice according to local sensitivities. Conditions that require hospital admission for incision and debridement and IV antibiotics include sepsis, extensive purulent bursitis, extensive surrounding cellulitis, suspected joint involvement, immunocompromise, or failure to respond to a course of oral antibiotics.[37] See specific treatment recommendations below.

OLECRANON BURSITIS

The olecranon bursa overlies the olecranon process on the extensor surface of the elbow. The bursa is tense and edematous. Pain elicited with range of motion at the elbow is minor until the motion tightens and compresses the distended overlying bursa. Gouty tophi on the extensor surface of the elbow may be palpable or visible if the cause of bursitis is crystal-induced bursitis. If bursal fluid is aspirated, uric acid crystals are evident on microscopy.

To aspirate the olecranon bursa, prepare the bursal skin and use antiseptic technique. The patient's arm can be extended to allow for maximal bursal distention. Use a lateral approach to the affected bursa. Remove as much fluid as possible, and send the aspirate to the laboratory for analysis for WBC, Gram stain, crystals, glucose, and culture.

Treatment depends on patient condition; if septic, the patient should be treated with vancomycin, 15 milligrams/kg, plus piperacillin/tazobactam, 4.5 grams IV, or meropenem, 500–1000 milligrams IV. Most patients can be treated as outpatients with a 14-day course of oral antibiotics.[37-39] Common antibiotics chosen include clindamycin, 300 milligrams three times per day for 10 days, or dicloxacillin, 500 milligrams four times per day.[39] Trimethoprim-sulfamethoxazole is an alternative.[38] Steroids are not indicated in the ED because infection cannot be definitively excluded by negative culture results. Admission is indicated for clinical toxicity, extensive surrounding cellulitis, failure of outpatient treatment, or immunocompromise. Some patients benefit from surgical excision of the bursa sac.[40]

PREPATELLAR BURSITIS

Bursitis may affect any of the four bursae surrounding the extensor aspect of the knee (see Figure 281-6). A history of overuse or repetitive trauma to the prepatellar area is typical.[37] The noninfected or aseptic bursa is enlarged and taut but nontender and not warm. There is full range of motion of the knee. If septic patellar bursitis is a consideration (**Figure 284-12**), aspirate the prepatellar bursa to obtain fluid for analysis. Prepare the skin overlying the bursa and use aseptic technique. Use either a lateral or medial approach. Fluid analysis and treatment are the same as for septic olecranon bursitis (see "Olecranon Bursitis" above).

TABLE 284-7 Characteristics of Bursal Fluid in Patients with Septic and Nonseptic Olecranon and Prepatellar Bursitis

	Septic	Traumatic and Idiopathic	Crystal Induced
Appearance	Purulent or serosanguineous	Straw colored, serosanguineous, or bloody	Straw colored to bloody
Leukocytes/mm^3	Range, 350–392,000; mean, 54,3300 ± 34,197; >3000 is considered diagnostic	Range, 0–11,700; mean, 2475 ± 1988	Range, 1000–6000; mean, 2900
Differential count	>50% polymorphonuclear cells is considered diagnostic	Predominantly mononuclear	Highly variable
Ratio of bursal fluid to serum glucose	<50% in 90% of cases (diagnostic)	>50%, 70%–80% in 98% of cases	Unknown
Gram stain	Positive in 70% (diagnostic)	Negative	Negative
Crystals present	No*	No	Yes
Culture results	Positive (diagnostic)	Negative	Negative

*The presence of crystals does not rule out infection.

CHAPTER 285

Soft Tissue Problems of the Foot

Mitchell C. Sokolosky

INTRODUCTION

This chapter discusses the common foot disorders that are likely to present to the ED. Patients with chronic or complicated foot problems generally should be referred to a dermatologist, orthopedist, general surgeon, or podiatrist, depending on the disease and local resources. Tinea pedis, foot ulcers, and onychomycosis are discussed in Section 20, "Skin Disorders," in chapter 253, "Skin Disorders: Extremities." Puncture wounds of the foot are discussed in Section 6, "Wound Management," in chapter 46, "Skin Disorders: Extremities.", "Puncture Wounds and Bites." Foot ulcers and osteomyelitis are discussed in Section 17, "Endocrine Disorders," in chapter 224, "Type 2 Diabetes Mellitus."

CORNS AND CALLUSES

Calluses are a thickening of the outermost layer of the skin and are a result of repeated pressure or irritation. Corns (clavus) develop similarly, but have a central hyperkeratotic core that is often painful. The causes can be external (poorly fitted shoe) or internal (bunion).

Calluses are protective and should not be treated if they are not painful. Calluses grow outward but may be pushed inward by continued pressure and become corns. Corns also develop in areas of scarring and between toes. Corns are classified as hard or soft. Hard corns are seen over bony protuberances where the skin is dry. Soft corns are seen between toes where the skin is moist. Corns may be painful or painless, but pressure on the corn usually produces pain. Diagnosis is based on clinical appearance. Corns interrupt the normal dermal lines and can thus be differentiated from calluses, which do not interrupt the normal dermal lines. Hard corns may resemble warts. However, when warts are pared, warts contain black seeds, which are thrombosed capillaries and may bleed, while corns do not bleed. Soft corns resemble tinea, and identifying tinea is important for proper treatment (see chapter 253).[1,2]

Keratotic lesions may indicate more severe underlying disease, deformity, local foot disorder, or mechanical problem. Differential diagnosis of keratotic lesions includes syphilis, psoriasis, arsenic poisoning, rosacea, lichen planus, basal cell nevus syndrome, and, rarely, malignancies.[2]

TREATMENT OF CORNS

Treatment of symptomatic corns often necessitates referral to a podiatrist because the treatment may involve repeated paring, use of keratolytic agents, and possibly surgery to correct any underlying source of pressure (bunion).[1-4] Salicylic acid treatments are more effective than paring with a scapel.[5] Recurrence can be prevented by weekly gentle trimming with a pumice stone or emery board after soaking in warm water for 20 minutes. Placing a pad on or around the lesion relieves pressure, and avoiding constrictive footwear also provides benefit.

PLANTAR WARTS

Plantar warts are caused by the human papillomavirus. Plantar warts are most common in children, young adults, and butchers or fishmongers. Infection occurs by skin-to-skin contact, with maceration or sites of trauma. The incubation period is 2 to 6 months. Spontaneous remission may occur in up to two thirds of patients within 2 years.[6] Recurrence is common. Single lesions are endophytic and hyperkeratotic. A mother-daughter wart is similar to a single lesion except for a small vesicular satellite lesion. Mosaic warts are often painless, closely grouped, and may coalesce. Diagnosis is clinical. The wart will obscure normal skin markings. If in doubt, use a #15 scalpel blade to pare down the lesion to expose thrombosed capillaries, called seeds. The only two effective treatments for warts are salicylic acid and liquid nitrogen (cryotherapy).[7,8] Some salicylic acid preparations are available without a prescription. Duct tape (silver or clear) as an adjunct provides no benefit.[8] Adequate paring is required for larger lesions.[7] Plantar warts may require prolonged treatment (several weeks or months) as well as cryotherapy, so refer to a dermatologist or podiatrist for follow-up.[8] Nonhealing lesions require referral to a specialist because they may represent undiagnosed melanoma.[7,9] Instruct patients to avoid touching warts on themselves or others, to wear slippers in public showers, and to not use paring down tools (pumice stone, file) on normal skin or nails.

INGROWN TOENAIL

Normal nail function requires maintenance of a small space between the nail and the lateral nail folds. Ingrown toenails occur when irritation of the tissue surrounding the nail causes overgrowth, obliterating the space.[10-12] Causes include improper nail trimming, using sharp tools to clean the nail gutters, tight footwear, rotated digits, and bony deformities.[10,12] Curvature of the nail plate is another predisposing factor.[12] Symptoms are characterized by inflammation, swelling, or infection of the medial or lateral aspect of the toenail. The great toe is the most commonly affected. In patients with underlying diabetes or arterial insufficiency, cellulitis, ulceration, and necrosis may lead to gangrene if treatment is delayed.

TREATMENT OF INGROWN TOENAILS

If infection or significant granulation is absent at the time of presentation, acceptable treatment is daily elevation of the nail with placement of a wisp of cotton or dental floss between the nail plate and the skin.[13] Daily foot soaks and avoidance of pressure on the nail help.[13] Another option, if no infection is present, is to remove a small spicule of the nail (**Figure 285-1**).[12]

A digital nerve block is placed (see Section 5, "Analgesia, Anesthesia, and Procedural Sedation," and chapter 36, "Local and Regional

FIGURE 285-1. Partial toenail removal. This method is used for small nail fold swellings without infection. After antiseptic skin preparation and digital nerve block, an oblique portion of the affected nail is trimmed about one to two thirds of the way back to the posterior nail fold. Use scissors to cut the nail; use forceps to grasp and remove the nail fragment.

Anesthesia"). Cleanse the area and prepare the skin for an antiseptic procedure. Trim an oblique portion of the affected nail about one to two thirds of the way back to the posterior nail fold. The nail groove should then be debrided and a nonadherent dressing placed.[10,11]

If granulation or infection is present, a larger partial removal of the nail plate is indicated (**Figure 285-2**). Preprocedure antibiotics are not needed unless the patient is systemically ill.[14] First, perform a digital nerve block and prepare the area for antiseptic technique. Longitudinally, cut the entire affected area, base-to-tip, cutting about one fourth of the nail plate, including the portion of the nail beneath the cuticle. Cutting the nail is made easier by first sliding mosquito forceps or small scissors between the nail and nail bed on the affected side, freeing the nail from the bed below. Rotate the forceps, turning up the portion of the nail on the affected side. A nail splitter is the optimal instrument for cutting the nail; however, sturdy scissors are a reasonable alternative. Then grasp the affected cut portion of the nail with a hemostat and, using a rocking motion, remove it from the nail groove. Then debride the nail groove.[10] Once the procedure is completed, place a nonadherent gauze or antibiotic ointment on the wound and a bulky dressing over that, covering the toe. Check the toe in 24 to 48 hours.[10,12] If phenol is used for chemical matricectomy, massage the involved nail matrix vigorously with a cotton-tipped swab dipped in an aqueous solution of phenol 88%, with a rotation directed toward the lateral nail fold, for 1 minute. Irrigate the nail matrix using isopropyl alcohol to neutralize completely the phenol solution.[15,16] Do not expose normal skin or tissues to the phenol solution. Postprocedure antibiotics are not needed unless cellulitis is proximal to the toe.[11]

For recurrent ingrown toenails, refer to a podiatrist for permanent nail ablation, which may require a combination of surgical excision plus chemical matricectomy (phenol ablation).[15,16]

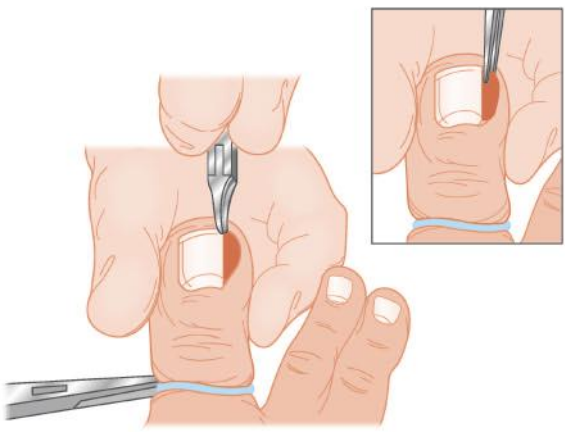

FIGURE 285-2. Partial toenail removal (infection present). This method is used for onychocryptosis in the setting of significant granulation tissue or infection. See "Treatment of Ingrown Toenails" for a description of the procedure.

OTHER NAIL LESIONS

Other common toenail afflictions include paronychia (see Section 23, "Musculoskeletal Disorders," chapter 283, "Nontraumatic Disorders of the Hand") and subungual hematoma (see Section 6, "Wound Management," chapter 43, "Arm and Hand Lacerations"), which are treated similarly to when they occur in the fingers. Hyperkeratotic toenails can be a problem in the elderly. These may become so severe as to affect gait and cause ulcerations and infections. Refer such patients to podiatry for repeated trimming or nail plate removal.

BURSITIS INVOLVING FEET

Calcaneal bursitis causes posterior heel pain that is similar to Achilles tendinopathy[17,18]; however, the pain and local tenderness are located at the posterior heel at the Achilles tendon insertion point. In contrast, Achilles tendinopathy causes symptoms 2 to 6 cm superior to the posterior calcaneus. Pathologic bursae can be divided into noninflammatory, inflammatory, suppurative, and calcified. Noninflammatory bursae are usually pressure induced and are found over bony prominences. Inflammatory bursitis is commonly due to gout or rheumatoid arthritis. Suppurative bursitis is due to bacterial invasion of the bursae (primarily staphylococcal species), usually from adjacent wounds. Acute bursitis can lead to the formation of a hygroma or calcified bursae. Diagnosis can be aided by the use of US and MRI[17] but is not indicated for evaluation in the ED. Treatment of the bursitis depends on its cause. For nonseptic bursitis, symptoms usually resolve with simple measures including heel lifts, comfortable footwear, rest, ice, and nonsteroidal anti-inflammatory drugs.[19] Management of septic bursitis is discussed in Section 23, "Musculoskeletal Disorders," in chapter 284, "Joints and Bursae." Diagnosis of these lesions is dependent on analysis of bursal fluid, which can be obtained by large-bore needle aspiration.[17]

PLANTAR FASCIITIS

Plantar fasciitis, inflammation of the plantar aponeurosis, is the most common cause of heel pain.[20-22] Peak age incidence is usually between 40 and 60 years old, but it has a younger peak in runners.[23,24] Plantar fasciitis is common among ballet dancers and those performing aerobics. The plantar fascia anchors the plantar skin to the bone and provides support to the foot during gait. The cause is usually overuse. Other causes of heel pain include abnormal joint mechanics, tightness of the Achilles tendon, shoes with poor cushioning, abnormal foot position and anatomy, and obesity.[17,20] In the younger patient, autoimmune and rheumatic diseases can be considered.

The symptom of plantar fasciitis is pain on the plantar surface of the foot that is worse when initiating walking. Examination usually reveals a point of deep tenderness at the anterior medial aspect of the calcaneus, the point of attachment of the plantar fascia. Pain and tenderness tend to be increased upon dorsiflexion of the toes. Diagnosis is clinical. Radiographic studies are not indicated unless other causes are being considered. The presence of heel spurs is of no diagnostic value because many patients without plantar fasciitis have this finding on imaging. For resistant cases, US and MRI may aid in diagnosis but are not indicated for evaluation in the ED.[17]

Plantar fasciitis is generally a self-limited disease. Eighty percent of cases resolve spontaneously within 12 months. Initial treatment consists of rest, ice, nonsteroidal anti-inflammatory drugs, heel and arch support shoe inserts, taping or strapping of the foot, and dorsiflexion night splints (molded ankle-foot orthotics that holds the plantar fascia and Achilles tendon stretched). Plantar-specific stretch exercises are the most beneficial treatment in the acute phase: with the ankle dorsiflexed, the patient uses one hand to dorsiflex the toes and with the other hand palpates the plantar surface of the foot, confirming tension.[25] Patients should be taught Achilles tendon stretching exercises and be told to avoid the use of flat shoes and barefoot walking.[17] In severe cases, a short-leg walking boot may be useful to unload and rest the plantar fascia. Corticosteroid injections provide short-term benefit, up to 1 month,[25] but are associated with plantar fascia rupture,[17] and are best left

to the orthopedist.[20,21] Refer patients to a podiatrist, orthopedist, or primary care physician for follow-up care.[20,21]

NERVE ENTRAPMENT SYNDROMES

TARSAL TUNNEL SYNDROME

Tarsal tunnel syndrome is an uncommon source of foot pain and numbness in runners due to compression of the posterior tibial nerve as it courses behind the medial malleolus.[26,27] The cause is usually from prior injury (scar tissue, bone or cartilage fragments, or bony spurs) and overpronation during running.[26,27] Overpronation (inward rotation) makes the nerve more vulnerable both to direct trauma from stretch and to indirect trauma from inflammation of the surrounding structures, resulting in compression.[26,27] Other causes include activities requiring restrictive footwear (ski boots, skates), edema from pregnancy, ganglion cysts, and tumors, but frequently, no inciting event is known.[28]

Symptoms include numbness or burning pain of the sole and may be limited to the heel, mimicking plantar fasciitis. Distal calf pain may be due to retrograde radiation (Valleix phenomenon). Weakness is uncommon. Pain is often worse with running, at night, and after standing, and often leads to the desire to remove the shoes. **Tinel sign** is positive with percussion inferior to the medial malleolus yielding pain radiating to the medial or lateral plantar surface of the foot. Simultaneous dorsiflexion and eversion of the ankle exacerbates symptoms. Diagnosis is aided by nerve conduction studies or MRI,[26,27] but these are not routinely ordered from the ED.

The differential diagnosis includes plantar fasciitis and, if limited to the heel, Achilles tendinitis. Plantar fasciitis will cause point tenderness over the plantar heel, and pain is worse upon morning standing. Tarsal tunnel syndrome causes greater medial heel and arch pain due to involvement of the abductor hallucis muscle. Tarsal tunnel pain worsens with ambulation throughout the day. In addition, tarsal tunnel syndrome may produce distal calf pain, whereas plantar fasciitis does not.

Initial treatment includes avoidance of the exacerbating activities, nonsteroidal anti-inflammatory drugs, shoe modification, and occasionally orthotics. If there is no improvement or symptoms recur after a few weeks, then orthopedic evaluation is recommended.[26,27]

DEEP PERONEAL NERVE ENTRAPMENT

Deep peroneal nerve entrapment occurs most commonly at the location where the nerve courses under the inferior extensor retinaculum[29] (**Figure 285-3**). Recurrent ankle sprains, soft tissue masses, trauma (both acute and repetitive),[30] chronic biomechanical misalignment, edema, and tight-fitting footwear (ski boots) are the most common causes. Symptoms are dorsal and medial foot pain and sensory hypoesthesia at the first toe web space. There may be loss of the ability to hyperextend the toes due to wasting of the extensor hallucis brevis and extensor digitorum brevis muscles. Pain and tenderness can be elicited on palpation of the peroneal nerve at the site of entrapment and by plantar flexion with inversion of the foot. Pain is exacerbated by activity and relieved by rest. Nighttime pain is common. Treatment is the same as for tarsal tunnel syndrome.

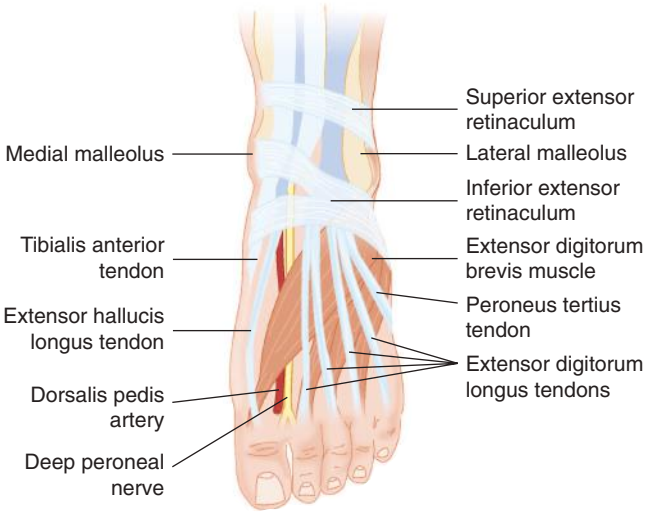

FIGURE 285-3. Tendons of the foot, anterior view, including deep peroneal nerve.

GANGLIONS OF THE FOOT

A ganglion is a common benign synovial cyst. Ganglions are 1.5 to 2.5 cm in diameter and are often attached to a joint capsule or tendon sheath. Although ganglions typically occur in the wrist or hand, they may also occur in the foot. Ganglions typically arise in the anterolateral aspect of the ankle, but can occur in many areas of the foot. The cause is unknown. Ganglions may appear suddenly or gradually, may enlarge and diminish in size, and may be painful or asymptomatic. On examination, a ganglion is a firm, cystic lesion. Diagnosis is usually made clinically, although US or MRI may exclude other causes when serious pathology is suspected. Aspiration and instillation of glucocorticoids by an orthopedist lead to the complete resolution of ganglions in some cases,[31] with surgical excision required for persistence.[32,33]

TENDON LESIONS OF THE FOOT

TENOSYNOVITIS AND TENDINITIS

Tenosynovitis and tendinitis may occur in the foot, usually due to overuse. Patients present with pain over the involved tendon (Figure 285-3). The flexor hallucis longus, posterior tibialis, and Achilles tendon are most commonly involved.[34] Treatment consists of rest, ice, and oral nonsteroidal anti-inflammatory drugs.[34]

Flexor hallucis longus tenosynovitis classically affects ballet dancers, but can also be seen in runners and nonathletes. Presentation is similar to plantar fasciitis and tarsal tunnel syndrome. Posteromedial ankle pain, medial arch pain, and a positive Tinel sign (see earlier description in "Tarsal Tunnel Syndrome") are seen. Conservative management (rest, mobilization, orthotic shoe implant, nonsteroidal anti-inflammatory drugs) is usually successful. Surgery is reserved for refractory cases.

TENDON LACERATIONS

Tendon lacerations can result from penetrating injuries to the dorsal or plantar aspect of the foot. Tendon repairs in the foot are complex, and orthopedic consultation is needed for repair.[34]

The foot should be casted in dorsiflexion after the repair of extensor tendons and in equinus after repair of flexor tendons.

TENDON RUPTURES

Spontaneous rupture of the Achilles tendon is common. Rupture of the anterior tibialis and posterior tibialis tendons may also occur.[34] Age and chronic corticosteroid and fluoroquinolone use are risk factors for spontaneous rupture. Diagnosis is usually clinical but is aided by US or MRI studies in difficult cases.

Achilles tendon rupture occurs when a sudden shear stress, such as sudden pivoting on a foot or rapid acceleration, is applied to an already weakened or degenerative tendon. Many patients report immediate sharp pain, and some hear an audible "pop." The peak age for rupture is 30 to 40 years, and rupture is four to five times more common in men than women.[35] Over 80% of ruptures occur during recreational sports ("weekend warrior"). Patients often present with pain, a palpable defect in the area of the tendon, and inability to stand on tiptoes. A minority of patients with complete tendon ruptures are able to ambulate and may be misdiagnosed as having an ankle sprain. Squeezing the calf of the prone patient whose knee is flexed at 90 degrees will normally cause the foot to plantar flex (calf squeeze or Thompson test. The absence of plantar flexion indicates a positive test indicative of rupture. Initial ED treatment consists of ice, analgesics, immobilization of ankle/foot in plantar flexion, crutches, and referral to an orthopedic surgeon. Definitive treatment is

generally surgical in younger patients and conservative (casting in equinus or plantar flexion) in older patients.[34,36,37] For further discussion, see chapter 44, "Leg and Foot Lacerations," and Figure 44-1 (Thompson test) in that chapter, in Section 6, "Wound Management."

Ruptures of the **anterior tibialis tendon** are rare. Ruptures usually occur after the fourth decade and are not excessively painful. Patients present with varying degrees of foot drop and a palpable defect distal to the ankle joint in the area of the tendon. In most cases, disability is minimal, and surgery is not necessary.[34]

Spontaneous ruptures of the **posterior tibialis tendon** also occur after the fourth decade. Two thirds of these cases occur in women. The presentation is usually chronic and insidious. Patients notice a gradual flattening of their arch, with modest discomfort and swelling over the medial ankle. Examination reveals absence of the tendon's normal prominence and weakness on inversion of the foot. Patients find it impossible to stand on tiptoes. Treatment may be conservative or surgical, depending on the duration of the tear and activity of the patient.[22]

Flexor hallucis longus rupture presents as a loss of plantar flexion of the great toe. The need for surgery will depend on the patient's occupation and lifestyle.[34]

Disruption of the **peroneal retinaculum** can occur as a result of direct trauma during dorsiflexion of the foot. Besides pain localized to the peroneal tendon behind the lateral malleolus, the patient complains of a clicking when walking as the tendon subluxes. Peroneal tendon injuries may lead to lateral ankle instability. Treatment is generally surgical repair.[34]

PLANTAR INTERDIGITAL NEUROMA (MORTON'S NEUROMA)

Neuromas may form in a plantar digital nerve, usually proximal to its bifurcation. Neuromas may occur in any of the digital nerves but are most common in the third interspace. The cause is thought to be local irritation of the nerve due to entrapment, usually from tight-fitting shoes. Women between the ages of 25 and 50 years old are the most commonly affected group. Patients present with pain located in the area of the metatarsal head. The pain is described as burning, cramping, or aching. Pain is worsened by ambulation and resolved by rest and removal of shoes. The pain may radiate to the affected toes, and patients may note numbness in the toes. Pain is usually easily reproduced upon palpation of the area, and at times, a mass is felt. Diagnosis is usually made clinically, but nerve conduction studies, electromyograms, US, and MRI may be helpful at times. Conservative treatment consists of wearing wide shoes with good metatarsal head supports and metatarsal head off-loading inserts.[38] Local glucocorticoid injections can sometimes be curative. Surgical removal may be necessary for refractory symptoms.

COMPARTMENT SYNDROMES OF THE FOOT

The foot has up to nine compartments. Compartment syndrome occurs when an elevation of tissue pressure within one of these nonyielding fascial compartments impedes vascular flow. The cause of compartment syndrome is a high-energy injury (crush injury)[39] associated with multiple fractures. Compartment syndromes have been reported in association with foot and ankle fractures (especially calcaneal and Lisfranc's fracture/dislocation), burns, contusions, bleeding disorders, postischemic swelling after arterial injury or thrombosis, venous obstruction, snakebites, exercise, and prolonged pressure to the affected area (e.g., cast immobilization, prolonged abnormal positioning).[40] Diagnosis begins with a high index of clinical suspicion based on the mechanism of injury. Pain out of proportion to injury is one of the early findings. Additional symptoms include pain that is worsened on active or passive movement, paresthesias, and neurovascular deficits. An absent pulse and complete anesthesia are late findings and may be difficult to assess due to underlying swelling. The only reliable objective method to diagnose compartment syndrome is by obtaining compartment pressures using an intracompartmental pressure monitoring system (Stryker STIC Device [Stryker, Kalamazoo, MI] or similar equipment). A difference between diastolic blood pressure and intracompartmental pressure of <30 mm Hg is an indication for fasciotomy.[41] Once the diagnosis is made, fasciotomy should be performed emergently. In the ED, elevate the extremity to the level of the heart pending fasciotomy. The sequelae of compartment syndrome range from transient neurologic compromise to complete myoneural necrosis, fibrosis, and ischemic contractures. The prognosis of compartment syndrome is directly related to the time delay in diagnosis and treatment (see Section 22, "Injuries to Bones and Joints," chapter 278, "Compartment Syndrome").[41]

Chronic exertional compartment syndrome is due to overuse.[42] Symptoms occur with exertion and are relieved by rest. Patients should be instructed to avoid overexertion and be referred for further investigation and treatment.

MALIGNANT MELANOMA

Malignant melanoma of the foot accounts for up to 15% of all cutaneous melanomas. Melanomas can present as an atypical, pigmented, or nonhealing lesion of the foot, including the nail. These malignancies often imitate more common foot disorders such as fungal infections, foot ulcers, and plantar warts. Because prognosis is directly related to early diagnosis, maintain a high index of suspicion for the diagnosis. Acral lentiginous melanoma is an aggressive malignant tumor that more commonly affects nonwhites. This tumor has a predilection for the plantar surface of the foot. It may present with atypical features leading to a delay in diagnosis and poor outcome. All skin lesions that are either atypical or not healing despite treatment should be referred for biopsy.[43]

PRACTICE GUIDELINES

For heel pain, the *Journal of Foot and Ankle Surgery* published a guideline, "The Diagnosis and Treatment of Heel Pain: A Clinical Practice Guideline–Revision." This can be found online at http://www.acfas.org/Research-and-Publications/Clinical-Consensus-Documents/Clinical-Consensus-Documents/.

Psychosocial Disorders

CHAPTER 286

Mental Health Disorders: ED Evaluation and Disposition

Leslie Zun

INTRODUCTION AND EPIDEMIOLOGY

Over the last two decades, the rate of ED mental health–related visits increased 38%, from 17.1 to 23.6 per 1000 U.S. population.[1] Mental health and/or substance abuse accounts for about one of every eight ED visits in the United States, and covert mental health problems may be present in over 40% of all ED patients.[2] ED visit increases are especially notable for older persons and those living in urban areas, and with visits related to mood and anxiety disorders, suicide attempts, and substance abuse. Behavioral disorders in children account for at least 1.6% of ED pediatric visits, of which nearly 20% are admitted. ED visits in children are often related to substance use, anxiety and attention deficit disorders, disruptive behavior, and psychosis.[3]

Because there are about 4000 general hospital EDs in the United States but <200 psychiatric EDs, the vast majority of acute behavioral problems are assessed and treated in general hospital EDs.[4,5] Patients with behavioral health problems often provide vague and nonspecific symptoms, and obtaining collateral information as part of the assessment is difficult and time-consuming.

ED disposition decisions can be especially challenging for homeless patients and for those with repeated ED visits. Given the complexities of assessment, diagnosis, and disposition, it is important to maintain a positive and nonjudgmental attitude toward patients with mental health disorders.

A decision strategy for emergency assessment of patients with mental health disorders should follow the sequence of actions in **Table 286-1**.

TABLE 286-1 Emergency Psychiatric Assessment Steps

Step	Comment
Safety and stabilization	Contain violent and dangerously psychotic persons to provide a safe environment for staff, patients, family, and visitors while simultaneously attending to airway, breathing, and circulation.
Identification of homicidal, suicidal, or other dangerous behavior	Determine whether the patient needs to be forcibly detained for emergency evaluation.
Medical evaluation	Determine the presence of any serious organic medical conditions that might cause or contribute to abnormal behavior or thought processes (e.g., hypoglycemia, meningitis, drug withdrawal, or other causes of delirium).
Psychiatric diagnosis and severity assessment	If the behavior change is not due to an underlying medical condition, it is primarily psychiatric or functional, requiring a psychiatric diagnosis and assessment of the severity of the primary psychiatric problems.
Psychiatric consultation	Determine the need for immediate psychiatric consultation.

This chapter presents an overview of the care of adult patients with mental health disorders from ED entry to departure—triage, patient and staff safety, medical and psychiatric evaluation, admission and disposition decisions, and the care of patients with prolonged ED stays. Diagnostic criteria of the psychiatric disorders are summarized. Behavioral and psychiatric disorders in children are discussed in chapter 147, "Behavioral Disorders in Children."

TRIAGE

Paramedics or police often provide advance notice to the ED, especially of the severely agitated patient, so preparations can be made for patient arrival. The best preparation includes assembly of an ED "psychiatric code" team, designation of an appropriate room, and having medications on hand. Team members may consist of an ED physician and nurse, hospital nurse manager, psychiatric clinical nurse, and security staff who can respond to threats of harm to others, patients with altered mental status, and patients trying to leave against medical advice.[6]

In most Western countries, psychiatric patients are triaged in the same manner as medical patients using the Emergency Severity Index, Canadian Triage Acuity Scale, Manchester Triage System, or Australasian Triage Scale/National Triage Scale. These triage tools were originally designed for medical patients. For psychiatric patients, behavior descriptors determine acuity. The most acute behaviors are actively dangerous (e.g., violent, possession of a weapon), with decreasing acuity as the likelihood of dangerousness to self or others declines.

THE PRECAUTIONARY PRINCIPLE

Agitated or distressed patients, those expressing suicidal or homicidal ideation, or patients who raise concern about harm to self or others should not be allowed to leave the ED before medical or psychiatric evaluation is completed, even if departure is formalized as "against medical advice."[7] Many institutions have a formal process to make sure staff are aware that the patient cannot leave. Processes include the writing of an order (e.g., "sitter with patient," "precautionary hold," "suicide precautions"), but while the process varies by institution, the goal is to ensure patient and staff safety during the time-consuming process of evaluation. The foundation of such action is called the "Precautionary Principle," which is the need to prevent or minimize harm before it occurs.[8]

SAFETY FIRST

Fragmented mental health care and mass deinstitutionalization of the severely mentally ill have ensured that many psychotic, violent, and chronically mentally unwell patients now visit the ED on a regular basis. Mental health emergencies include situations in which patients are highly distressed, suicidal, and/or homicidal. Patients with suicidal or homicidal ideation, suicide or violence plans, or suicide or homicide attempts require measures to minimize the possibility of harm to themselves or others. Mental health disorders coexisting with substance abuse are also a recipe for violence.[9] In one study of psychiatric patients in a veteran's hospital, about one third of patients who committed violence during hospitalization did so in the ED. Violent incidents have been associated with dementia, court-ordered admission, and mood disorder.[10] Violent and aggressive behavior frequently demands immediate chemical or physical restraint to protect the patient, other patients, staff, and visitors.[11]

Although hospital security forces and police are often available to subdue violent patients and reduce risks of staff or patient injury, ED

staff must be educated and equipped with a range of skills to protect themselves. These skills include enhanced awareness of risk factors and warning signs of violent behavior, verbal de-escalation techniques, quick access to rapidly tranquilizing or neuroleptic medications, and emergency strategies for getting help quickly in explosive circumstances.

Approach patients with potentially dangerous behavior cautiously and with a nonthreatening attitude, with adequate security nearby. If necessary, isolate and restrain threatening patients before they are disrobed, gowned, and searched for weapons. **Medical and nursing staff should stay distant from the patient; avoid excessive eye contact; maintain a calm, controlled posture and tone of voice; and stand in a location that neither threatens the patient nor blocks the exit of the healthcare worker from the room.**

A number of techniques can help de-escalate aggressive patient behaviors. Allow patients to verbally ventilate feelings. Provide an environment that decreases stimulation. Place the patient alone in a room designed for patient safety, but with close monitoring by staff. Offer food or drink. Set limits on acceptable behavior and respond with neutral comments. Adequate force nearby should be visible to the patient, and tell the patient that uncontrolled behavior will result in restraint.

EXAMINATION ROOMS AND SECLUSION

Waiting rooms and examination rooms need to be designed to ensure safety. Steps that promote safety include security staff, metal detectors, rooms with doors that permit rapid and easy exit, panic buttons, and the removal of any objects that could be used in violent attacks or suicide attempts (including neckties of both staff and patient, large earrings, patient belts or belt buckles, shoes, shoelaces, stethoscopes, blood pressure cuffs, and cutting instruments).

Seclusion rooms may be used to protect patients and staff. Remove or carefully secure any objects that could be used for self-injury or against staff. Austere seclusion rooms may be useful for some agitated patients by providing relief from external stimuli. Search patients before entry, and remove potentially dangerous objects, clothing, or weapons. Make sure staff are aware of the location of exits and of panic buttons. Initially, leave the door open, but if the patient remains agitated, lock the door. Keep the patient advised of each action and the expected duration, and explain the consequences of violent behavior. Monitor the patient in a seclusion room with a personal guard or nurse-monitor, by closed-circuit television, or by individual checks about every 10 minutes. Give the patient opportunities to comply with staff demands for acceptable behavior that can lead to release from seclusion. If violent behavior persists, physical restraint is justified. Document all steps in the use of seclusion and medical and physical restraints.

CHEMICAL RESTRAINT

Pharmacologic/chemical restraint of violent or agitated patients is discussed in detail in chapter 287, "Acute Agitation." The Sedation Assessment Tool score (SATS) is one method of grading behavior and assessing medication options.[12] Treatment options can be selected based on behavior (**Table 286-2**).

Ketamine has been used for acute agitation or depression, but concerns about hypoxia or oversedation, and lack of large clinical ED studies, limit its use in the ED at the present time.[13-15]

PHYSICAL RESTRAINTS

In many cases, there is no substitute for the application of physical limb restraints. Restraints should be applied rapidly and safely by individuals trained and skilled in their use. A team of five staff members is recommended: one team leader and one person for each limb. Sometimes, the show of force and the presence of many staff may in itself be sufficient to subdue the patient without recourse to restraints. The team leader oversees and orchestrates the procedure. The patient and any family members present should be provided with clear, ongoing explanations of all procedures. Place the patient on a bed or stretcher, and secure all four limbs with leather restraints. Be careful to avoid injury. Elevate the patient's head, if possible, to minimize risk of aspiration. Once the patient is restrained, offer medications, and if refused, administer medications involuntarily.[11]

TABLE 286-2 Sedation Assessment Tool Score (SATS) and Treatment Suggestions

Sedation Assessment Tool Score	Description	Treatment
3+	Combative, violent, out of control with continual loud outbursts	Physical restraint Lorazepam 1–2 milligrams IM AND Haloperidol 5–10 milligrams IM OR Olanzapine (Zyprexa®) 5–10 milligrams IM OR Droperidol 2 milligrams IM
2+	Very anxious and agitated with loud outbursts	As above, or if will take PO, lorazepam 1 milligram PO and haloperidol 5 milligrams PO OR Olanzapine ODT 5 milligrams
1+	Anxious and restless with normal to talkative speech	If will take PO, lorazepam 1 milligram PO and haloperidol 5 milligrams PO OR Olanzapine ODT 5 milligrams
0	Awake and calm, cooperative with normal speech	
–1*	Asleep but rouses if name is called with prominent slowing/slurred speech	
–2*	Responds to physical stimulation with few recognizable words	
–3*	No response to stimulation	

*Repeat Sedation Assessment Tool score 40–60 minutes after medication; goal score is 0 or –1. May repeat treatment if Sedation Assessment Tool score is >1+.

Abbreviation: ODT = orally disintegrating tablet.

Hospital policies dictate the frequency and type of observation (e.g., vital signs, pulses, range of motion, skin integrity, toileting) with written orders that limit the time in restraint and require renewal as needed. Once the patient is calm and compliant, restraints can be removed one at a time, while staff carefully monitor the patient to ensure the safety of all concerned.

MEDICAL EVALUATION OF PSYCHIATRIC PATIENTS

The initial steps include simultaneous medical and psychiatric evaluation while maintaining patient and staff safety.[16] Obtain vital signs including pulse oximetry, and perform point-of-care blood glucose determination. Simultaneously assess the patient's potential for dangerous behavior, such as harming self or others or leaving the ED without medical advice; stabilize the behavior; and evaluate the chief complaint. Then, obtain a focused history; perform physical examination and mental status/neurologic testing to identify comorbid or primary medical issues; and assess the need for hospitalization. Formulating a specific diagnosis is not as important as determining whether the patient is harmful to self or others or is unable to take care of self and needs hospitalization. Determining that an individual is suicidal and in need of protection and hospitalization, for instance, is more important than deciding whether that person has schizophrenia or psychotic depression.

The medical evaluation of patients with apparent psychiatric symptoms should be the same as for those with medical conditions[17] (**Table 286-3**). The findings of the history and physical examination should guide laboratory testing and diagnostic inquiry. The combined findings from history, physical examination, laboratory testing, and diagnostic inquiry form the basis of the medical description of the patient.

The evaluation of the patient with psychiatric symptoms in the ED is commonly termed "**medical clearance**." This term is a misnomer because many patients have medical problems and the term does not really mean that the patient's medical problems have been "cleared." Rather, this process identifies medical problems and their relationship to the patient's presentation. One alternative to the term "medically clear" is a discharge note that includes key features of the history, physical examination, and mental status and neurologic examination; laboratory results; discharge instructions; and follow-up plans.[18] Alternatively, the term "**medically stable**" could be used if a specific term is required.

The **medical evaluation** is used to determine whether the patient has a medical condition that causes or exacerbates the psychiatric illness. The medical evaluation process is also used to identify medical illnesses or injuries that are coincident to the psychiatric illness and that need to be identified and treated prior to a psychiatric admission. The determination of a medical versus psychiatric cause for psychiatric illness or behavioral change is difficult because many psychiatric patients have medical comorbidities and some with medical illness have undiagnosed psychiatric disorders. The most frequent medical comorbidities include diabetes, cardiovascular disease, and pulmonary disease.[17] If the patient with medical comorbidities needs hospitalization, be sure the psychiatric facility can provide care for concurrent medical illnesses.

MEDICAL AND BEHAVIORAL HISTORY

Medical comorbidities may produce changes in behavior. Ask specifically about fever, head trauma, immunocompetence (including malignancies and risk factors for human immunodeficiency virus infection), diabetes, pulmonary diseases, and toxic ingestions or overdose.

TABLE 286-3 Medical Evaluation of Psychiatric Patients

Document behavioral changes through history.
Identify medical symptoms.
Determine medical comorbidities.
Obtain medication and drug history.
Perform physical examination.
Perform neurologic examination.

Obtain information about recent changes in behavior from the patient, as well as from caregivers and family members. Obtain the history of previous psychiatric illness and treatment to identify patterns of relapse. Family and social history may identify stressors in the patient's environment that are a direct cause of changes in behavior or that accentuate any responses to underlying disease. Whenever possible, corroborate all history provided by the patient, with information from family members, care providers, or law enforcement. Compare direct observations of the patient's behavior with reports from the patient's family and caregivers. This is especially important for institutionalized or group home patients whose baseline mental capacity is often unclear to ED staff.

MEDICATION/DRUG HISTORY

Mental health disorders and substance abuse disorders frequently coexist.[19] The syndromes associated with alcohol and substance abuse that can result in altered behavior include intoxication, withdrawal, delirium, hallucinosis, paranoid behavior, and dementia. Identify any initiation of substance abuse, changes in the patterns of abuse, and medication compliance.

Behavioral changes may be due to prescription or over-the-counter drugs, especially sedatives-hypnotics, stimulants, psychotropic agents, anticonvulsants, anticholinergic agents, angiotensin-converting enzyme inhibitors, β-blockers, corticosteroids, fluoroquinolone antibiotics, histamine-2 receptor blockers, opioids, salicylates, selective serotonin reuptake inhibitors, thiazide diuretics, and antiparkinsonian agents.[20] The increasing use of serotonergic agents makes it important to check drug interactions (e.g., linezolid, tramadol) to identify serotonin syndrome as a cause of behavioral change.[21] Over-the-counter analgesics or herbals and alternative medications containing salicylates, anticholinergics, antihistamines, or bromides may produce delirium or toxic psychosis.[20] Alcohol and street drugs, such as phencyclidine, lysergic acid diethylamide, mescaline, amphetamines, and cocaine, can produce a toxic psychosis. Hypnosedatives, such as barbiturates and benzodiazepines, may produce a confusional state or delirium in both intoxication and withdrawal. Ask about alcohol and substance use in psychiatric presentations, even when the odor of ethanol or evidence of substance use is absent.

Psychoactive drugs are associated with a variety of hematologic and metabolic abnormalities. Clozapine, olanzapine, phenothiazines, and carbamazepine can cause neutropenia/agranulocytosis.[22] Hyponatremia (sodium level <136 mmol/L) can occur with typical and atypical antipsychotics.[23] Hepatotoxicity, manifested as transaminitis, obstruction, or hepatic failure, has been reported with norepinephrine-selective reuptake inhibitors more than with selective serotonin reuptake inhibitors, and also with tricyclics/tetracyclics, monoamine oxidase inhibitors, and typical and atypical antipsychotics.[24] Of the herbal medications, kava-kava can cause serious hepatotoxicity, while St. John's wort has been indirectly associated with hepatotoxicity due to its effects on the P450 system of other medications.[25]

PHYSICAL EXAMINATION

Perform a physical examination on every patient.[25-27] Measure vital signs, including temperature, and oxygen saturation by pulse oximetry. Investigate abnormal vital sign values, and do not dismiss them as due to anxiety or stress. Fever is especially important, because both local and systemic infections can cause altered mental status, as can meningitis, encephalitis, and brain abscess. Neuroleptic malignant syndrome and serotonin syndrome are causes of psychoactive drug-related fever.[28]

Patients with abnormal vital sign values, abnormal mental status examination results, psychosis, mental retardation, or advanced age usually require a complete head-to-toe physical examination, with street clothing removed and dressed in a hospital gown. Look for signs of trauma to the head, face, and neck, and reconstruct any mechanisms of injury. In the homeless, or in those with exposure, assess for hypothermia and check the extremities for frostbite. Examine for skin rash, extremity trauma, and needle tracks. Neurologic examination typically includes an assessment of most cranial nerves, gait, mental status, and general motor function and strength. For more focused neurologic examinations, test for apraxias, agnosias, right-left disorientation, aphasias, visual field cuts, and inability to follow complex spoken and written commands. Such

TABLE 286-4 Signs and Symptoms Suggesting Medical Cause of Behavioral Abnormalities
Abnormal vital sign values
Disorientation with clouded consciousness
Abnormal mental status examination findings
Recent memory loss
Age >40 y without a previous history of psychiatric disorder
Focal neurologic signs
Visual hallucinations
Important abnormalities on physical examination

signs may or may not occur in association with other localizing neurologic signs, such as asymmetric reflexes, paralysis, or hemiparesis.

Table 286-4 lists signs and symptoms associated with medical causes of behavioral abnormalities. Sudden onset of major changes in behavior, mood, or thought in a previously normal patient, or definite deterioration in a patient with a chronic behavioral disorder should stimulate evaluation for an underlying medical or neurologic disorder. A sudden change in behavior, especially in a patient >45 years old, is an important indicator of a possible medical disease process. Evaluate neurologic symptoms such as fainting, dizziness, disorientation, impairment of speech, confusion, loss of consciousness, headaches, difficulty performing routine tasks, new cognitive deficits, and focal weakness.

MENTAL STATUS EXAMINATION

The mental status examination is conducted to understand the patient's mental state and, when combined with the history and physical examination, aids the formulation of a diagnosis and disposition. A mental status examination can help identify delirium, medical disorders, and psychiatric disorders; identify patients who are dangerous to themselves or others; and help assess patient disposition (**Tables 286-5** and **286-6**). A great deal of the information obtained in mental status examinations becomes evident through observing the patient's appearance, behavior, language, comprehension, and affect during the initial patient interview. However, cognitive assessment and determination of suicidal or homicidal ideation or hallucinations and delusions generally require additional questioning.

Important components of the mental status examination include ability to provide historical information, attention, speech patterns, language comprehension, affect and mood, hallucinations and delusions, level of cognitive functioning, degree of insight and capacity for introspection, and ability to establish a therapeutic relationship. Abnormal findings in any of the above components may suggest a medical basis for abnormal thought or behavior. Liability of affect, the need for simple questions to be repeated, irritability, disorientation, and lack of cooperation are some additional signs of medical dysfunction.

During the examination, the patient's affect or outward display of emotion should be evaluated for sadness, euphoria, and anxiety, and whether such emotions are appropriate to the current situation. This may help distinguish between cognitive disturbance induced by depressive disorders and dementia due to cerebral pathology. An examiner can draw some conclusions regarding a patient's thought processes during the patient's telling of his or her personal history. Disordered thought processes include paranoid or grandiose delusions, fixed false beliefs, and delusional denial of illness. Such beliefs should be compared with reports from family and friends. **Visual hallucinations** can occur in psychiatric illnesses (schizophrenia or affective disorder) but most often result from medical disease; assume medical pathology until proven otherwise. Judgment can be gained by asking the patient to describe how he or she would deal with day-to-day problems, such as finding the way home from the hospital. Judgment may be impaired in medical disease, so ask about historical evidence of faulty judgment.

TABLE 286-5 Mental Status in the ED: An Outline	
Behavior	What is the patient doing?
Affect	What feelings is the patient displaying?
Orientation	Does the patient know what is happening, where, and when?
Language	Is the patient understanding and being understood?
Memory	Can the patient recall historical details, recent and remote?
Thought content	Is the patient reporting beliefs that make little sense?
Perceptual abnormalities	Is the patient experiencing unusual sensory phenomena?
Judgment	Is the patient able to make rational decisions?

COGNITIVE ASSESSMENT

Assess cognitive impairment to identify the presence of dementia or delirium. Cognitive impairment often is not detected in ED patients, despite estimates suggesting that from 26% to 40% of older ED patients are cognitively impaired.[29] There are many tests of cognitive function, from simple to complex, but few have been investigated in the ED.

The **Quick Confusion Scale** consists of seven items and takes about 3 minutes to administer (**Table 286-7**; see also **Table 168-3**). A cut-off of ≤11 points has a sensitivity of 64% and specificity of 85% for identifying cognitive impairment.[30]

Another self-administered screening test for cognitive function is the **clock test**. Give the patient a piece of paper with a circle drawn on it, and ask the patient to "place the numbers on it to make it look like a clock." After completing this task, then ask the patient to place the hands of the clock to read a time such as "10 past 11." Although there are various methods for scoring the clock drawing test, the easiest for ED use is the simplest: correct or not correct. Using a more complex 10-point scoring system, the sensitivity for dementia detection was reported as 76% and specificity was 81%. Clock test results do not appear to be affected by depression.[31]

The **Mini-Mental State Examination** is a widely used tool for assessing cognitive impairment and to follow changes in cognition over time[32] but is not practical for general ED use.

LABORATORY EVALUATION

Obtain laboratory testing based on abnormalities in the history and the physical examination. There is no unanimity between specialties about the need for extensive laboratory testing for all ED psychiatric patients.[33,34] The psychiatric literature reports that 46% to 80% of psychiatric patients have undiagnosed medical illness,[35,36] whereas the emergency medicine literature supports a selective approach to laboratory testing in the ED.[37,38] Often, routine testing is a requirement of the psychiatric consultant or is part of the admission process of the psychiatric hospital.[39,40] The best approach is to collaboratively establish standards for testing on a local level.

For adults with new psychiatric complaints, obtain a through laboratory evaluation including a CBC, electrolytes, liver and renal function studies, urinalysis, and possibly chest radiograph, neuroimaging, or drug and alcohol testing depending on the patient and the circumstances.

Many institutions require drug and alcohol testing for all patients with psychiatric complaints whether the patient admits to substance abuse or not. However, specific drug and alcohol testing is not clinically necessary if the patient admits to using alcohol and drugs when asked and is awake and cooperative.[41] Urine drug testing and blood alcohol concentrations do not correlate with the degree of intoxication. The patient's cognitive abilities, rather than a specific blood alcohol level, should be the basis for assessment. On the other hand, patients with altered mental status without known cause need a complete evaluation including alcohol and drug testing.

One guide for the discretionary use of testing is provided in **Table 286-8**.[41,42] Documenting items in **Table 286-8** can also be used as a communication tool to psychiatrists about the ED evaluation process.

Advanced testing such as radiographs, electrocardiograms, and electroencephalograms should be based on the patient's clinical condition and suspicion for medical illness. CT and related brain imaging should be considered for a clear change in behavior or if an intracranial cause is suspected.

TABLE 286-6 Features of Delirium, Dementia, and Psychiatric Disorder

Clinical Feature	Delirium	Dementia	Psychiatric Disorder*
Onset	Acute, over days	Slow	Varies
Course over 24 h	Fluctuates	Stable	Varies
Consciousness	Reduced or hyperalert	Alert	Alert or distracted
Attention	Disordered	Normal	May be disordered
Cognition	Disordered	Impaired	Rarely impaired
Hallucinations	Visual and/or auditory	Often absent	Usually auditory
Delusions	Transient, poorly organized	Usually absent	May be present
Body movements	Tremor, asterixis, jerks	Often absent	Varies

*Features vary with the type of psychiatric disorder.

The type of diagnostic imaging depends on findings from the history, mental status examination, physical examination, and differential diagnosis.

DIAGNOSIS

Provisional psychiatric diagnoses can be made in the ED to facilitate treatment and disposition. Recognition of specific behavioral syndromes can assist in evaluating the presenting complaint, pursuing associated symptoms, and determining treatment and disposition. Emergency physicians should be sufficiently familiar with commonly seen psychiatric illnesses to describe their predominant clinical features.

The current official diagnostic nomenclature, most recently published in 2000 by the American Psychiatric Association, is the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (text revision), commonly known as DSM-IV-TR.[43] A copy of DSM-IV-TR should be available for reference in the ED, because it contains a list of criteria for each disorder and additional material on demographics, associated symptoms and syndromes, and differential diagnoses. As of this writing, the fifth edition of the DSM is in preparation, and publication is anticipated later in 2013.

The DSM-IV-TR diagnoses are structured on a multiaxial system in which each axis refers to a different domain of information **(Table 286-9)**.[43] This system aids in making a comprehensive assessment, organizing complex clinical information, and communicating with other professionals. **More details concerning selected psychiatric diagnoses are found at the end of this chapter, in the Overview of Axis I to V Disorders section.**

A useful strategy for making a DSM-IV-TR diagnosis is to classify the primary feature into a major category, consider possible nonpsychiatric causes for the complaint, and then use the decision trees in the appendix of DSM-IV-TR to identify the appropriate diagnosis. The decision trees guide the clinician who is unfamiliar with the intricacies of the criteria within a category to identify the features that distinguish closely related conditions. An example of the decision tree for evaluating acute psychosis to determine the diagnosis is shown in **Figure 286-1**. There are five other decision trees that aid in the differential diagnosis and demonstrate the hierarchical nature of the DSM-IV-TR: mental disorders due to a general medical condition, substance-induced disorders, mood disorders, anxiety disorders, and somatoform disorders.

TABLE 286-7 The Quick Confusion Scale (abnormal ≤11 points)

Item	Score
What year is it?	2
What month is it?	2
State short key phrase to remember; have patient repeat it immediately	
What time is it?	2
Count backward from 20 to 1	2
Say months in reverse	2

GENERAL CRITERIA FOR DISPOSITION DETERMINATION

The determination to admit a patient with psychiatric illness from the ED is based on an assessment of danger to self or others and the ability to care for oneself. Some authorities also use additional criteria, such as desire and ability to cooperate with treatment and available support systems.

Many patients may benefit from outpatient or community resources instead of admission.[44,45] Knowledge of the specific options available in one's community helps determine disposition. The web site of the **Substance Abuse and Mental Health Services Administration (www.samhsa.gov)** is an excellent reference for local and community services. Once at the Substance Abuse and Mental Health Services Administration home page, select the "Topics" tab and query the Substance Abuse Treatment Services Locator or the Mental Health Treatment Services Locator. Resources can be identified by state, city, county, or zip code location and insurance status.

Psychiatric services available to the ED can reduce voluntary hospitalizations and increase patient compliance with outpatient visits.[46]

The determination for psychiatric admission is based on the ED psychiatric assessment, sometimes with limited information and most often within a short time frame for assessment. A study involving psychiatrists in four urban psychiatric emergency services identified five variables, in declining order of importance, that predicted admission: level of danger to self, severity of psychosis, ability for self-care, impulse control, and severity of depression.[47]

There are no currently validated tools that help determine the need for admission from the ED. The **Crisis Triage Rating Scale** (**Table 286-10**)[48] was developed by a community hospital's crisis intervention service but has not been validated for ED use. The scale ranks elements from three categories: dangerousness, support system, and ability to cooperate. A clinical scale/score cannot predict future behavior by a patient, but the scale items help in assessment of various factors to determine disposition.

Psychiatric consultation, by psychiatrists or psychiatric social workers, can be very helpful in determining patient disposition, especially when assessing danger to self or need for hospitalization.[49] Telepsychiatry

TABLE 286-8 A Suggested Medical Clearance Checklist*

Does the patient have a new psychiatric condition?	Yes	No
Is there a history of an active medical illness requiring evaluation?	Yes	No
Are there any abnormal vital signs?	Yes	No
Are there any abnormal findings on physical examination (conducted with the patient disrobed and in hospital gown)?	Yes	No
Are there any mental status abnormalities indicating medical illness?	Yes	No

*If the answer to any of the five questions is "Yes," follow with additional testing.

TABLE 286-9 Multiaxial Psychiatric Assessment

Axis I	Mental disorders: schizophrenia and other psychotic disorders; substance-related disorders; malingering; mood disorders; anxiety disorders; sleep disorders; eating disorders; factitious disorders; somatoform disorders; and dissociative disorders Delirium, dementia, and amnestic disorders; mental disorders due to a medical condition
Axis II	Personality disorders and mental retardation
Axis III	General medical conditions Medical conditions that impact mental health
Axis IV	Psychosocial and environmental problems
Axis V	Global assessment of functioning

TABLE 286-10 Crisis Triage Rating Scale

Ranking	Element
	Dangerousness
Most severe	Active SI or HI; current serious SI or HI attempt; unpredictable
	History of violent or impulsive behavior but no current signs
	Ambivalent SI/HI but ineffective gestures
	SI or HI but wants to control behavior
Least severe	No SI or HI and no history of violent or impulsive behavior
	Support System
Worst	None
	Some but limited effectiveness
	Some but not easy to mobilize
	Yes but limited
Best	Yes and good support
	Cooperation
Worst	Not able or refuses
	Little interest in cooperating
	Passive acceptance of help
	Wants help but desire limited
Best	Strong desire for help and will cooperate

Abbreviations: HI = homicidal ideation; SI = suicidal ideation.

can provide psychiatric consultations to facilities that do not have psychiatric resources. It is useful for rural, remote, and isolated populations and for a wide variety of diagnoses, ages, and mental health complaints. This resource can provide consultations, diagnostic assessment, medication management, and family and patient psychotherapy. It can aid in the determination of admission and care for psychiatric boarders.[50]

In the absence of medical indications for admission, refer to a psychiatrist or a psychiatric facility. Provide results of the ED medical and psychiatric evaluation to the consultant. For patients who can safely leave the ED, provide clear discharge instructions, and schedule specific follow-up.

ASSESSMENT OF HARM TO SELF OR OTHERS

The most difficult determination and highest risk is the assessment of self-harm. Assessment of suicide risk requires attention to diagnosis and treatment and to immediate and long-term safety. The interests of other people must be considered, because homicide may be a risk, especially when partner or family conflict exists. A full history is needed, a diagnosis must be reached, and a plan of management must be instituted, all with the patient's involvement insofar as that is possible. Establishing rapport and a therapeutic alliance is critical. The key points in initial assessment and management are summarized in **Table 286-11**.

Arrange privacy for an assessment and show respect and courtesy. Carefully elicit any symptoms of psychological and physical illness. Assess especially for evidence of depression, psychosis, or substance abuse. Identify predisposing and triggering risk factors. Avoid challenging or critical questions. Empathic comments like "You must have been pretty upset" encourage patients to share their difficulties. An open-ended question like "Can you tell me more about it?" is particularly useful. Some patients may resist. When the interviewer stresses the need to understand the story and displays willingness to listen actively, most patients respond and rapport increases. Direct questions may be necessary to elucidate events leading to suicidal ideation and behavior. A

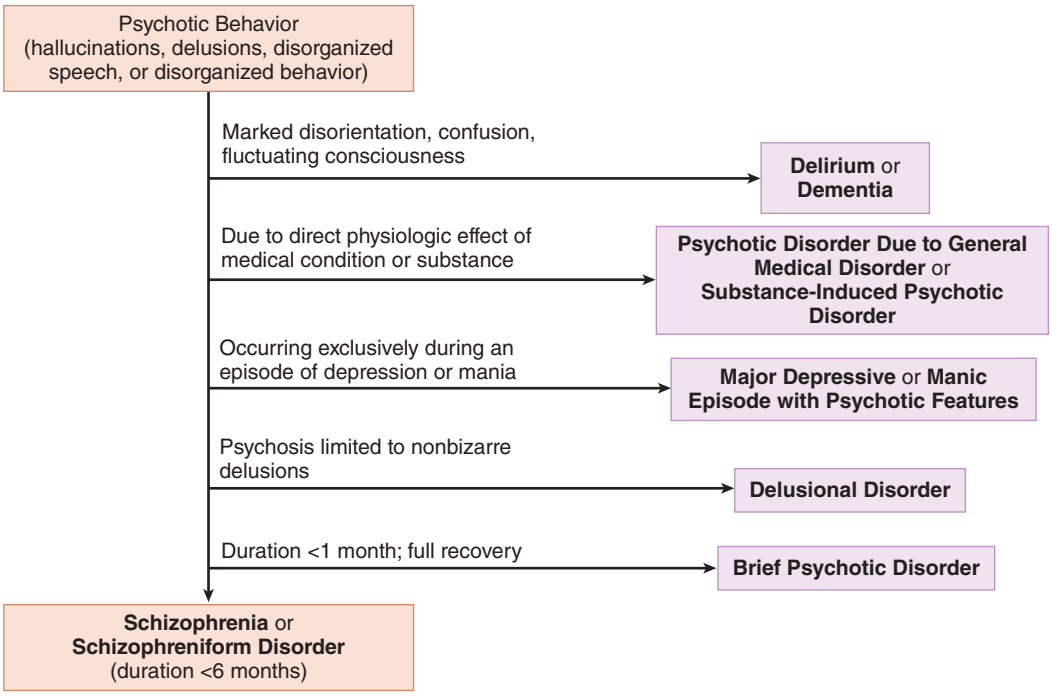

FIGURE 286-1. Decision tree for evaluating psychosis.

TABLE 286-11 Key Points in Assessment and Management of Suicidal Patients

Establish rapport.
Assess suicidal intent.
Determine access to means of suicide.
Assess current mental state.
If no evidence of a mental disorder, offer a safety plan, including help-seeking and problem-solving strategies.
If interpersonal or family issues, allow catharsis and offer problem-solving strategies; consider psychosocial referral.
If a mental disorder is present, arrange appropriate referral or management.
Ensure that a safety plan is in place before discharge.
Arrange follow-up before discharge.

systematic inquiry into stressful life events, relationships with family and other relevant people, and available social supports is always required.

After these are mapped out, decisions about future risk and treatment can be made. In general, risk of further suicidal behavior increases exponentially with increased number of health, mental health, and psychosocial risk factors.

SUICIDE RISK

A useful aid to assessing suicide risk is provided by the acronym **SAD PERSONS**, which is based on the first letters of 10 literature-identified suicide risk factors (**Table 286-12**).[51] Clinical rating scales cannot predict suicide in the individual. Strict cut-off scores should not be used to dictate admission to the hospital. There are at least 31 tests of risk of suicidal intent, but few were designed or validated for ED use. None of these tools have sufficient sensitivity and specificity to predict discharge from the ED. Rather, these tools are components in the determination of suicidal risk and can serve as guides to document the reasons for admission or discharge.

Suicidal intent can be determined based on the degree of planning, the lethality of the method considered, and the existence (and content) of any suicide notes. If patients are asked open-ended questions such as "What were your feelings about living and dying?" or "I guess you had mixed feelings about living and dying" instead of "Did you really want to live or die?" they are better able to verbalize their motivations, including ambivalence. When appropriate tact is used, the question, "What has stopped you from killing yourself so far?" may reveal protective factors and also remind patients of reasons to continue living.

Patients who are single, divorced, separated, widowed, or recently unemployed are at higher risk than those who are married and employed. Recently widowed older white males with access to lethal means (e.g., a firearm) form the population at highest risk for completing suicide in the United States and thus should elicit a very careful evaluation. A psychotic patient who attempts suicide requires careful observation, with whatever restraint is necessary, and evaluation by a psychiatrist. A psychotic patient may respond unpredictably to distorted perceptions in a fearful or driven manner.

TABLE 286-12 SAD PERSONS*

S	Sex
A	Age
D	Depression
P	Previous attempt
E	Ethanol use
R	Rational thinking loss
S	Social supports lacking
O	Organized plan
N	No spouse
S	Sickness

*Each factor is assigned 1 point, and patients who score ≥5 points should be considered at high risk of suicide.

Source: Reproduced with permission from Patterson WM, Dohn HH, Bird J, Patterson GA: Evaluation of suicidal patients: The SAD PERSONS Scale. *Psychosomatics* 24: 343, 1983. Copyright Elsevier.

An important opportunity to assess future suicide risk is provided by asking patients their thoughts and feelings during the interview immediately after the suicide attempt.[52,53] For some patients, self-injury or suicide attempts appear to serve as a form of catharsis or emotional release, similar to weeping, talking to a friend, or becoming inebriated. Such patients did not undertake the attempt to die and do not identify the event as an attempt to do so. Often such patients may describe the attempts as being made when they were feeling angry, hurt, humiliated, ashamed, or vengeful and wanted to hurt others or extract a reaction from others. Patients who indicate remorse, shame, or embarrassment at having made a suicide attempt generally appear to have a lower risk of further suicidal behavior than those who do not show these responses. A patient who sits quietly; engages poorly with the physician; voices regret at surviving; expresses feelings of hopelessness, helplessness, or exhaustion; and refuses to provide additional information should be considered at high risk.

Secondary Gain *Secondary gain* is a term that indicates that although the primary motive for a suicide attempt appears to be death, the attempt may meet another need, such as a desire to gain attention or receive emotional help. When such needs are met by the attempt, a secondary gain is achieved, and the risk of subsequent suicide attempt is lessened momentarily. It is dangerous, however, to assume that secondary gain is the cause of a suicide attempt during an initial evaluation in an ED. All suicide behaviors should be taken seriously.

SUICIDE RISK AND DISPOSITION

Patient disposition can be assessed by estimating the lethality of the attempt and the likelihood of rescue, with the patient's perceptions and understanding of these taken into account. When there is a high likelihood of rescue and low lethality, there may be a lower risk of further suicidal behavior than if the possibility of rescue was remote and the patient believed the lethality of the agent or method was high. A patient who attempted suicide by hanging in an isolated area of the woods is at greater risk than a person who swallowed a few tablets of a substance of relatively low toxicity in front of witnesses.

Patients who have made previous suicide attempts are at greater risk for further suicide attempts and for suicide. Prior attempts are a particularly significant warning if the intensity and apparent lethality of the suicide attempts escalate with each subsequent attempt. **Table 286-13** provides details of assessment.

Table 286-13 also provides high-risk and low-risk suicide profiles. **High-risk patients** with strong, pervasive suicidal intent require psychiatric hospitalization. **Moderate-risk patients** are those who present in a serious suicidal crisis but who, because of a positive response to initial intervention and favorable social support, may not be in immediate danger. Hospitalization can often be avoided for such patients, provided outpatient treatment can be established immediately and the patient engages with treatment. Such disposition decisions are most often made in concert with a psychiatric consultant. Before discharge, develop a safety plan with the patient and the patient's family, remove available means of suicide (such as firearms or drug supplies), prescribe conservative amounts of psychotropic medication (usually no more than a 2-week supply), and provide help-seeking advice and problem-solving strategies. It is important to have a family member take responsibility for managing a patient's medications.

Low-risk patients frequently present with suicidal ideation, threats, plans, or minor attempts that occur in the context of a clearly definable external crisis. Family and social support is usually readily available, caring, and sympathetic. Low-risk patients with the following stipulations may be discharged from the emergency department: medical treatment not needed, no prior suicidal attempt, not actively suicidal, adult in house with good relationship, adult agrees to monitor, adult will remove guns and medications, contact for deterioration available, follow-up

TABLE 286-13 Evaluation of Suicide Risk in Adults

Demographic, Health, and Social Profile	High Risk	Lower Risk
Gender	Male	Female
Marital status	Separated, divorced, or widowed	Married
Family history	Chaotic, conflictual	Stable
	Family history of suicide	No family history of suicide
Job	Recently unemployed	Employed
Relationships	Recent conflict or loss of a relationship	Stable relationships
School	In disciplinary trouble	No disciplinary problems
Religion	Weak or no suicide taboo	Strong taboo against suicide
Health	Acute or chronic, progressive illness	Good health
Physical	Excessive drug or alcohol use	Little or no drug or alcohol use
Mental	Depression (SIG E CAPS + MOOD)*	No depression
	History of schizophrenia or bipolar disorder	No psychosis
	Panic disorder	Minimal anxiety
	Antisocial or disruptive behavior	Directable, oriented
	Feelings of helplessness or hopelessness	Has hope, optimism
	Few, weak reasons for living	Good, strong reasons for living
	Unstable, inappropriate affect	Appropriate affect
Suicidal ideation	Frequent, intense, prolonged, pervasive	Infrequent, low intensity, transient
Suicide attempts	Repeated attempts	No prior attempts
	Realistic plan, including access to means	No plan, lacks access to means
	Previous attempt(s) planned	Previous attempt(s) impulsive
	Rescue unlikely	High likelihood of rescue
	Lethal method	Method of low lethality
	Guilt	Embarrassment about suicide ideation
	Unambiguous or continuing wish to die	No previous or continuing wish to die; large appeal component
Relationship with health professional	Lacks insight	Insight
	Poor rapport	Good rapport
Social support	Unsupportive family, friends	Concerned family, friends
	Socially isolated	Socially integrated

*SIG E CAPS + MOOD is a mnemonic for the eight symptoms of depression plus depressed mood: S = sleep disturbance; I = loss of interest in usual pleasurable activities; G = guilt; E = loss of energy; C = inability to concentrate; A = loss of appetite; P = psychomotor slowing; S = suicidal thoughts; MOOD = depressed mood (i.e., "Have you felt blue, down, or depressed most of the day for most days in the last 2 weeks?"). Fulfillment of five or more of the eight items from the list of eight symptoms indicates the presence of major depression. Symptoms must be present nearly every day for 2 weeks and must include depressed mood or loss of interest or pleasure in activities. Symptoms must represent a change from previous functioning resulting in social, occupational, or other life impairment, and they cannot be the direct result of substance use, a medical condition, or bereavement.

arranged, and patient and support group agreement to plan and recommendations.[54]

Before discharge, ensure that good social support is available to the patient. Social support includes a place to live and family or friends who will support the patient emotionally. Obtain agreement that a supportive individual can spend the next 24 hours with the patient.

However, because many attempts that appear trivial on first glance are found to have more serious implications on closer examination, carefully assess all patients coming to the ED after a suicide attempt. If there are any concerns about the safety of discharging a suicidal patient and psychiatric consultation is not immediately available, hospitalize the patient involuntarily.

No-Harm Contracts "**No-harm contracts**" or "suicide prevention contracts" have sometimes been used as a method to lower suicidal risk. Typically, the no-harm contract is a verbal or written agreement initiated by the physician or psychiatrist in which the suicidal patient agrees not to harm or kill himself or herself and to adopt agreed-upon help-seeking behaviors if a crisis arises. Although proponents argue that the no-harm contract can be therapeutic by helping to reveal the intent of the patient and reduce it, and diagnostic by eliciting the nature and severity of a patient's suicidality, there is little evidence that such contracts prevent further suicidal behavior.[54] Currently, the use of no-harm contracts is not supported. Rather, the preparation of a joint safety plan with the patient and the patient's family or a commitment by the patient to treatment is more likely to be of therapeutic benefit.

Self-Injury Behaviors Young adult and adolescent patients may present to the ED because of self-harm behaviors that are not dangerously suicidal but nonetheless require both medical and mental health care.[29] Typically, such patients cut or scratch their arms to "relieve tension" or burn themselves in an effort to feel a certain way. Females tend to more often cut themselves, while young men tend more often to burn themselves. Such acts are usually heralded by a state of mounting tension with depersonalization, followed by relief after the self-mutilating behavior. Self-injury is usually not suicidal behavior but rather a poorly learned coping mechanism that is used to reduce tension, self-soothe, and communicate feelings. For most young patients, self-injurious behavior appears to be time-limited and linked to problems with parents and is not associated with severe clinical symptoms or suicidality. However, some self-injuring patients do have clinical symptoms including high anxiety and active suicidality. In addition to tetanus prophylaxis and wound care, assess

patients for suicidal ideation and further plans for self-harm. Nonsuicidal self-harm or self-mutilatory behaviors are seen in patients who may insert foreign bodies into their bladder, rectum, nose, or other orifices and may require GI or surgical intervention. Outpatient psychiatric follow-up and evaluation are usually appropriate for this type of behavior.

VIOLENCE TOWARD OTHERS

Potential victims who are clearly identified may need to be warned.[55] This can be done through the psychiatric consultant or hospital or local police. Clues that suggest potential violence include hostile behavior; homicidal ideas, fantasies, or preoccupations; verbal aggressiveness; statements about violent intent; weapons skill and access; motives for violence; and preattack planning and preparation.[55] Patients need immediate hospitalization.

ED TREATMENT

Treatment of acute agitation is discussed in detail in chapter 287, "Acute Agitation."

Psychiatric patients who are noncompliant to their psychotropic medications need to be restarted on their medications. Mental health patients with a new psychiatric diagnosis also need to start treatment. For schizophrenic patients, haloperidol 2 to 5 milligrams IM and lorazepam 1 to 2 milligrams IM have the quickest effect. Oral risperidone (Risperdal®) 3 to 6 milligrams per day or olanzapine (Zyprexa®) 15 milligrams daily also may be useful. Do not given benzodiazepines with olanzapine, because the two drugs coadministered can result in hypotension an hour later. Historically, it takes weeks to months for antidepressant medications to have a clinical effect, and so medications are not typically started in the ED unless in close consultation with the follow-up psychiatric provider.

Ketamine is proposed as a quick treatment for depression and suicidal ideation. Ketamine results in improvement within 2 hours and has an effect after 24 hours.[56] In a small trial of suicidal patients, 15 suicidal patients received a subanesthetic IV dose of ketamine. Thirteen of 14 patients were completely free of suicidal ideation at 10-day follow-up.[57]

Some advocate for treatment of suicidal patients in the ED. Techniques include a brief intervention, enhanced follow-up, video patient education, and family therapy, with a rapid ED response team consisting of a psychiatrist and psychiatric nurse or social worker. Such programs depend on sufficient ED resources and the ability to arrange solid follow-up.[58-60]

PSYCHIATRIC BOARDERS IN THE ED

Unfortunately, a nationwide scarcity of inpatient psychiatric beds has led to the phenomenon of "psychiatric boarders," patients staying for days in the ED before psychiatric admission. Psychiatric boarders have also increased because some patients are sent to the ED for conflict resolution or respite from family, group home, or nursing home. The ED becomes the arbitrator in social issues that are better handled by police, counselors, or social workers. Boarding psychiatric patients is thought to result in premature ED discharge,[61] increased complications while in the ED, escalated medical and psychiatric problems, and reduced ED efficiency. Psychiatric boarders in the ED stay longer in the ED than other patients.[62]

Protocols for appropriate use of the ED for these patients and alternative care sites need to be explored, such as mobile crisis teams, expanded use of social workers, and police training in crisis intervention.[63] Community treatment consisting of supportive services, case management, emergency care, medications, and assistance of daily living can reduce ED use. Mobile crisis units can provide crisis stabilization in patient homes.

PSYCHIATRIC OBSERVATION UNITS

The best option for reducing psychiatric admissions is the acute psychiatric stabilization unit, which is similar to medical observation units. Acute psychiatric stabilization units are usually managed by psychiatric services, whereas medical observation units are often managed by the emergency service. Psychiatric stabilization units provide psychiatric assessment, crisis stabilization and drug treatment, and linkage with community resources before discharge. Acute stabilization of psychiatric patients allows time for diagnostic clarity, development of alternatives to admission, and a respite for the patient and family.[64]

OVERVIEW OF AXIS I TO V DISORDERS

Axis I disorders include the clinical syndromes of mental disorders (**Figure 286-2**). For more than one axis I diagnosis, list the most important diagnosis first. **Axis II** includes personality disorders and developmental disorders, including mental retardation (**Figure 286-3**). The presence of axis II disorders complicates management of all other axis disorders. **Axis III** encompasses general medical conditions that are or could be relevant to the understanding or management of the patient's psychiatric illness. **Axis IV** consists of psychosocial and environmental stressors or problems. Axis IV conditions relate to primary support group, social environment, and educational, occupational, housing, economic, healthcare access, and legal issues. **Axis V** relates to the patient's current overall functioning using the global level of functioning scale. This scale ranges from 0 to 100, with 0 representing persistent danger to self or others and 100 indicating superior functioning in a wide range of

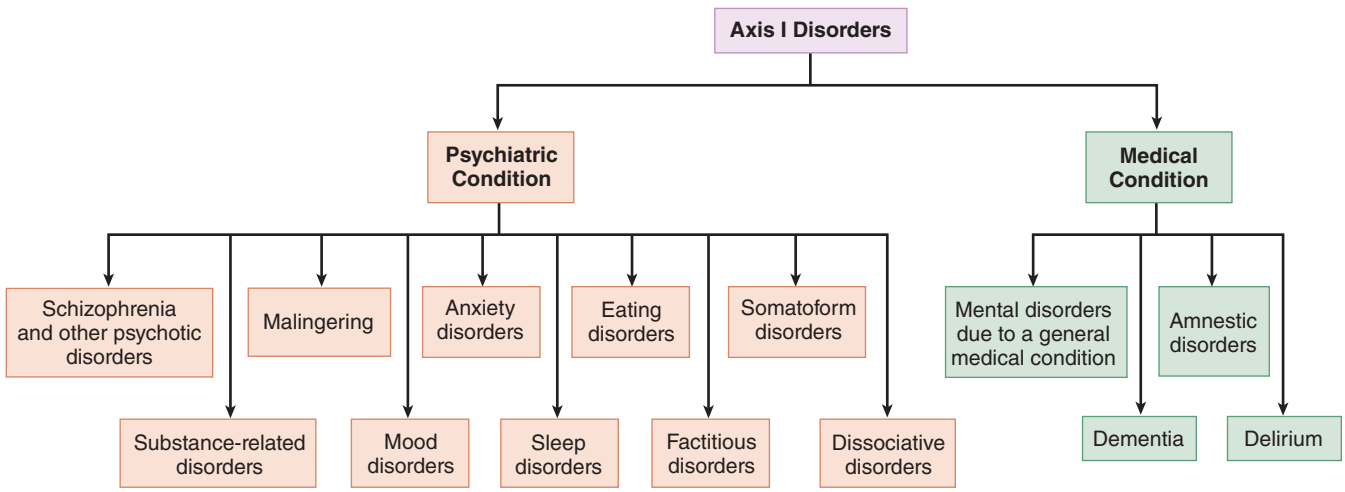

FIGURE 286-2. Axis I disorders (psychiatric syndromes).

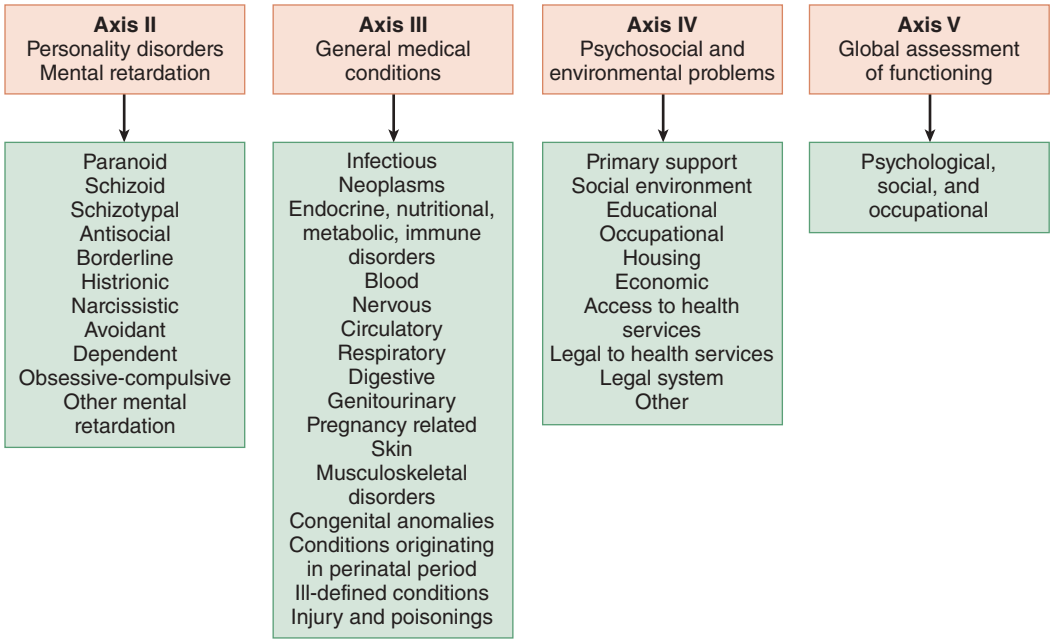

FIGURE 286-3. Axis II to V disorders.

activities. The axis I disorders most clinically relevant to ED practice are summarized below.

AXIS I: PSYCHOSES

SCHIZOPHRENIA

Schizophrenia is the most prevalent psychosis. The essential features of schizophrenia are a deterioration in functioning, characteristic positive symptoms (hallucinations, delusions, disorganized speech, disorganized behavior, and catatonic behavior), negative symptoms (blunted affect, emotional withdrawal, lack of spontaneity, anhedonia, and attentional impairment), cognitive impairment manifested by loose associations or incoherence for at least 1 month, and the relative absence of a mood disorder. Schizophrenia is most likely a group of disorders with different causes that share a final common pathway. There is no evidence that psychosocial stressors or poor parenting is responsible for causing the illness, although these may have a profound effect on the patient's adaptation to this usually chronic disorder.

Symptoms of schizophrenia usually begin in late adolescence or early adulthood, although the onset can occur at any age. The childhood history of schizophrenics often is marked by shyness, odd or eccentric behavior, school difficulties, or paranoid behaviors, but such features are not always present. A prodromal phase, in which a gradual deterioration of function is noted, usually precedes the development of active delusions or hallucinations. Such deterioration usually includes the worsening of social withdrawal or the new onset of social withdrawal, odd behavior or speech, and difficulty in functioning at school or work. Patients or their families rarely seek care until the onset of the active phase of psychosis. Schizophrenic individuals seldom seek care at all because they lack insight; they do not realize that their perceptions, thoughts, and behavior are abnormal.

Disorganization of thinking and behavior characterizes schizophrenia. Disheveled appearance and poor grooming, bizarre behavior, poor judgment, and loosening of associations indicate such disorganization.

SCHIZOAFFECTIVE DISORDER

Schizoaffective disorder is diagnosed when the patient has depression, mania, or mixed episode together with classic schizophrenic symptoms such as delusions, hallucination, disorganized speech, disorganized or catatonic behavior, and affect flattening. Delusions or hallucinations need to occur for at least 2 weeks after the mood symptoms have ceased. The mood symptoms should be present for a substantial portion of time and not be due to drug use or medical conditions.

BRIEF PSYCHOTIC DISORDER

Some individuals may become acutely psychotic after exposure to an extremely traumatic life experience. If such a psychosis lasts for <4 weeks, it is termed a brief psychotic disorder. Precipitants include the death of a loved one or a life-threatening situation such as combat or a natural disaster. Emotional turmoil, confusion, and extremely bizarre behavior and speech are common in this disorder.

AXIS I: SUBSTANCE-RELATED DISORDERS

Substance-related disorders are due to ingestion of a drug of abuse or alcohol, side effects of a prescribed or over-the-counter medication, toxic exposure, or substance withdrawal.[43] The specific features of intoxication syndromes commonly seen in the ED are described in chapters on specific agents in the Toxicology section (Chapters 176 to 207) and Chapter 292, Substance Use Disorders.

The diagnosis of withdrawal is made by identifying the withdrawal toxidrome and evidence of recent use of the substance in a pattern sufficient to produce withdrawal when the amount ingested is decreased or stopped. Specific withdrawal patterns depend on the agent.

AXIS I: MALINGERING

Malingering is the intentional invention or exaggeration of physical or psychological symptoms for external gain. The external gain may be maladaptive to avoid work or obtain drugs, or adaptive in response to being an enemy combatant in wartime. Malingering is distinguished from factitious disorders by the presentation of symptoms for a known secondary gain.

AXIS I: MOOD DISORDERS

The mood disorders are the most prevalent of the major psychiatric disorders. The lifetime prevalence of mood disorders in the age group of 17 to 39 years was reported as 11.5% in the National Health and Nutrition Examination Survey III.[65]

Mood, or affective, disorders differ from the normal extremes of sadness and happiness in that characteristic clusters of psychological and vegetative symptoms (depressive or manic syndrome) are present, and functioning is impaired. Depressive disorders are the major cause of completed suicide.

Mood disorders tend to be episodic, with periods of remission and normal function. Any of the features of schizophrenia such as delusions, hallucinations, or disorganization may be present, but if a full depressive or manic syndrome exists, the diagnosis is likely psychotic mood disorder. The more common mood disorders are briefly discussed in the following sections.

MAJOR DEPRESSION

The essential features of major depression are a persistent sad or depressed (dysphoric) mood or pervasive loss of interest in usual activities lasting for at least 2 weeks. Associated psychological symptoms include guilt over past deeds, self-reproach, feelings of worthlessness or hopelessness, inability to experience pleasure, and recurrent thought of death or suicide. Vegetative symptoms involve physiologic functioning and include weight loss or gain, sleep disturbance, fatigue, inability to concentrate, and psychomotor agitation or retardation. Depression may begin gradually or rapidly but is usually present for several weeks before the patient seeks help.

Major depression is often superimposed on other mental disorders, such as substance abuse, personality disorders, and anxiety disorders, and such conditions are frequently comorbid conditions. Major depression is often recurrent, so certain patients must be maintained on long-term treatment to prevent relapse.

DYSTHYMIC DISORDER

Dysthymic disorder is a more chronic and less severe form of depressive illness and was previously termed depressive neurosis. Depressed mood must have been present most of the day, more days than not, for at least 2 years. Psychotic features are not seen, and patients with this disorder often have a lifelong gloomy, pessimistic outlook. Women are affected more often than men, and the onset is typically in childhood, adolescence, or early adulthood.

BIPOLAR DISORDER

Bipolar disorder, previously termed manic-depressive illness, is characterized by periods of mania cycling with periods of depression. A full manic syndrome is one of the most striking and distinctive conditions in clinical practice. The essential disturbance in mood is one of elation or irritability. Manic patients feel "on top of the world," expansive, and energetic. The state is precarious, however, and patients may quickly become argumentative, hostile, irritable, and sarcastic, especially when their plans are thwarted. Bipolar disorders are classified into types I and II based on the presence of mania, which is found in bipolar I disorder and not found in bipolar II.

The disorder is equally common in men and women, and the onset is usually in the third and fourth decades. Complications include suicide, substance abuse (excessive alcohol use is common during the manic phase), and marital and occupational disruptions. The course of bipolar disorder is episodic, with the duration, frequency, and regularity of the episodes varying greatly. Depressive episodes are more frequent than manic episodes.

AXIS I: ANXIETY DISORDERS

The anxiety disorders are mental disorders in which apprehension, fears, and excessive worry dominate the psychological life of the individual. Pathologic degrees of anxiety are accompanied by different degrees of autonomic activity (sweating, tachycardia, or dizziness) out of proportion to any real danger or threat. Because anxiety is a ubiquitous condition and frequently associated with medical illness, depression, neurologic syndromes, and psychoses, a diagnosis of a primary anxiety disorder is made after exclusion of other causes.

PANIC DISORDER

Patients who experience recurrent attacks of severe anxiety are said to suffer from panic disorder. A panic attack consists of a sudden extreme surge of anxiety and dread accompanied by autonomic signs, including palpitations, tachycardia, shortness of breath, chest tightness, dizziness, sweating, and tremulousness. The symptoms develop over a few minutes at most and may be unprovoked or stimulus related.

GENERALIZED ANXIETY DISORDER

When anxiety attacks are absent but the patient complains of persistent worry, tension, or free-floating anxiety, a diagnosis of generalized anxiety disorder should be considered. This condition lasts at least 6 months and is characterized by apprehensive worrying, muscle tension, insomnia, irritability, restlessness, jumpiness, or distractibility. Associated autonomic symptoms include the cardiopulmonary, GI, and neurologic symptoms that are seen in panic attacks.

POSTTRAUMATIC STRESS DISORDER

Posttraumatic stress disorder is an anxiety reaction to a severe psychosocial stressor, such as military combat, fire, rape, a terrorist event, or natural disaster. Symptoms involve repetitive and intrusive memories of the event, nightmares, emotional numbing, survivor guilt, and different degrees of depression and anxiety. Substance abuse is a frequent complication.

OBSESSIVE-COMPULSIVE DISORDER

Obsessive-compulsive disorder is a mental disorder in which the patient experiences intrusive thoughts or images that cannot be eliminated from the mind. Typical thoughts involve images of graphic violence to self or others, contamination, or perverse sexual behavior that the patient would not carry out but nevertheless obsessively fantasizes about. To control the obsessive thoughts, the individual may engage in compulsive behavior or rituals, such as excessive washing, repetitive checking, or counting. When the obsessions and compulsions occupy a great deal of time, the patient may become significantly disabled and seek psychiatric attention.

AXIS I: SLEEP DISORDERS

Sleep disorders include hypersomnia, insomnia, and narcolepsy. Hypersomnia and insomnia can occur in association with other mental disorders. Narcolepsy is a neurologic sleep disorder, not caused by a mental disorder.

AXIS I: EATING DISORDERS

The eating disorders anorexia nervosa and bulimia nervosa are discussed in chapter 291, "Eating Disorders."

AXIS I: FACTITIOUS DISORDERS

Factitious disorders are characterized by physical or psychological symptoms that are exhibited in order to assume a sick role. Patients may fabricate complaints, falsify vital sign values, self-inflict an illness, or exaggerate a preexisting medical condition. A factitious disorder demonstrates a psychological need to be in the sick role without external incentives. Munchausen syndrome is an extreme form of this disorder. Munchausen by proxy, or factitious disorder by proxy, is inducing or fabricating disease in a child to get medical attention.

AXIS I: SOMATOFORM DISORDERS

Many patients have particular complaints or symptoms for which no medical explanation can be identified. These symptoms must cause the patient significant distress or impairment in social, occupational, or other areas of functioning. When a physical cause has been clearly eliminated and the complaint is not delusional or occurring in the context of a depression or anxiety disorder, somatoform disorders may be considered in the differential diagnosis. When the complaint involves a loss of function, usually in the neurologic system (e.g., paralysis, blindness, or numbness) and psychological factors are deemed etiologic, a conversion disorder may be present. **Conversion disorders** are much more common in culturally and psychologically unsophisticated persons. This diagnosis should be made with extreme caution, if at all, in the ED, because studies indicate that many patients (up to 50%) diagnosed with conversion disorder eventually develop signs of a physical disorder that explains the symptom.

Some patients have a wide variety of complaints and long, complicated histories of medical problems that have no apparent medical cause. Such individuals may have somatization disorder, a disorder beginning in the teens and twenties, usually in women, and leading to considerable unnecessary diagnostic and surgical intervention. The prototypical patient is a middle-aged woman who describes a "positive review of systems" in a dramatic and confusing way. As with conversion disorder, a diagnosis of somatization disorder should not be made on the basis of an ED visit, but the identification of somatizing behavior is useful for future reference, because patients frequently make repeated contacts with medical providers.

AXIS 1: DISSOCIATIVE DISORDERS

The dissociative disorders comprise a group of uncommon and poorly understood conditions in which the central feature is a sudden alteration in the normal integration of identity and consciousness. The dissociation often occurs under severe stress and may or may not be recurrent, although it is rarely permanent. The forms of dissociative state relevant to emergency practice are dissociative amnesia, a temporary loss of memory for important personal details related to a traumatic or stressful situation that is not due to a medical cause, and dissociative fugue, in which a similar loss of memory and assumption of a new identity are accompanied by travel away from home. Dissociative disorders are difficult to distinguish from malingering, in which an individual in pursuit of a clear goal, such as avoiding incarceration or military duty, may consciously feign amnesia. As always, medical illnesses and drug intoxication that may cause loss of memory, such as that resulting from transient global amnesia, must be ruled out.

AXIS I DISORDERS: MEDICAL CONDITIONS

This group of syndromes includes dementia, delirium, amnestic disorders, and other cognitive disorders characterized by a clinically significant deficit in cognitive or memory function due to a general medical condition. Dementia and delirium are also discussed in chapter 288, "Mental Health Disorders of the Elderly." Refer to **Tables 286-6** for features of delirium and dementia.

DEMENTIA

Dementia is a pervasive disturbance of cognitive functioning in several areas, including memory, abstract thinking, judgment, personality, and other higher cortical functions such as language. If clouding of consciousness is present, then the patient does not have solely a dementing illness but has delirium, intoxication, or withdrawal. The presence of global cognitive impairment may be detected through the use of a bedside cognitive examination (see **Table 286-7** and the **clock test**). Early in the course of dementia, anxiety, depression, or psychosis may dominate the clinical picture and obscure cognitive dysfunction. Maintain a high degree of clinical suspicion for dementia when evaluating an elderly patient with no prior psychiatric history who develops new psychiatric problems. Dementia is discussed in more detail in chapter 288, "Mental Health Disorders of the Elderly."

DELIRIUM

Delirium is characterized by global impairment in cognitive function but is distinguished from dementia in two major ways. In delirium, the patient has clouding of consciousness, a reduction in the awareness of the external environment (manifest as difficulty sustaining attention), varying degrees of alertness ranging from drowsiness to stupor, and sensory misperception. In most patients, an underlying general medical condition, substance intoxication, or withdrawal or medication use is the cause of the delirium. Delirium must be distinguished from psychiatric illnesses such as psychotic, mood, anxiety, and stress disorders. There is a long list of causes of delirium, including intoxicants, withdrawal syndromes, infections, trauma, seizures, endocrinopathies, inflammatory processes, shock, organ failure, and neoplasia.

The primary distinguishing feature of delirium is a typical acute course, with rapid deterioration in hours or days, rather than in months as with dementia. Also, the severity of delirium fluctuates over the course of hours; the patient may appear normal at one time and wildly agitated a few hours later. Hallucinations, often visual, are common. Delirium is discussed in more detail in chapter 288.

AMNESTIC DISORDERS

Amnestic patients typically are unable to learn new information or to recall information that is already learned. Amnestic disorders cause a problem in carrying out social and occupational functions and are not part of delirium or dementia. Causes of amnestic disorder include brain trauma, stroke, carbon monoxide poisoning, substance abuse, and chronic nutritional deficiency. Acute onset of amnesia needs to be carefully investigated.

MENTAL DISORDERS DUE TO A GENERAL MEDICAL CONDITION

When there is evidence that a psychiatric disturbance is a direct physiologic consequence of a general medical condition or substance, the mental disorder is specified as "due to" the medical problem, for example, "major depression due to hypothyroidism." The mental condition cannot be caused by another mental disorder, and it cannot be part of the course of delirium.

The diagnostic features of mental disorders due to a general medical condition rely on evidence from patient history, physical examination, and laboratory results indicative of a causative medical condition. Sometimes the cause cannot be determined in the ED, and the patient may need admission for further evaluation. General medical conditions may cause amnestic, psychotic, mood, and anxiety disorders.

CHAPTER 287

Acute Agitation

Shauna Garris
Caitlin Hughes

INTRODUCTION AND EPIDEMIOLOGY

EDs are the portal of access to the healthcare system for most patients with acute agitation and acute behavioral or mental health disorders.[1] Agitation is one of the most common manifestations of mental health and behavioral disorders, dementia, and intoxication and withdrawal syndromes. The last consensus updates for acute agitation were published in 2006,[2] prior to the release of newer therapeutic agents and prior to the recognition of QT_c prolongation with acutely administered psychotropics. This review provides a general pharmacotherapeutic approach for acute agitation and acute behavioral emergencies.

GENERAL THERAPEUTIC APPROACH

Try to obtain vital signs, obtain a patient history and perform a physical examination, and obtain baseline laboratory data. Psychosis, mania, withdrawal syndromes, drug intoxication, delirium, or even depression and anxiety can cause psychomotor agitation, aggressive behaviors, or disorientation. Other causes of acute agitation include adverse effects of medications, pain, substance abuse, or worsening of a chronic underlying illness.

TABLE 287-1 Comparison of Important Adverse Effects of Agents for Acute Agitation

	Benzodiazepines	Typical or First-Generation Antipsychotics	Atypical or Second-Generation Antipsychotics
Somnolence	++	+	+
Postural hypotension	+	+/–	+/–
Extrapyramidal symptoms	–	++	+
Respiratory depression	+	–	+/–
Neuroleptic malignant syndrome	–	+	+
QT_c prolongation/ torsades de pointes	–	+	+
Paradoxical CNS disinhibition	+	–	–

The most important goal in the care of the agitated patient is ensuring the safety of the patient and staff involved. Management of the patient's undifferentiated agitation ensures immediate safety and allows a more thorough evaluation for serious acute pathology.

Provide a sitter and try to address patient comfort needs. Decrease external stimuli by placing the patient in a quiet room. Remove potentially dangerous objects from the immediate environment. Use physical restraints if there is imminent harm to healthcare workers, other patients or visitors, or the patient him/herself.[1-4]

When considering pharmacologic treatment options, assess the underlying diagnosis, presenting signs and symptoms, and potential risks/benefits of specific agents (**Tables 287-1** and **287-2**), and determine the proper dose and easiest mode of administration. Because the oral and parenteral routes are equivalent for some agents,[5-8] offer oral agents first, if appropriate and feasible. If repeated dosing is needed, try to wait 1 hour before the next dose to adequately assess patient behavior and medication effect. Generally, all antipsychotics have similar efficacy at comparable dosages and may be used to treat acute agitation.

The FDA recommends evaluating the QT_c interval prior to the use of many of these agents, because all antipsychotic agents carry a bolded warning for altered cardiac conduction and risk of fatal arrhythmias. In clinical situations in which rapid tranquilization is necessary, prior determination of the QT_c interval is usually impractical and often impossible. If an electrocardiogram is available from a prior hospital visit, review it for evidence of QT_c prolongation.

The QT interval is used as a surrogate marker for the potential development of abnormal cardiac conduction. In general, the QT_c interval is considered prolonged when it is ≥450 milliseconds in men and 460 milliseconds in women.[9] **Medication-induced QT_c prolongation is considered highly significant at ≥500 milliseconds.**[9-12] Unfortunately, **QT_c prolongation does not directly correlate with clinical risk of dysrhythmias or the development of the malignant arrhythmia torsade de pointes**.

PHARMACOLOGY OF AGENTS FOR AGITATION

BENZODIAZEPINES

Of the benzodiazepines, **lorazepam** is the agent with the highest level of guideline and literature support for acute use and is considered first-line therapy in the treatment of undifferentiated agitation. Much of this preference is due to its availability for administration by the PO, IM, PR, or IV route; relatively quick onset of action; and lack of active hepatic metabolites. Benzodiazepines bind to benzodiazepine-1 receptors on the postsynaptic γ-aminobutyric-A receptor, which results in increased influx of chloride ions into the postsynaptic neuron, leading to hypoexcitability and neuronal stabilization.[13]

The initial dose of lorazepam for acute agitation is 2 milligrams, with repeated dosing, if needed, given at least 30 minutes after the initial dose. Cumulative studied dosage is 4 milligrams over 2 to 4 hours; however, dosage regimens of up to 8 milligrams have been described.[14-16] Onset of action is 0.5 to 1 hour, with a duration of 6 to 8 hours and a terminal half-life of 12.9 hours in adults that is extended to 15.9 hours in the elderly and up to 72 hours in patients with renal failure.

Lorazepam is effective in both undifferentiated and psychotic agitation, and 2 milligrams may be as effective 5 milligrams of haloperidol, with additive benefits when given in combination with other agents (except olanzapine).[5,14,17] The most common adverse effect of lorazepam or other benzodiazepines is sedation, and sedation is greater than that with haloperidol alone.[5,14] Lorazepam can cause respiratory depression and hypotension, particularly with repeated and high-dose administration. Another notable adverse effect is paradoxical agitation, or activation or worsening of confusion, most commonly seen in patients with delirium and in the elderly.

TYPICAL, OR FIRST-GENERATION, ANTIPSYCHOTICS

Typical antipsychotics are also called first-generation or conventional antipsychotics, classic neuroleptics, or major tranquilizers. This class of drugs blocks dopamine receptors and is strongly associated with extrapyramidal symptoms, such as dystonias, akathisia or restlessness, and parkinsonism, and anticholinergic blockade (dry mouth,

TABLE 287-2 Considerations When Treating Acute Agitation

Subgroup of Patients	Special Considerations
Agitation caused by alcohol/substance abuse Agitation of unknown origin	Consider benzodiazepine for added benefits of preventing potential withdrawal symptoms.
Agitation caused by psychosis/mania	Consider typical/atypical antipsychotic over benzodiazepine to concomitantly treat underlying psychosis; also beneficial when conversion to PO required.
Agitation caused by dementia	Consider atypical antipsychotic (especially if elderly) and use lowest effective dose.
Elderly	If using a benzodiazepine, use lorazepam, oxazepam, or temazepam ("LOT") because these are metabolized via glucuronidation and are safest. Consider atypical antipsychotic over typical antipsychotic, but use lowest effective dose and be aware of FDA Black Box warning in elderly.
History of seizures	Avoid haloperidol and atypical antipsychotics (lower seizure threshold); consider benzodiazepine.
Recent history of MI	Ziprasidone is contraindicated.
Prolonged QT_c	Benzodiazepines first choice; atypical antipsychotics second choice; typical antipsychotics last choice.
Concern for bradycardia or hypotension	Avoid olanzapine (and especially avoid olanzapine + benzodiazepine because this increases risk).
Uncooperative patient requiring rapid tranquilization	Consider IV or IM route.

Abbreviations: FDA = U.S. Food and Drug Administration; MI = myocardial infarction.

TABLE 287-3 Potency of Typical Antipsychotics Commonly Used for Agitation

Generic Name	Brand Name	D_2 Receptor Potency	FDA Warning or Concern	Available Routes of Administration
Chlorpromazine	Thorazine®	Low	QT_c prolongation	PO, IM
Fluphenazine	Prolixin®	High		PO, IM
Haloperidol	Haldol®	High	QT_c prolongation with high-dose or IV administration	PO, IM, IV
Droperidol	Inapsine®	High	QT_c prolongation, even with no risk factors Not approved by FDA for treatment of agitation	PO, IM, IV

Abbreviation: FDA = U.S. Food and Drug Administration.

hypotension, glaucoma exacerbation, delirium). Typical antipsychotics are classified as low, intermediate, or high potency when compared to 100 milligrams of chlorpromazine (Thorazine®). Low-potency typical antipsychotics tend to be more sedating and are associated with hypotension, dizziness, and anticholinergic symptoms. High-potency medications are less sedating but are associated with extrapyramidal symptoms (**Table 287-3**).

Agents commonly used for acute agitation within this class include haloperidol, fluphenazine, and chlorpromazine because these agents are available in multiple dosage forms and have decades of clinical and anecdotal data supporting their efficacy. Droperidol has historically been commonly used for agitation; however, U.S. Food and Drug Administration concerns of QT_c prolongation have limited its use for this purpose.

Adverse effects limiting the use of these medications in acute agitation include sedation, hypotension, risk of extrapyramidal symptoms, and QT_c prolongation and the risk of torsades de pointes. While all antipsychotics can increase the QT_c interval and risk of torsades de pointes, several agents within this first-generation subclass have been implicated for adverse outcomes. Among antipsychotics used for acute agitation, **haloperidol** and **droperidol** carry additional Food and Drug Administration warnings regarding QT_c prolongation, torsades de pointes, and sudden cardiac death.[18,19]

Neuroleptic malignant syndrome, though rare, is a potentially life-threatening adverse effect that consists of a constellation of signs including altered mental status, hyperthermia, muscular rigidity, autonomic instability, and elevated creatinine phosphokinase. Contributing factors for neuroleptic malignant syndrome may include high dose, rapid dose escalation, use of a high-potency first-generation agent, history of previous neuromuscular malignant syndrome, agitation, or dehydration.[20]

Common extrapyramidal symptoms encountered with the acute administration of first-generation agents include akathisia and the parkinsonian symptoms of tremor and gait disturbances. Acute dystonias, which occur less frequently but can be severe, include torticollis, laryngeal spasm, and oculogyric crisis. Acute dystonia is associated more frequently with the high-potency agents (e.g., fluphenazine, haloperidol, and droperidol). The mechanism of extrapyramidal symptoms is thought to be related to secondary acetylcholine dysregulation in response to decreased dopamine in the nigrostriatal pathway. **Treat acute dystonias with anticholinergic agents such as IM or IV diphenhydramine (25 to 50 milligrams) or benztropine (2 milligrams).** Coadministration of these agents with a typical IM antipsychotic to prevent dystonia and other extrapyramidal symptoms is also common practice. Be aware that diphenhydramine and benztropine carry their own risks of adverse reactions including sedation, constipation, and blurred vision.

Droperidol Despite strong clinical evidence supporting efficacy in acute agitation, **droperidol** is no longer U.S. FDA–approved for this use.[18] The FDA warning includes reports of death from QT_c prolongation even with use at low dosage and in patients with no cardiac risk factors. These risks led to removal of the drug from the European markets. Droperidol is still available in the United States and is Food and Drug Administration–approved for perioperative nausea and vomiting and is to be used only when other treatment methods fail. The maximum initial dosage is 2.5 milligrams given IV or IM, with repeat doses of 1.25 milligrams given until desired effect is achieved.

Haloperidol **Haloperidol** also carries an additional warning from the U.S. FDA regarding QT_c prolongation, specifically related to IV administration, and by any route at dosages higher than recommended,[21] most commonly defined as >35 milligrams/d or single doses of 20 milligrams or greater. Data supporting this warning include 73 cases of torsades de pointes, including 11 fatalities.[19] It is also important to note that, while used in common practice, haloperidol is not Food and Drug Administration–approved for IV administration. If used IV, doses of 2 to 10 milligrams have been studied, with repeat dosing every 15 to 30 minutes as needed to achieve calming effects, and subsequent administration of 25% of the required bolus dosing. Use the lowest effective single and cumulative dose. Continuous cardiac monitoring should be maintained after IV dosing.

IM haloperidol is often used for acute agitation and is considered second only to lorazepam as standard-of-care therapy.[22] Doses between 2.5 and 10 milligrams have been evaluated in clinical trials as either the primary medication or active comparator, with the most common dosage of 5 milligrams initially, with repeated dosing in 1 to 2 hours as needed. Coadministration with lorazepam has additive calming effects but a higher incidence of sedation.

Fluphenazine **Fluphenazine** IM is an additional injectable, high-potency, first-generation antipsychotic option. Its efficacy is generally considered interchangeable with haloperidol.[23] The average dosing of IM fluphenazine is 2.5 to 5 milligrams per injection, with a recommended dosing range of 1.25 to 10 milligrams per injection.[22]

Chlorpromazine **Chlorpromazine**, a low-potency, first-generation antipsychotic agent, may also be administered PO or IM at doses of 12.5 to 25 milligrams initially, with repeat doses of 25 to 50 milligrams given if necessary to calm agitation.[24] Chlorpromazine may also be given IV, although this is seldom done in clinical practice for the treatment of acute agitation. While this agent does not carry a formal bolded U.S. FDA warning, its label still advises cardiac monitoring, because QT_c prolongation is a concern.[25] Additionally, frequent monitoring of vital signs and orthostatic blood pressure is recommended with acute administration because hypotension, tachycardia, and sedation are common and can be profound. These adverse effects limit the usefulness of this agent in acute agitation.

ATYPICAL, OR SECOND-GENERATION, ANTIPSYCHOTICS

Atypical antipsychotics are also called **second-generation antipsychotics**. These agents block dopamine receptors, but their precise action is not known. Atypical antipsychotics are less likely than typical antipsychotics to cause extrapyramidal symptoms or neuroleptic malignant syndrome and have lower rates of tardive dyskinesia. These features have served to propel them to first-line therapy within the field of psychiatry. Another advantage of atypical antipsychotics is the decreased need for coadministration of medications to combat adverse anticholinergic effects. Less need for concomitant benzodiazepines is also an advantage, especially in the elderly.

Several agents in this class can be given orally or IM. Oral disintegrating tablets of olanzapine and risperidone, oral solution of risperidone, and IM preparations of olanzapine, ziprasidone, and aripiprazole have all been studied specifically for use in acute agitation. Additionally, **quetiapine** is effective for agitation in delirious critical care patients.[26] **Table 287-4** outlines dosage forms for the available options in this class.

TABLE 287-4 Dosage Form Availability for Selected Antipsychotic Agents

Antipsychotic	Oral Solution	Orally Disintegrating Tablet	IM Injection	Tablets or Capsules	IV
Chlorpromazine (Thorazine®)			X	X	X*
Fluphenazine (Prolixin®)	X		X	X	
Haloperidol (Haldol®)	X		X	X	X†
Risperidone (Risperdal®)	X	X		X	
Olanzapine (Zyprexa®)		X	X	X	
Ziprasidone (Geodon®)			X	X	
Aripiprazole (Abilify®)	X	X	X	X	
Quetiapine (Seroquel®)				X	

*not recommended due to hypotension

†IV is unlabeled use

Risperidone **Risperidone** (Risperdal®) has been studied in both ED and psychiatric settings for the treatment of acute agitation. It is not available as an IM preparation, but the oral liquid or rapid oral dispersible tablet (M-Tab®) is comparable to IM haloperidol with and without concomitant lorazepam. It is effective beginning 30 to 60 minutes after administration and has lower rates of extrapyramidal symptoms and sedation than haloperidol.[6,7] It also has comparable efficacy to olanzapine PO and IM, but with a longer time to onset of effect.[8,27]

Olanzapine **Olanzapine** (Zyprexa®) is available as a rapidly dissolving oral tablet (Zydis®) and an IM preparation. It is as effective as haloperidol or risperidone, with less extrapyramidal symptoms than haloperidol, but with more hypotension than risperidone.[8,27,28] Olanzapine given either orally or IM has a faster onset of action than IM haloperidol or oral risperidone, with effect beginning within 15 minutes after administration.[8]

Hypotension with IM olanzapine is a serious adverse effect and has led to fatalities in patients coadministered benzodiazepines or chlorpromazine.[29] **The product information for olanzapine warns against coadministration with benzodiazepines, because life-threatening sedation and hypotension can occur 1 hour after administration of lorazepam 2 milligrams IM.**[30] While recommendations differ, it is best to wait 1 to 2 hours between administering benzodiazepines with IM olanzapine, and if coadministering with oral olanzapine, monitor blood pressure frequently.

Ziprasidone **Ziprasidone** (Geodon®) is available in an IM preparation and has been compared with haloperidol for the treatment of patients with bipolar disorder or schizophrenia. Doses of 20 milligrams IM are comparable to 5 milligrams of IM haloperidol.[31,32] A potential barrier to use for ziprasidone is its effects on QT_c prolongation. In a direct-comparative study, IM ziprasidone was found to increase QT_c approximately 9 to 14 milliseconds longer than four other antipsychotic agents, including haloperidol.[33] As a result, ziprasidone is contraindicated in patients with a known history of QT_c prolongation, recent myocardial infarction, or uncompensated heart failure, or who are taking other medications known to prolong the QT_c interval. If possible, magnesium and potassium levels should be obtained and corrected prior to administration of ziprasidone, and the drug should be discontinued in patients with a QT_c >500 milliseconds.[31-33] This warning has limited its use for acute agitation in the ED.

Aripiprazole **IM aripiprazole** (Abilify®) is effective for acute agitation when compared with IM haloperidol, with onset of response within 1 hour. Patients treated with aripiprazole had lower rates of extrapyramidal symptoms when compared with patients treated with haloperidol, but a higher incidence of headache.[34,35] No studies have researched the utility of oral aripiprazole in the management of acute agitation. The dose of IM aripiprazole is 9.75 milligrams per injection, with a maximum dose of 30 milligrams per day. Aripiprazole is not recommended for use in children or adolescents with acute agitation due to an increased rate of akathisia in this patient group.[36]

Quetiapine **Quetiapine** is an atypical antipsychotic that has shown benefits for agitation associated with delirium in a critical care population.[37] Dosing ranges from 12.5 to 200 milligrams twice daily, and the most common adverse effects include somnolence and hypotension. Quetiapine has not been studied specifically for the treatment of undifferentiated or psychotic agitation in adults. Dosage forms are limited to oral tablets.

ANTIHISTAMINES

The most commonly used antihistamines for the treatment of agitation include diphenhydramine and hydroxyzine. Diphenhydramine is available in both liquid and parenteral dosage forms, but carries a higher rate of sedation and anticholinergic burden than hydroxyzine or other agents for agitation. Efficacy most supports the use of antihistamines in the treatment of anxiety in pediatric and adolescent patients, but antihistamines may be used as a single agent or adjunctive therapy in a generally agitated patient, particularly if the symptoms are anxiety driven.[38]

ANTICONVULSANTS

Anticonvulsants have been studied as agents for agitation, particularly in the acutely aggressive patient, as well as for anxiety. **Gabapentin** has shown some efficacy as adjunctive therapy of agitation in patients with major mental illnesses,[39] as well as some benefits in anxiety or agitation associated with dementia. Overall efficacy, however, is considered to be modest.[40] In patients with bipolar disorder, it is reasonable to consider **valproic acid/divalproex** as a treatment option for agitation because it can be "loaded" (i.e., dosed in a fashion that promotes efficacy for bipolar agitation quickly) and often produces calm and sedation as adverse effects.[41] Other anticonvulsants indicated for bipolar disorder such as **carbamazepine** or **lamotrigine** must be titrated to effect to avoid Stevens-Johnson syndrome and other adverse effects, therefore limiting their use in acute agitation associated with bipolar disorder. The same limitation applies for lithium as well, rendering it ineffective in acute symptom management.

α_2-AGONISTS

Clonidine, a centrally acting α_2-agonist, has historically been tried to combat acute agitation. Unfortunately, hypotension and bradycardia, along with mixed data for efficacy in this patient group, limit its use. However, the sedative agent **dexmedetomidine**, also an α_2-agonist, has gained attention for use in acute agitation in the intensive care unit setting.[42] It is currently under investigation for use in alcohol detoxification in intensive care unit patients as well. It is further hypothesized that the potential benefits of quetiapine and risperidone may be, in part, due to their alpha-agonist effects.[37] Although clonidine and dexmedetomidine are potentially of benefit, the current literature supports limiting them to adjunctive or alternative strategies.

TREATMENT

Acute agitation is acutely treated with either benzodiazepines or antipsychotic medications, or both. For children and adolescents or for adjunctive use, consider antihistamines. Agent-specific information is found in **Tables 287-3** to **287-6**.

SPECIAL POPULATIONS

Table 287-2 provides guidelines for pharmacotherapy in special circumstances and special populations.

TABLE 287-5 IM Atypical Antipsychotic Comparison to Haloperidol

Medication	IM Dose	Maximum IM Dose	Maximum IM Dose per 24 Hours	Time to Onset	Time to Repeat Dose	Half-Life (hours)
Haloperidol	2.5–10 milligrams	10 milligrams	30 milligrams	15 min	0.5–1 h	20
Lorazepam	2 milligrams	4 milligrams	10 milligrams	15 min	0.5–1 h	13
Chlorpromazine	12.5–25 milligrams	50 milligrams	200 milligrams	15 min	1 h	2
Fluphenazine	1.25–2.5 milligrams	5 milligrams	10 milligrams	≤60 min	4 h	15
Ziprasidone	10–20 milligrams	20 milligrams	40 milligrams	60 min	4 h	2–5
Olanzapine	5–10 milligrams	10 milligrams	30 milligrams	15–60 min	2–4 h	21–54
Aripiprazole	9.75 milligrams	15 milligrams	30 milligrams	45 min	2 h	75

THE ELDERLY PATIENT

No pharmacologic therapy has proven optimal for agitation in the elderly patient presenting to the ED with or without dementia. Nonpharmacologic therapies such as reorientation to surroundings; offering food, water, and bathroom facilities; and making sure the patient has his or her hearing aids and glasses are important. If medication is needed, select an agent based on its adverse effect profile at the lowest effective dose and least invasive route of administration. For delirium, treat the underlying disease processes.

Most atypical antipsychotics have not been investigated in the elderly for treatment of agitation in the ED setting, but small studies have investigated the safety and efficacy of IM ziprasidone and IM olanzapine in this group. Data for 15 patients aged 65 to 87 who received at least one dose of 20 milligrams of IM ziprasidone showed outcomes similar to those in patients treated with lorazepam and haloperidol together, or with physical restraints, with no spontaneous reports of adverse effects or changes in electrocardiogram parameters.[43,44] In a single study of agitated inpatients or nursing home residents with comorbid Alzheimer's disease, acute agitation decreased from 2 to 20 hours after a dose of 2.5 or 5 milligrams of IM olanzapine, with somnolence reported as the predominant adverse effect.[44] However, systematic evaluation of specific atypical antipsychotics in elderly patients with dementia showed minimal efficacy, even when used for up to 27 weeks.[45]

Overall, elderly patients are more susceptible to extrapyramidal symptoms, sedation, and confusion than younger populations, and, **if treatment with an antipsychotic agent is warranted, initial dosing should be lower than that in the general adult population**. **Suggested dosing ranges are described in Table 287-7** based on the data available for treatment of agitation (acute or chronic) in elderly patients.

Unfortunately, all antipsychotic agents carry a Black Box warning because their use increases all-cause mortality in the elderly, especially in those with dementia. Benzodiazepines should be used with caution, because they can cause paradoxical disinhibition and increased agitation in elderly patients, even at doses as low as 1 milligram of lorazepam.[45] If a benzodiazepine is used, consider a short-acting, glucuronidated agent such as **lorazepam, oxazepam, or temazepam** to minimize prolonged benzodiazepine effects. **Antihistamines have strong anticholinergic effects and can induce or worsen delirium in this patient group, and thus are generally avoided.**[45]

CHILDREN

The mainstays of therapy in children are antihistamines and benzodiazepines. If an antipsychotic regimen is needed, chlorpromazine, haloperidol, risperidone, olanzapine, or IM ziprasidone may be used.[36,38] Dosing information from these guidelines is presented in **Table 287-8** for patients aged 6 to 18 years.[36,38]

ACUTE WITHDRAWAL OR INTOXICATION SYNDROMES

Withdrawal or intoxication from substances can often lead to acute agitation, resulting in the potential for violence. History is often lacking, so it is necessary to treat without knowing the offending substance.

Benzodiazepines are considered the preferred treatment of agitation for the patient with alcohol or substance abuse. Benzodiazepines are beneficial for short-term sedation and cessation of agitation. They are associated with fewer cardiac and extrapyramidal side effects; however, be cautious of sedation and respiratory depression in an intoxicated patient. **Of the benzodiazepines, lorazepam is the favored agent** due to its lack of hepatic metabolites, rapid and complete IM absorption, and quick onset of action. Lorazepam may be given PO, IV, or IM. For agitation, using lorazepam "as needed" is as effective as a scheduled regimen. A typical starting dose is lorazepam 1 milligram PO, IV, or IM and repeating as needed. Higher doses may be required in a very agitated patient. In an elderly patient, considering a lower starting dose of lorazepam (0.5 milligram PO, IV, or IM once) and assessing efficacy is appropriate.

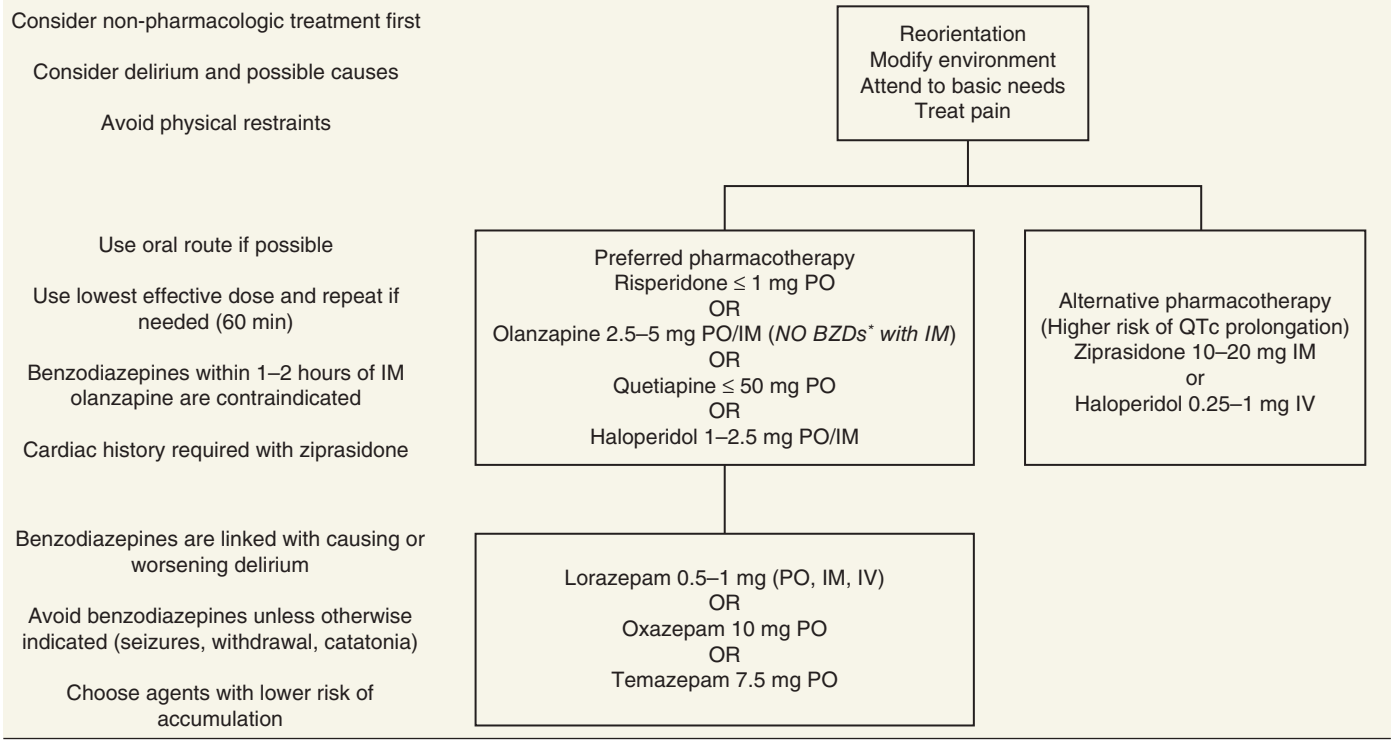
Acute Withdrawal Syndromes Withdrawal syndromes may result from the abrupt discontinuation of various substances including alcohol, opiates, benzodiazepines, and other prescription medications or illicit drugs. Intoxicated patients often present to the ED confused, agitated, combative, and disoriented. The goals of therapy are rapid reduction in agitation, maintaining patient and staff safety, and avoiding excessive sedation. Try to decrease external stimuli by providing a quiet room. The ED staff should communicate a safe and respectful attitude and remove any potentially dangerous objects from the patient's room.

Alcohol Withdrawal The abrupt discontinuation of alcohol can lead to delirium tremens and withdrawal seizures, which may be fatal. The **Clinical Institute Withdrawal Assessment Scale for Alcohol, Revised**

TABLE 287-6 PO Atypical Antipsychotic Comparison to Haloperidol

Medication	PO Dose	Maximum PO Dose	Maximum PO Dose per 24 Hours	Time to Onset	Time to Peak (hours)	Half-Life (hours)
Haloperidol	2.5–10 milligrams	10 milligrams	40 milligrams	30–60 min	2–6	20
Lorazepam	1–2 milligrams	4 milligrams	10 milligrams	30–60 min	2	13
Chlorpromazine	25–50 milligrams	100 milligrams	2000 milligrams	30–60 min	2.8	30
Fluphenazine	2.5–5 milligrams	20 milligrams	20 milligrams	≤60 min	0.5	15
Olanzapine (Zyprexa®, Zydis®)	5–10 milligrams	10 milligrams	30 milligrams	≤60 min	5–8	30
Risperidone (M-Tab®, PO solution)	1–2 milligrams	2 milligrams	8 milligrams	60–120 min	1–2	20
Quetiapine	12.5–50 milligrams	200 milligrams	800 milligrams	≤90 min	90 min	6

TABLE 287-7 Acute Agitation in the Elderly: Dosing Considerations



*BZDs = benzodiazepines

is often used to assess symptom severity.[46] The severity of alcohol withdrawal syndrome and history of complications will determine whether the patient can be managed with "symptom-triggered" or "as-needed" medication administration or a fixed-schedule detoxification (**Table 287-9**).

Benzodiazepine Withdrawal Treatment of agitation secondary to benzodiazepine withdrawal is very similar to the treatment of alcohol withdrawal. A slow taper of the benzodiazepine is recommended. Consider switching short or intermediate half-life drugs to an equivalent dose of diazepam (multiply triazolam dose by 20, alprazolam dose by 10, and lorazepam dose by 5), and then taper. **A recommended tapering strategy is to decrease the dose by 25% the first week, by 25% the second week, and then by 12.5% every 7 days.**[47]

Opiate Withdrawal Opiate withdrawal is not fatal but can result in agitation and combative behavior. **Benzodiazepines are the treatment of choice in patients with acute agitation from opiate withdrawal.** Because patients often have polysubstance abuse, benzodiazepines will provide a sedative effect as well as prevent possible withdrawal seizures from alcohol or benzodiazepine withdrawal. Other options for managing symptoms of opiate withdrawal are discussed in chapters 186 and 292.

Acute Intoxication Syndromes Intoxication can occur from alcohol, prescription medications, hallucinogens, synthetic drugs, and a variety of drugs of abuse. Stimulants include prescription medications (e.g., methylphenidate, dextroamphetamine) and illicit substances (e.g., cocaine, methamphetamine). Hallucinogens, as categorized by the Substance Abuse and Mental Health Services Administration, include lysergic acid diethylamide (LSD or "acid"), phencyclidine (PCP), peyote, mescaline, psilocybin mushrooms, and methylenedioxymethamphetamine (MDMA or "ecstasy"). Synthetic drugs are easily obtained and are not detected on traditional drug screens.

TABLE 287-8 Pediatric Dosing of Drugs for Acute Agitation

Medication	Dose and Maximum Dosing	Time to Repeat Dose	Prepubertal Dosing	Pubertal Dosing
Diphenhydramine	1 milligram/kg/dose for 2–4 doses	20 min	25–50 milligrams PO/IM	50–100 milligrams PO/IM
Lorazepam	0.05 milligram/kg/dose until sedated	20 min	0.5–2 milligrams PO/IM	1–2 milligrams PO/IM
Chlorpromazine	0.5–1 milligram/kg PO 0.5 milligram/kg IM	30 min	25 milligrams PO (max, 100 milligrams/24 h) 12.5 milligrams IM (max, 75 milligrams/24 h)	50 milligrams PO (max, 200 milligrams/24 h) 25 milligrams IM (max, 100 milligrams/24 h)
Haloperidol	0.025–0.075 milligram/kg	60 min PO 30 min IM	0.5–2 milligrams PO/IM	1–2 milligrams PO/IM
Risperidone	0.025–0.05 milligram/kg for 2–4 doses until sedated	60 min	0.25–0.5 milligram	0.5–1 milligram
Olanzapine	0.1 milligram/kg for two doses	30 min	2.5 milligrams PO/IM	5–10 milligrams PO/IM
Ziprasidone			5 milligrams IM (≥6 years old)	10 milligrams IM

TABLE 287-9 Benzodiazepine Dosages for Fixed-Schedule Detoxification in Patients with Alcohol Withdrawal Syndrome[7]

Benzodiazepine	Dosage
Long-acting (12–24 h)	
Diazepam (Valium®)	10 milligrams every 6 hours for four doses, followed by 5 milligrams every 6 hours for eight doses
Chlordiazepoxide (Librium®)	50 milligrams every 6 hours for four doses, followed by 25 milligrams every 6 hours for eight doses
Short-acting (2–12 h)	
Lorazepam (Ativan®)	2 milligrams every 6 hours for four doses, followed by 1 milligram every 6 hours for eight doses
Oxazepam	30 milligrams every 6 hours for four doses, followed by 15 milligrams every 6 hours for eight doses

Herbal marijuana, commonly known as K2 or Spice, is a combination of synthetic cannabinoids and plant material. Marijuana alternatives are often sold as incense and potpourri and may induce anxiety, paranoia, agitation, delusions, and psychosis. Synthetic cathinones, or "bath salts," produce amphetamine-like euphoria, increased talkativeness, increased energy, and sexual arousal. **Supportive care and benzodiazepines are first steps in the management of agitation from suspected acute intoxication. However, for severe agitation impacting patient and staff safety that is not controlled with benzodiazepines, antipsychotics such as haloperidol or droperidol may be the only effective therapeutic options.**

CHAPTER 288

Mental Health Disorders of the Elderly

Kristen Barrio
Kevin Biese

INTRODUCTION

This chapter discusses the diagnosis and differentiation of delirium and dementia in the elderly and provides an overview of selected common mental health disorders in the aging population.

The proportion of ED visits by older adults continues to increase with the exponential growth of the geriatric population.[1] Delirium, dementia, and depression can affect older adults, and the disorders are often interrelated. It can be difficult to identify delirium in patients with dementia, particularly because individuals with dementia are more likely to develop delirium.[2] Patients who develop delirium are more likely to develop dementia later in life.[3-6] Distinguishing between dementia and delirium is an important aspect of caring for older patients.

It can also be difficult to diagnose depression in patients with dementia given that both can present with similar symptoms such as apathy.[7] Also, depression in late life has been associated with increased risk of developing dementia, further demonstrating that dementia, delirium, and depression are interconnected, increase the risk of each other, and are all associated with increased risk of mortality and morbidity.[8-14] **Table 288-1** provides distinguishing features of delirium, dementia, and psychiatric disorders. Chapters 168, "Altered Mental Status and Coma," and 286, "Mental Health Disorders: ED Evaluation and Disposition," also discuss the distinctions between delirium, dementia, and psychiatric disorders.

TABLE 288-1 Features of Delirium, Dementia, and Psychiatric Disorder

Characteristic	Delirium	Dementia	Psychiatric Disorder
Onset	Over days	Insidious	Varies
Course over 24 h	Fluctuating	Stable	Varies
Consciousness	Reduced or hyperalert	Alert	Alert or distracted
Attention	Disordered	Normal	May be disordered
Cognition	Disordered	Impaired	Rarely impaired
Orientation	Impaired	Often impaired	May be impaired
Hallucinations	Visual and/or auditory	Often absent	May be present
Delusions	Transient, poorly organized	Usually absent	Sustained
Movements	Asterixis, tremor may be present	Often absent	Varies

DELIRIUM

Delirium is an acute change in cognition that fluctuates rapidly over time and is often reversible.[15] Delirium is frequently the first sign of underlying acute medical illness. Patients demonstrate altered levels of consciousness, inattention, disorganized thinking, and altered perception.[15] There are three main types of delirium: hypoactive, hyperactive, and mixed.[16] By far, the most common types are hypoactive and mixed delirium, which also have the highest potential to be missed.[17-23] Hypoactive delirium has been called "quiet delirium" because patients have decreased psychomotor activity and can appear somnolent. If hypoactive delirium is confused for depression, the underlying medical disorder causing the delirium can be missed.[24-26] Hyperactive delirium, in contrast, is characterized by increased psychomotor activity, and patients are often agitated, anxious, and sometimes combative. Mixed type can present with a combination of both hyperactive and hypoactive states that fluctuate over time.

Delirium is thought to be present in 7% to 10% of older patients presenting to the ED.[17,27,28] Environmental risk factors for delirium include functional dependence, living in a nursing home, and hearing impairment.[17,29] Delirium is an independent marker for mortality and is associated with a longer length of hospital stay than the median, increased hospital complications, discharge to long-term care facilities, and lasting cognitive deficits.[30-37] Even though delirium is a common disorder in the elderly, the diagnosis is missed by providers in 57% to 83% of cases.[27,38-41] If delirium is missed in the ED, it is likely to be missed on the inpatient services as well.[17]

CLINICAL FEATURES

The differential diagnosis of delirium includes dementia, depression, or another underlying psychiatric disorder. Such conditions can also be comorbidities of each other. However, first assess for delirium and then consider the possibility of the other disorders.

History Focus history taking on identifying the patient's baseline mental status and level of functioning and the time course of changes. Ask about past medical history and recent illness. Obtain an accurate medication list, and ask about over-the-counter medications, medications with anticholinergic properties, or any new medications.[42] Ask about substance abuse to assess the likelihood of intoxication or withdrawal. Any past psychiatric history requires close investigation of prior diagnoses, hospitalizations, and medications. Determine the patient's ability to make informed medical decisions, and determine whether another individual has legal power of attorney for medical decision making.

When attempting to differentiate delirium from dementia, consider several key factors. An acute change in mental status is more consistent with delirium than with dementia, and a fluctuating course over time is also more likely due to delirium.[43] Altered level of consciousness, inattention, and disorganized thinking are all more common in delirium than in dementia.[43]

TABLE 288-2 Mental Status Examination

Appearance, behavior, and attitude
Is dress appropriate?
Is motor behavior at rest appropriate?
Is the speech pattern normal?
Disorders of thought
Are the thoughts logical and realistic?
Are false beliefs or delusions present?
Are suicidal or homicidal thoughts present?
Disorders of perception
Are hallucinations present?
Mood and affect
What is the prevailing mood?
Is the emotional content appropriate for the setting?
Insight and judgment
Does the patient understand the circumstances surrounding the visit?
Sensorium and intelligence
Is the level of consciousness normal?
Is cognition or intellectual functioning impaired?

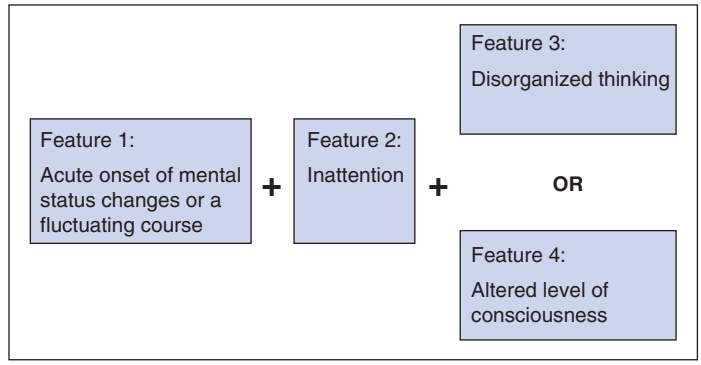

FIGURE 288-1. Confusion Assessment Method (CAM). To make a diagnosis of delirium, the patient must have features 1 and 2 and either 3 or 4.

Physical Examination The physical examination should be thorough. Vital signs must be complete, to include oxygen saturation and temperature. Determine the blood glucose level. Baseline blood pressures may be higher than in younger age groups, and tachycardia can be masked by pharmacologic and/or physiologic limitations. Older patients have lower basal temperatures, with means of 97.3 to 97.8°F depending on the time of the day, so the threshold for a fever is lower than the assumed "normal" of 98.6°F.[44] Look for evidence of trauma, as patients may not recall falling or injuring themselves. Examine the entire body, making sure to look at the patient's back and heels for evidence of decubitus ulcers. Perform a complete neurologic exam, checking for focal findings, abnormal posturing, or difficulty with gait, coordination, or vision. A normal physical examination does not exclude the diagnosis of delirium.

Mental Status Examination Mental status examination is performed to identify delirium and differentiate it from other conditions.[27,35,38-41,45,46] The examination consists of an assessment of six mental-behavioral components (**Table 288-2**).

Two of the most common screening tests used to detect delirium are the **Confusion Assessment Method** for general use and the **Confusion Assessment Method–Intensive Care Unit** for intubated patients who are not heavily sedated.[47,48] **Figure 288-1** demonstrates the components of the Confusion Assessment Method. Inattention is characterized by an easily distracted patient who has difficulty keeping track of the conversation. Disorganized thought processes are rambling, unclear, or illogical. An altered level of consciousness is lethargy, lack of responsiveness, or coma—essentially anything other than alert. The diagnosis of delirium requires features 1 and 2 and either 3 or 4. See **Table 288-3** for further details about using the Confusion Assessment Method and the Confusion Assessment Method–Intensive Care Unit.[47,48]

Laboratory Testing and Imaging Laboratory testing and imaging are obtained to identify the treatable causes of delirium (**Tables 288-3 and 288-4**).[46]

In geriatric patients, infections, such as urinary tract infections and pneumonia, are associated with nearly half of cases of delirium,[49] and medications may account for another 40%.[50-52]

Laboratory Testing **Check point-of-care glucose as soon as possible after patient arrival in the ED.** Obtain CBC and basic metabolic studies, including calcium, phosphorus, and hepatic enzymes. Urinalysis is necessary because urinary tract infections are a frequent cause of delirium. Obtain cardiac markers. Consider an arterial blood gas analysis, especially in patients with chronic lung disease, because hypercarbia can cause delirium.[42] Obtain thyroid function studies.[53] Urine or serum toxicologic studies may be in order. Lumbar puncture may be necessary (after CT scan) if there is suspicion for meningitis or encephalitis or if the patient has had a new-onset seizure.[43] Further studies may be needed depending on the results of history, examination, and basic tests.

Imaging/Ancillary Tests Electrocardiogram and chest radiograph are essential.[54] Head CT scan is advised for patients with signs of, or a history of, trauma, focal neurologic deficits, impaired level of consciousness, or an otherwise unrevealing evaluation.[55,56]

TREATMENT

Medical Treatment Direct treatment to the underlying cause of delirium. Withhold or remove medications that are responsible for delirium. Treat infection, provide IV fluids for dehydration, correct hypoglycemia, and treat pain. Select doses of analgesics and narcotics for each individual patient and monitor for adverse effects.

The Medical Environment Provide the patient with his/her glasses or hearing aids, allow family or caregivers at the bedside, provide frequent reorientation about surroundings and course of care, and make sure there is access to a bathroom.[57] The Multicomponent Intervention to Prevent Delirium in Hospitalized Older Patients identified six risk factors (cognitive impairment, sleep deprivation, immobility, visual impairment, hearing impairment, and dehydration) for the development of delirium and targeted each risk factor with specific interventions carried out by a multidisciplinary team.[57] Precipitating factors in the development of delirium in the hospital include the use of physical restraints, malnutrition, use of a bladder catheter, more than three medications added, and any iatrogenic event.[58] Preventing and minimizing these factors are especially important when long ED stays are unavoidable.

Agitation If the patient is agitated, begin with a nonpharmacologic approach by addressing patient needs (such as using the restroom and, if possible, allowing the patient to eat or drink), providing comfortable surroundings, and having the family close by.[57,59] Avoid bladder catheters. Physical restraints should be an absolute last resort. If basic interventions are not successful, consider medication (**Figure 288-2**). **We recommend the avoidance of benzodiazepines in the elderly if at all possible, unless alcohol withdrawal is the cause of delirium.**[60] Benzodiazepines can cause paradoxical disinhibition and increased agitation in the elderly. If a benzodiazepine is used, consider a short-acting, glucuronidated agent such as **lorazepam, oxazepam, or temazepam** to minimize prolonged benzodiazepine effects. **Avoid antihistamines**, because this drug class has strong anticholinergic effects and can induce or worsen delirium in the elderly.

DISPOSITION AND FOLLOW-UP

The vast majority of patients with delirium should be hospitalized. Criteria for possible discharge include identification and treatment

TABLE 288-3 Confusion Assessment Method and Confusion Assessment Method (CAM)–Intensive Care Unit*

	Confusion Assessment Method	Confusion Assessment Method–Intensive Care Unit Version
Feature 1. Acute Onset and Fluctuating Course	Is there evidence of an acute change in mental status from the patient's baseline? Did the (abnormal) behavior fluctuate during the day, that is, tend to come and go, or increase or decrease in severity? Sources: Family or nurse	Is there evidence of an acute change in mental status from the baseline? Did the (abnormal) behavior fluctuate during the past 24 h, that is, tend to come and go or increase and decrease in severity? Sources of information: Serial Glasgow Coma Scale or sedation score ratings over 24 h, as well as readily available input from the patient's bedside critical care nurse or family
Feature 2. Inattention	Did the patient have difficulty focusing attention, for example, being easily distractible or having difficulty keeping track of what was being said?	Did the patient have difficulty focusing attention? Is there a reduced ability to maintain and shift attention? Sources of information: Attention screening examinations by using either picture recognition or Vigilance A random letter test. Neither of these tests requires verbal response, and thus they are ideally suited for mechanically ventilated patients.
Feature 3. Disorganized Thinking	Was the patient's thinking disorganized or incoherent, such as rambling or irrelevant conversation, unclear or illogical flow of ideas, or unpredictable switching from subject to subject?	Was the patient's thinking disorganized or incoherent, such as rambling or irrelevant conversation, unclear or illogical flow of ideas, or unpredictable switching from subject to subject? Was the patient able to follow questions and commands throughout the assessment? "Are you having any unclear thinking?" "Hold up this many fingers." (examiner holds two fingers in front of the patient) "Now, do the same thing with the other hand." (not repeating the number of fingers)
Feature 4. Altered Level of Consciousness	Is the patient's mental status anything other than alert, for example, vigilant, lethargic, stuporous, or comatose?	Any level of consciousness other than "alert." Alert—normal, spontaneously fully aware of environment and interacts appropriately Vigilant—hyperalert Lethargic—drowsy but easily aroused, unaware of some elements in the environment, or not spontaneously interacting appropriately with the interviewer; becomes fully aware and appropriately interactive when prodded minimally Stupor—difficult to arouse, unaware of some or all elements in the environment, or not spontaneously interacting with the interviewer; becomes incompletely aware and inappropriately interactive when prodded strongly Coma—unarousable, unaware of all elements in the environment, with no spontaneous interaction or awareness of the interviewer, so that the interview is difficult or impossible even with maximal prodding

*To diagnose delirium, the patient must have features 1 and 2 and *either* 3 or 4.

TABLE 288-4 DELIRIUM: Mnemonic for Reversible Causes of Delirium

Drugs	Any new additions, increased dosages, or interactions Consider over-the-counter drugs and alcohol Consider high-risk drugs*
Electrolyte disturbances	Dehydration, sodium imbalance, thyroid abnormalities
Lack of drugs	Withdrawals from chronically used sedatives, including alcohol and sleeping pills Poorly controlled pain (lack of analgesia)
Infection	Especially urinary and respiratory tract infections
Reduced sensory input	Poor vision, poor hearing
Intracranial	Infection, hemorrhage, stroke, tumor Rare; consider only if new focal neurologic findings, suggestive history, or diagnostic evaluation otherwise negative
Urinary, fecal	Urinary retention: "cystocerebral syndrome" Fecal impaction
Myocardial, pulmonary	Myocardial infarction, arrhythmia, exacerbation of heart failure, exacerbation of chronic obstructive pulmonary disease, hypoxia

*High-risk drugs: anticholinergics, anticonvulsants, antidepressants, antihistamines, antiparkinsonian agents, antipsychotics, barbiturates, benzodiazepines, H_2-blocking agents, zolpidem, opioid analgesics.

Reproduced with permission from: Marcantonio ER: Delirium. In: Pacala JT, Sullivan GM, eds. *Geriatrics Review Syllabus: A Core Curriculum in Geriatric Medicine*, 7th ed. New York, NY: American Geriatrics Society; 2010:297.

of the source of delirium; the patient returns to baseline function and mentation in the ED; the patient is discharged to the care of an active, capable individual or to a responsible facility; and the patient has access to follow-up in 24 hours or has the ability to return immediately to the ED if conditions deteriorate. Patients with unrecognized delirium who are discharged home are less apt to understand discharge instructions and less likely to seek further treatment, underscoring the importance of screening for delirium in geriatric patients.[61]

DEMENTIA

Dementia is a general term used to describe several types of disorders that gradually cause loss of cognitive functioning in two or more aspects of a person's life. The *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, definition of dementia requires memory impairment and at least one of the following: aphasia, apraxia, agnosia, or disturbance in executive functioning.[15] The diagnosis cannot be made in the setting of delirium, and the patient must show a decline in previous level of functioning that impacts social, functional, or occupational activities.[15] The most common form of dementia is Alzheimer's dementia, which affects approximately 5 million people in the United States.[62] Alzheimer's dementia is reported in 6% to 8% of those >65 years old and in ≥30% of those >85 years old.[63] Some other common types of dementia are vascular dementia, Lewy body dementia, frontotemporal dementia, dementia associated with Parkinson's disease, and mixed dementia.

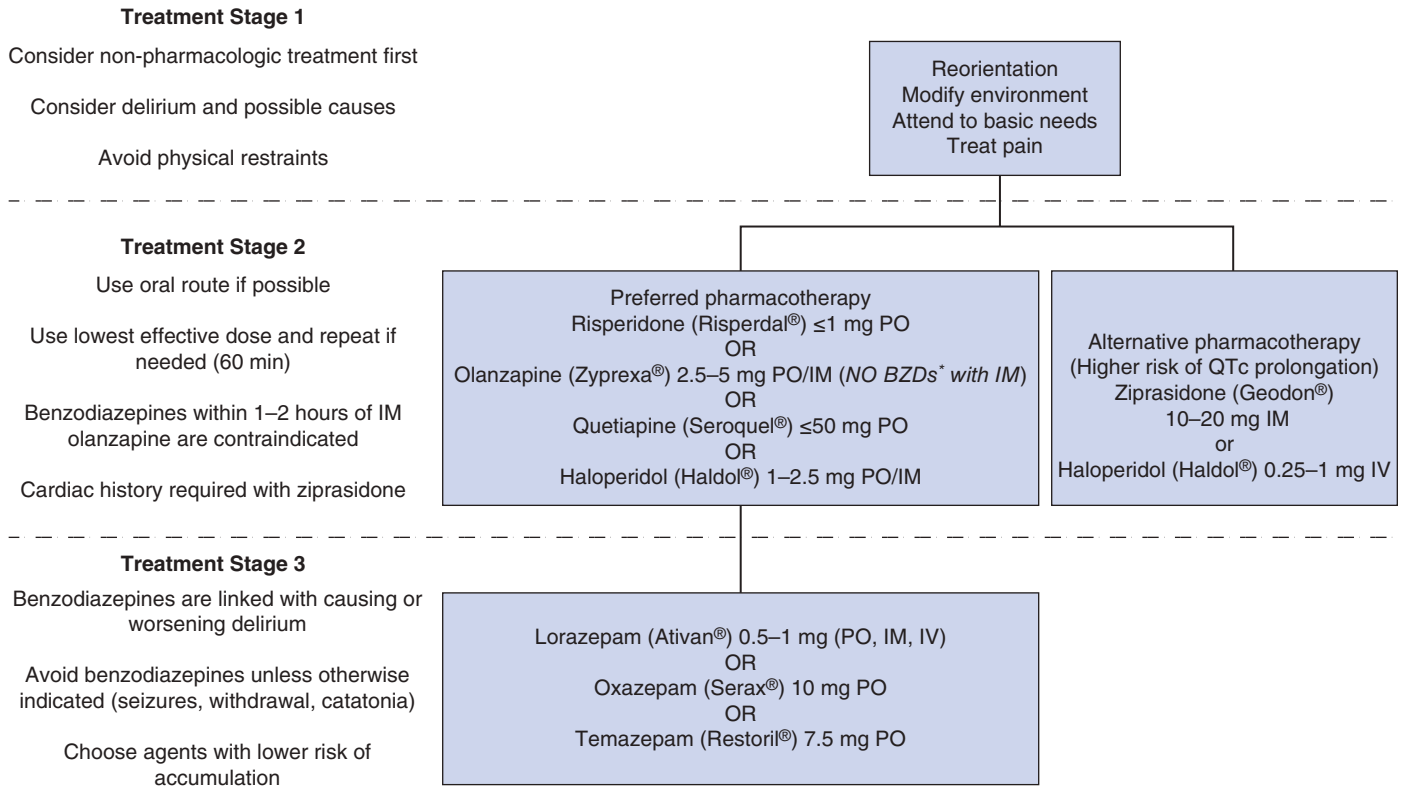

FIGURE 288-2. Acute agitation in the elderly: dosing considerations. *BZDs = benzodiazepines.

PATHOPHYSIOLOGY

Alzheimer's disease has a gradual onset and primarily affects memory. The disease can also result in personality changes and visual-spatial problems.[62] Vascular dementia characteristically has a sudden or stepwise onset, and symptoms typically correlate with the area of brain ischemia.[62] Lewy body dementia has a gradual onset and presents with deficits in memory, and patients will also frequently have hallucinations and parkinsonian-like features.[62] **Patients with Lewy body dementia do very poorly when given typical antipsychotics, so avoid them in these patients.**[64,65] Patients with Lewy body dementia also frequently resemble patients with delirium given that patients can have a rapid decline, fluctuating course, and perceptual disturbances.[43] Frontotemporal dementia often presents in patients <60 years old and is associated with disinhibition, apathy, language difficulties, and atrophy in the frontal and temporal lobes.[62]

CLINICAL FEATURES

The main pharmacologic therapy for patients with dementia is cholinesterase inhibitors. The side effects of these medications include GI upset, anorexia, urinary incontinence, bradycardia, dizziness, and abdominal cramps; patients may come to the ED secondary to such complaints.[62]

Behavioral disturbances are frequently encountered in patients with dementia and are common reasons for ED presentation, especially when caregivers are feeling overwhelmed. The first steps are to screen for delirium and to identify the presence of a comorbid medical disorder (see earlier discussion and **Tables 288-1**, **288-3**, and **288-4**, and **Figure 288-1**). Subsequent management strategies for agitation are listed in **Figure 288-2**.

Mental Status Examination Perform a mental status exam on all geriatric patients because patients with dementia can often appear intact if formal evaluation is not performed. The Mini-Mental State Examination can be used to assess for dementia when there is appropriate time to administer the exam, but it is lengthy, and copyright restrictions sometimes limit access.[66] In the ED, short screening tests such as the **Mini-Cog**, which takes 3 minutes to complete, are more efficient. The Mini-Cog (**Figure 288-3**) combines a three-word recall with a **clock drawing test**.[67] Ask patients to remember three words (e.g., apple, table, penny). Then ask them to immediately repeat the words and remember them. Three minutes later, ask for the three words again. If patients can recall all three words, they do not need to complete the clock drawing test and do not have signs of cognitive impairment. If patients are not able to recall *any* of the words, assume cognitive impairment, and the clock drawing test is not needed. If patients recall one or two words, they will need to perform the clock drawing test. Ask the patient to draw a specific time, indicating hour and minute. The test is graded as either normal (negative for cognitive impairment) or abnormal (positive for cognitive impairment).[67] Alternatively, while waiting the 3 minutes to test

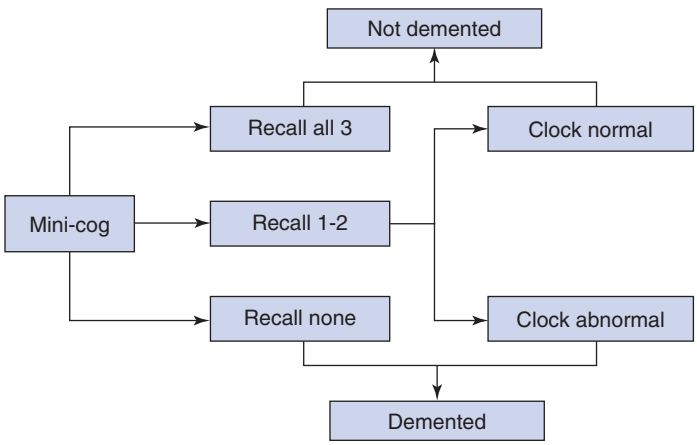

FIGURE 288-3. MINI-COG Screening Test. Scoring is as follows: 1 point for each word recalled and clock drawing test is rated as either normal or abnormal. If the patient scores a 0 in word recall or can recall one or two words but has an abnormal clock drawing test, this is consistent with cognitive impairment.

the patient's recall, ask the patient to draw the clock, as valuable information can be obtained from that exercise alone.

MENTAL HEALTH DISORDERS

As the population of older adults continues to increase, so will the number of geriatric patients with mental health disorders. One estimate predicts that the number of geriatric patients with mental illness will increase by 275% from 4 million in 1970 to 15 million in 2030.[68] Emergency medicine providers need to feel comfortable identifying and managing common mental health disorders in geriatric patients. A recent meta-analysis revealed that the mental health disorders with the highest estimated prevalence rates among geriatric patients were major depression and alcohol use disorders.[69] Significant research remains to be done in the field of geriatric psychiatry. The next sections will give a short overview of what is currently known regarding several mental health disorders found in older patients including depression, bipolar disorder, schizophrenia, and eating disorders.

DEPRESSION AND SUICIDE

Although the prevalence of major depressive disorder among community-dwelling older adults is low (1.4% to 4.4%), the proportion of patients with symptoms of depression below the threshold of major depressive disorder can be quite high, with most studies reporting around 8% to 16%.[7,70,71] Older patients with overt and subclinical depression can benefit from treatment.[72]

Depression in the geriatric population is associated with chronic medical illness, disability, increased use of health services, and poor health outcomes.[7,72,73] Risk factors associated with development of depression in older adults include lack of social support, living alone, being unmarried, cognitive impairment, bereavement, and lower socioeconomic status.[7,73]

Depression presents differently in older adults compared to younger age groups. Older adults with depression frequently report loss of appetite or sexual interest, rather than crying spells, feeling sad, or feeling like life is a failure.[7] They are more likely to be irritable and withdrawn than appear sad.[74] Older patients may also present with somatic or cognitive complaints when they are actually suffering from depression, which can make the diagnosis difficult.[7] Caregivers and patients themselves may attribute depressive symptoms to normal aging, again making the diagnosis difficult.[7] Comorbid anxiety is common with depression, and generalized anxiety disorder is frequently seen in the elderly population, with a reported lifetime prevalence of 15% in older adults.[75]

There are several screening tests for depression currently available to practitioners. Many are lengthy and would be difficult to use in the ED setting. The Patient Health Questionnaire-2 and Patient Health Questionnaire-9 are two- and nine-item self-administered questionnaires that have been developed to screen for depression based on *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, criteria.[76] The Patient Health Questionnaire-9 assesses nine features of depression: anhedonia, depressed mood, trouble sleeping, feeling tired, change in appetite, guilt or worthlessness, trouble concentrating, feeling slowed down or restless, and suicidal thoughts. The Patient Health Questionnaire-2 has two questions addressing anhedonia and low mood.[76] See **Table 288-5** for the Patient Health Questionnaire-2.[77] Both questionnaires can easily be located and have been found to be comparable to longer scales used to screen for depression with more evidence supporting the use of the Patient Health Questionnaire-9.[78] Several sources recommend starting with the Patient Health Questionnaire-2 and, if positive, then administering the Patient Health Questionnaire-9. It is important to find a screening test that you are familiar with and use it to screen for depression.

Screening for **suicide** is vital in the assessment of geriatric patients with depression.[79] People >65 years old have the highest rates of completed suicide of any age group.[80]

Older adults may give fewer warning signs of suicidal intent, and they are more successful in attempting suicide.[81] **Depression is the largest risk factor for suicide. Other risk factors include perceived poor health status, poor sleep quality, alcohol abuse, absence of a confidant, physical illness, functional decline, and presence of a firearm.**[79]

Treatment combines both nonpharmacologic and pharmacologic interventions.[7] It is unlikely that new medications will be started in the ED for depression in geriatric patients, but recognizing depressive symptoms and assuring that the patient has appropriate follow-up are important. Review antidepressant doses, side effects, and drug interactions, as ED visits may be precipitated by symptoms from side effects or interactions. Selective serotonin reuptake inhibitors and selective norepinephrine reuptake inhibitors are some of the most frequently prescribed and effective antidepressants, but they can be associated with serotonin syndrome.[7]

TABLE 288-5 Patient Health Questionnaire-2

Scores range from 0 to 6. A score of 3 or greater indicates the need for further screening.
Over the past 2 weeks, how often have you been bothered by any of the following problems?
Feeling down, depressed, or hopeless?
0 = Not at all
1 = Several days
2 = More than half the days
3 = Nearly every day
Have you often been bothered by little interest or pleasure in doing things?
0 = Not at all
1 = Several days
2 = More than half the days
3 = Nearly every day

SUBSTANCE ABUSE

Substance abuse is relatively common in the geriatric population and may increase with the baby-boomer cohort.[82] One estimate is that the number of older adults who will need substance abuse treatment is expected to increase from 1.7 million in 2000–2001 to 4.4 million in 2020.[82] Although the vast majority of substance abuse in the elderly is related to alcohol and prescription medications, there are reports of increased illicit drug use as well, highlighting the need to ask all patients about drug use.[83]

Alcohol abuse in geriatric patients specifically is frequent. In a cross-sectional study of 12,000 geriatric primary care patients, 15% of patients were felt to be at risk for, or were affected by, problem drinking.[84] Other community surveys estimate the prevalence of at-risk or problem drinking to be between 1% and 15%.[85-87] The current recommendation is that older adults consume no more than one standard drink per day or seven standard drinks per week.[88] Alcohol-related problems, such as falls, confusion, and malnutrition, may be attributed to normal aging, and thus alcohol abuse may be missed.[88] Physiologic changes from advancing age may also change alcohol tolerance, increasing risk for complications.[88] If at-risk drinking is identified, refer the patient to an inpatient or outpatient treatment facility. Also, if the plan is to admit a patient with known alcohol or substance abuse, notify the admitting physician so plans can be made to mitigate withdrawal.

BIPOLAR DISORDER

Bipolar disorder is a spectrum of illness that affects an individual's ability to regulate mood. There are four types: type I, which requires a manic episode for the diagnosis; type II, which requires one or more depressive episodes and a hypomanic episode; cyclothymia (cycling moods that do not meet criteria for depression or mania); and bipolar not otherwise specified.[89] Research regarding bipolar disorder in older adults is limited. The prevalence of bipolar disease in older adults is reported to be approximately 0.08% to 0.5%.[89] Given this low rate, older adults who

present with new-onset mania require a complete medical evaluation before a new diagnosis of bipolar disorder should be made. Even though the prevalence rate of older adults in the community with bipolar disorder is low, one study found that 17% of patients >60 years old presenting to a psychiatric ED carried a diagnosis of bipolar disorder.[90] There are some differences between younger and older patients with bipolar disorder. Older people with bipolar disorder are more likely to be female. Late-onset bipolar disorder (onset between age 30 and 50 years) is associated with fewer genetic associations and more neurologic illnesses.[91] The frequency of psychotic features is essentially the same in young and old patients with bipolar disorder.[91] Older patients with bipolar disorder can have either early- or late-onset disease.

The treatment and adverse effects of treatment of bipolar disorder have implications in the elderly. One of the most customary treatments for bipolar disorder is lithium, which is a mood stabilizer.[92,93] Older patients can demonstrate beneficial effects at lower serum levels of lithium than younger patients. The renal clearance of lithium decreases with age, increasing the elimination half-life and predisposing to lithium toxicity.[94] Neurotoxicity can develop at serum levels that are therapeutic in younger adults.[94] Frequently reported side effects of lithium include tremor, muscle twitches, GI symptoms, and CNS effects such as sedation.[94] Many common medications interact with lithium, including thiazide diuretics, nonsteroidal anti-inflammatory agents, and angiotensin-converting enzyme inhibitors, which can increase serum lithium concentrations and the risk of toxicity.[94] **An older patient taking lithium can display signs of toxicity even if the level is in the therapeutic window.** See chapter 181, "Lithium," for further details of toxicity and treatment. Three anticonvulsants have also been approved to treat bipolar disorder: valproate, carbamazepine, and lamotrigine. The literature regarding their use in older adults is sparse.[89]

PSYCHOSIS (SCHIZOPHRENIA)

Several disorders, such as schizophrenia, psychosis associated with dementias, and more acute processes such as delirium, can present with symptoms of psychosis (hallucinations and delusions) in geriatric patients. This section provides a brief discussion of schizophrenia in older adults (please see earlier discussion regarding delirium and behavioral disturbances in dementia).

The estimated prevalence rate of schizophrenia in geriatric patients ranges from 0.1% to 0.5%.[95-97] The majority of patients with schizophrenia develop the disease in the second or third decade of life (considered early-onset schizophrenia), meaning that most geriatric patients with schizophrenia have had the disorder since they were much younger.[98] There are two other groups of patients with schizophrenia: late-onset schizophrenia (>40 years old) and very-late-onset schizophrenia-like psychosis (>60 years old).[98] Individuals with late-onset schizophrenia have many of the same attributes as patients with early-onset schizophrenia, but late-onset patients have fewer problems with learning, abstraction, and flexibility.[99] The diagnosis of very-late-onset schizophrenia-like psychosis is rare, but patients >60 years old can develop a late-life primary psychosis disorder.[98] Very-late-onset patients tend to have a lack of negative symptoms, greater risk of tardive dyskinesia, and evidence of a neurodegenerative process rather than a neurodevelopmental process.[98]

Schizophrenia in geriatric patients represents complexity in the psychiatric, medical, and social realms. Nonadherence to medical therapy is common.[100] Mortality secondary to cardiovascular disease is more than twice as common as in the general population, likely due to high rates of smoking, diabetes mellitus, hypertension, and obesity in schizophrenic patients. Older patients with schizophrenia typically have a sedentary lifestyle and poor diet.[100] Atypical antipsychotics used for treatment increase the risk of metabolic syndrome and weight gain, which in turn increase the risk of cardiovascular diseases.[101] The use of typical antipsychotics is limited because the risk of tardive dyskinesia is elevated in geriatric patients.[102] One study noted that the cumulative annual incidence of tardive dyskinesia in patients >45 years old treated with low-dose typical antipsychotics was 26%, which is five to six times greater than in younger patients.[102] Antipsychotic medications should be carefully selected and doses titrated upward slowly with close monitoring for side effects. Older patients with schizophrenia can also benefit from adjunctive psychosocial interventions. For example, Functional Adaptation Skills Training, a group therapy targeting everyday life skills, improves the functional adaptation of older patients with schizophrenia.[103-105]

EATING DISORDERS

There is little information regarding eating disorders such as anorexia nervosa and bulimia nervosa in older adults. One recent study examined women >50 years old for the presence of eating disorders and found that about 13% reported some form of core current eating disorder symptoms. Current binge eating, and purging in the absence of binge eating, were the most common symptoms.[106] Approximately 71% of women in the study were currently trying to lose weight.[106] Another review identified 48 cases of eating disorders in adults >50 years old. In this article, 88% were female and 60% were >65 years old. The most frequent diagnosis was anorexia nervosa (81% of cases).[107] Of the 48 cases, 79% had the onset of eating disorders later in life.[107] Importantly, this study identified a strong connection between eating disorders and other psychiatric conditions (60% of cases), with major depression being the most important. Eating disorders were often preceded by a stressful event, such as widowhood, bereavement, and marriage difficulties.[107] Of the 48 patients reviewed, 21% of the patients died from complications of the eating disorder.[107]

Diagnosis is difficult and is made by excluding any physical or medical cause of unexplained weight loss. Eating disorders in older patients are treated similarly to those in any other age group, with a combination of cognitive-behavioral treatment and pharmacotherapy.[107]

CHAPTER 289

Mood and Anxiety Disorders

Tracy M. DeSelm

MOOD DISORDERS

Mood disorders are divided into **depressive** and **bipolar disorders**. Worldwide, depressive disorder affects approximately 10% of the population,[1] whereas bipolar disorder has a lifetime prevalence of 2.4%.[2] In the United States, there is a 21% lifetime prevalence of any mood disorder.[3] One urban study showed that 32% of ED patients screened positive for depressive disorder, and 7% screened positive for bipolar disorder.[4,5] Depressive disorder affects women twice as often as men, whereas bipolar disorder affects men and women equally. **Bipolar disorder** is characterized by mania cycling with periods of depression. The depressive periods tend to last longer that the manic periods.

Although mood disorders may occur at any age, the average onset of depressive disorder is about 40 years of age, and that of bipolar disorder is about 30 years of age. There are no differences in prevalence regarding race.[6]

DEPRESSIVE DISORDER

Depressive disorder is often unrecognized, as the investigation of somatic complaints usually takes priority during patient evaluation.[7,8]

Adolescents[9] and the elderly (especially nursing home patients)[10] appear to be particularly vulnerable populations for depression. Increased rates of depressive disorder are seen in many chronic illnesses including CNS diseases,[11,12] cardiovascular disorders,[13] and cancer.[14] Also, patients with depressive disorder have increased risk of certain medical diseases, such as diabetes and coronary artery disease.[15]

The most common type of depressive disorder is **major depressive disorder** (also called **unipolar or major depression**). Diagnosis requires at least 5 of the 10 following symptoms: depressed mood, anhedonia (loss of pleasure in things that used to give pleasure), suicidal ideation with or without a specific plan, significant weight loss or gain, insomnia or hypersomnia, feelings of restlessness, agitation or psychomotor retardation, feelings of worthlessness or inappropriate guilt, fatigue or loss of energy, and difficulty with concentration. At least one of the symptoms must be depressed mood or anhedonia. Symptoms must be present for at least 2 weeks, cannot be due to substance abuse or a medical condition, and must cause significant impairment in normal functioning.[16]

PATHOPHYSIOLOGY

The pathophysiology of depressive disorder is likely multifactorial including genetic, biological, and psychosocial factors. A genetic predisposition, as evidenced by a 37% concordance rate in twin studies,[17] heightens susceptibility. Malfunctioning monoamine neurotransmitters (especially serotonin, norepinephrine, and dopamine)[18-20] are implicated and may explain the effectiveness of some current medical therapies. Abnormal γ-aminobutyric acid and glutamate levels in various areas of the brain have been noted.[21] Early childhood stress may alter corticotropin-releasing hormone cells in the hypothalamus to heighten future stress responses.[22,23] Four areas of the brain involved in normal emotional responses (the prefrontal cortex, anterior cingulate cortex, hippocampus, and amygdala) appear to be altered in patients with depressive disorder. Finally, psychosocial factors including isolation, lack of family support, stressful life events,[24,25] and substance abuse are risk factors for development of depression.

CLINICAL FEATURES

The most important part of evaluation is the assessment of suicide risk. The acronyms **SAD PERSONS**[26] (**Table 289-1**) and **SIG-E-CAPS** (**Table 289-2**) are helpful tools to assess suicide risk and identify depressive disorder, respectively. The easiest method is using straightforward, nonthreatening questions regarding the patient's suicide or homicide thoughts or intent, but seek corroborative information from family members, friends, law enforcement, EMS, or outside providers.

If the patient is at potential risk for harm to self or others, perform a thorough search for weapons, medicines, and potentially harmful items, and place the patient in a safe environment with monitoring. Follow with appropriate history taking, physical examination, and laboratory studies. Detailed evaluation of patients with mental health disorders is provided in chapter 286, "Mental Health Disorders: ED Evaluation and Disposition" and Table 286-1 of that chapter.

Consider depressive disorder in a patient with vague, general complaints with unclear medical etiologies and multiple ED visits.[27] Two simple questions that have only been validated for depressive disorder assessment in primary care[28] but may prove useful in the ED setting are as follows:

1. During the past month, have you been bothered by feeling down, depressed, or hopeless?
2. During the past month, have you been bothered by little interest or pleasure in doing things?

Ask about substance abuse, because alcohol and drug abuse are important comorbidities.[29] Alcohol abuse is associated with an increased risk of suicide, and many of those with completed suicide demonstrate positive alcohol levels at autopsy. **Patients cannot be adequately evaluated for depression or suicidal intent until they are no longer intoxicated.** This does not necessarily mean an alcohol level of 0, but rather a return to normal (or baseline) cognition.

TABLE 289-1 SAD PERSONS (Assessment Tool for Suicide Risk)

S	Sex (male > female risk)
A	Age (older white men greatest risk)
D	Depression
P	Previous attempt
E	Ethanol/other substance abuse
R	Rational thinking loss
S	Social support lacking
O	Organized suicide plan
N	No spouse
S	Sickness (medical or psychiatric comorbidities)

Note: Each factor assigned 1 point; ≥5 points considered high risk of suicide.

TABLE 289-2 SIG-E-CAPS (Prescribe Energy Capsules) (Assessment Tool for Depressive Disorder)

S	Sleep (too much or too little)
I	**Interest (lack of interest or pleasure and depressed mood)***
G	Guilt (excessive or inappropriate, or feeling worthless)
E	Energy (low)
C	Concentration (poor)
A	Appetite (increased or decreased weight)
P	Psychomotor (slowed or agitation)
S	Suicide (ideation/plan)

*Must include "I (lack of interest or pleasure and depressed mood)" to make diagnosis of depressive disorder.

DIFFERENTIAL DIAGNOSIS

A large number of medical disorders, as well as many medications and substances of abuse, may cause symptoms of depression. Important medical mimickers include neurologic (CNS infection, cerebrovascular accident), endocrine (hypo- and hyperthyroid, hypoglycemia), and infectious disorders (especially in the elderly). Opiates, barbiturates, benzodiazepines, alcohol abuse, and corticosteroids may all cause depressive symptoms. A thorough history, examination, and appropriate laboratory studies will help differentiate the disorders. Consider medical causes of depression in patients with new symptoms of depression, in the elderly, and in those with complex medical problems.

TREATMENT OF DEPRESSIVE DISORDERS

Antidepressants are usually prescribed by primary care physicians or psychiatrists for conditions such as depression, neurogenic pain, or smoking cessation. The side effect profiles, potential serious adverse effects, and toxicities of common antidepressants are reviewed in **Table 289-3** and in the Toxicology section of this text. Antidepressant therapy is typically not initiated in the ED, although resumption of a well-tolerated, recently stopped medication may be considered. Antidepressants take about 2 to 3 weeks to have clinical effects. Ideally, any antidepressant prescribed from the ED should be done in conjunction with the follow-up practitioner, and the patient should be seen in follow-up within a week. Antidepressants may pose fetal risk, so the risks and benefits during pregnancy must be weighed carefully under the guidance of a psychiatrist and obstetrician. Sertraline and paroxetine are safe to use while breastfeeding (see **Table 289-3**).

The major categories of antidepressants in use today are the **heterocyclic antidepressants** (HCAs), **monoamine oxidase inhibitors**

TABLE 289-3 Commonly Used Antidepressants in the United States

Class of Antidepressant	Generic Name	Brand Name	Mechanism of Action for Class	Most Common Side Effects/Adverse Effects for Class	Starting Dose	Comments
Selective serotonin reuptake inhibitors (SSRIs)	Citalopram	Celexa	Blockage of presynaptic serotonin uptake	N/V, drowsiness, HA, dizziness, insomnia, agitation, precipitation of mania, paresthesias, sexual dysfunction, cognitive dysfunction, weight gain	10 milligrams once a day	
	Fluoxetine	Prozac			10 milligrams once a day	
	Fluvoxamine	Luvox			50 milligrams once a day	
	Paroxetine	Paxil			10 milligrams once a day	
	Sertraline	Zoloft			25 milligrams once a day	OK for breastfeeding
	Escitalopram	Lexapro			10 milligrams once a day	OK for breastfeeding
Serotonin norepinephrine reuptake inhibitors (SNRIs)	Duloxetine	Cymbalta	Blockage of presynaptic uptake of serotonin and NE	Same as for SSRIs, except less sexual dysfunction, elevated BP, urinary hesitancy/retention	30 milligrams once a day	
	Venlafaxine	Effexor			37.5 milligrams once a day	
Atypical	Bupropion	Wellbutrin Zyban	DA and NE reuptake inhibitor	Increase seizure risk, dry mouth, nausea, restlessness, insomnia, HA, pharyngitis, constipation	150 milligrams twice a day	Less sexual dysfunction, less weight gain, also used for smoking cessation
	Bupropion SR	Wellbutrin SR			150 milligrams twice a day	
	Bupropion XL	Wellbutrin XL			150 milligrams twice a day	
	Mirtazapine	Remeron	DA and NE reuptake inhibitor Increase release of NE, serotonin by antagonizing inhibitor receptors	Increase seizure risk, dry mouth, nausea, restlessness, insomnia, HA, pharyngitis, constipation, dizziness, somnolence, weight gain, malaise	15 milligrams once a day	Less sexual dysfunction, less weight gain, also used for smoking cessation Quicker onset of action by 1 week, low therapeutic index
	Trazodone	Desyrel	Serotonin antagonist and reuptake inhibitor	Marked sedation, priapism, orthostatic hypotension, ventricular dysrhythmias in patients with known cardiac disease	50 milligrams once a day	Also used in insomnia, anxiety disorders
Heterocyclic	Amitriptyline	Elavil	Blockage of presynaptic reuptake of NE, serotonin	Cardiotoxic: prolonged QTc/AV block Anticholinergic: sedation, dry mouth, tachycardia, constipation	75 milligrams once a day for pain control	Also used for chronic/neurogenic pain control, low therapeutic index

Abbreviations: AV = atrioventricular; BP = blood pressure; DA = dopamine; HA = headache; NE = norepinephrine; N/V = nausea and vomiting.

(MAOIs), **selective serotonin reuptake inhibitors** (SSRIs), the **selective serotonin norepinephrine reuptake inhibitors** (SNRIs), and the **atypical antidepressants**.

Heterocyclic Antidepressants HCAs, once commonly used for depression, are prescribed less often now due to low therapeutic index, many possible side effects at prescribed doses, and dangerous overdose potential. The side effects are mainly anticholinergic related and cardiotoxic, including prolonged QT_c interval and atrioventricular block. One agent in this category, **amitriptyline**, is commonly prescribed for chronic or neurogenic pain.

Monoamine Oxidase Inhibitors MAOIs are rarely used first line in treating depression because of potentially lethal drug–drug and dietary interactions. MAOIs block oxidative deamination of tyramine and may precipitate a sometimes fatal hypertensive crisis when certain drugs **(sympathomimetic amines, levodopa [L-dopa], narcotics, and heterocyclic antidepressants)** or **tyramine-containing foods or beverages** (aged cheese, beer, and wine) are co-ingested.

Selective Serotonin Reuptake Inhibitors and Selective Serotonin Norepinephrine Reuptake Inhibitors The mainstays of current antidepressant therapy are the SSRIs and SNRIs, which increase the amount of intrasynaptic serotonin or serotonin and norepinephrine, respectively. A significant advantage of SSRIs and SNRIs over other classes of antidepressants is their high therapeutic index and favorable side effect profile.

Common side effects for the **SSRIs** include nausea and vomiting, drowsiness, headache, changes in sleep patterns, sexual dysfunction, cognitive dysfunction, and precipitation of mania in bipolar patients. SSRIs may increase suicidal ideation, and the U.S. Food and Drug Administration currently requires that all antidepressants carry a black box warning that antidepressants may increase suicide risk in patients <25 years old. **When SSRIs are abruptly stopped, a withdrawal syndrome may occur**, characterized by a flulike symptoms, including nausea, vomiting, fatigue, myalgias, vertigo, headache, insomnia, and paresthesias. Although these symptoms are not life threatening, they may be very uncomfortable.

Serotonin syndrome, a potentially life-threatening adverse drug reaction, may occur in patients taking SSRIs (or any other antidepressant) when used in combination with another agent that has serotonergic activity such as MAOIs, opiates (including **tramadol**), CNS stimulants, serotonin agonists, St. John's wort, lithium, dextromethorphan, risperidone, olanzapine, ondansetron, and metoclopramide. The syndrome is manifest by neuromuscular hyperactivity (tremor, myoclonus, clonus, hyperreflexia, seizures), altered mental status (restlessness, agitation, excitement, confusion), autonomic hyperactivity (tachycardia, tachypnea, fever, diaphoresis), and GI irritability (nausea, vomiting, diarrhea). Treatment consists of discontinuation of the affecting agents, administering benzodiazepines, and supportive care.

SNRIs are very similar to SSRIs in side effect profile, although they may cause elevated blood pressure and less sexual dysfunction. Withdrawal may also occur several days after discontinuation of an SNRI.

Atypical Antidepressants Atypical antidepressants include **bupropion, mirtazapine, and trazodone**. Bupropion, a dopamine reuptake inhibitor, is also used for smoking cessation. It typically causes less weight gain and less sexual dysfunction than other antidepressants. Trazodone is a serotonin antagonist and reuptake inhibitor that is more sedating than other antidepressants with less anticholinergic effects and is also commonly used for anxiety or as a sleep aid. Mirtazapine is related to the HCAs, tends to cause weight gain, and has an onset of action of about 1 week. As with the other antidepressants, these medications may cause withdrawal when abruptly stopped.

DISPOSITION

The disposition of the depressed patient is based on the assessment of harm to self or others, the ability to care for one's self, level of supportive environment at home, and complicating medical or substance abuse problems. Any of the above may require psychiatric consultation for admission evaluation. Patients who may safely go home need specific follow-up plans with a primary care provider, psychiatrist, or other appropriate counselor. One helpful resource for patients and providers is the **Substance Abuse and Mental Health Services Administration** Web site at www.samhsa.gov.

SPECIAL CONSIDERATIONS

Mental disorders in the elderly are discussed in chapter 286 and mental disorders in children are discussed in chapter 147, "Behavioral Disorders in Children."

Postpartum Depression Postpartum depression affects 10% to 15% of women within 1 year of delivery,[30] but usually occurs within the first month. Symptoms are extreme fatigue, ambivalent feelings about caring for the newborn, guilt about those feelings, as well as the other classic depressive disorder symptoms. Low energy is in excess of the normal fatigue felt by most women postpartum. Risk factors for postpartum depression are prior depression, young age, low socioeconomic status, and partner abuse.[31] In one urban pediatric ED, one third of postpartum patients screened positive for depression.[32] Recognition in the ED is important to identify infant vulnerability.

Cross-Cultural Issues Surveys of depressive disorder show a wide range of prevalence across diverse cultures, although it is unclear how much of this difference is due to each culture's definition and expressions of depressive disorder. Non-Western cultures may emphasize somatic symptoms of depression, whereas in Western cultures, it may be more acceptable to express psychological complaints. Avoid stereotyping, but acknowledge the possibility of cultural influence in symptom description.

BIPOLAR DISORDER

Bipolar disorder, previously called **manic-depressive disorder**, is the other major type of mood disorder and is characterized by mania, usually cycling with periods of depression. The depressive periods tend to last longer than the manic periods. Mania can be diagnosed if there is a distinct period of elevated, expansive, or irritable mood for at least 1 week.[16] Mania may exist with or without psychotic features. Bipolar disorder is divided into several subtypes including bipolar I (mania, with or without major depressive episodes), bipolar II (intermittent hypomania with depressive episodes), and cyclothymic (recurrent dysthymic and hypomania episodes). A "mixed" state is one in which the patient meets the criteria for a manic episode plus depressive disorder symptoms for at least 1 week. It is not necessary for the emergency physician to delineate between the different subtypes of bipolar disorder, but rather understand that different types exist.

PATHOPHYSIOLOGY

The pathogenesis of bipolar disorder is likely multifactorial. There is a strong genetic component, with about 50% of all bipolar patients having a parent with a mood disorder.[6] The concordance rate is 40% in monozygotic twins compared with 6% in dizygotic twins.[33] Areas of the brain involved in normal emotional responses, ventral prefrontal networks and limbic regions, demonstrate decreased connectivity on functional MRIs.[33] Environmental factors, such as negative life events, increase the likelihood of developing bipolar disorder in predisposed persons.[34]

CLINICAL FEATURES

The manic patient may seem "fun," energetic, and expansive, but beware; the patient may quickly become irritable or even hostile if plans are antagonized by providers or family members. Manic patients may experience grandiose or delusional ideas and loss of cognitive abilities, with little insight. The initial evaluation of the manic patient is similar to that of patients with other psychiatric disorders and is discussed in chapter 286. Consider nonpsychiatric causes of agitation, such as thyroid disease, acute toxic ingestions (cocaine, stimulants), and drug withdrawal (antidepressants, alcohol, benzodiazepines). Consider other psychiatric diseases, such as schizophrenia and attention deficit disorder, because features may mimic the manic phase of bipolar disorder. Patients exhibiting

mania should be questioned about a previous history of depressive disorder, because most bipolar disorder patients are initially diagnosed with depressive disorder.

TREATMENT OF BIPOLAR DISORDER

Treatment for bipolar disorder is complex, often requires more than one medication, and thus should not be initiated by the emergency physician, except for treatment of acute agitation (see chapter 287, "Acute Agitation") or to restart lithium or an anticonvulsant medication that has been recently stopped. Medications to treat the acutely manic patient include "**mood stabilizers**," such as **lithium, valproic acid, or carbamazepine**, with or without the addition of an antipsychotic, such as **haloperidol or a benzodiazepine** (**Table 289-4**). The same mood stabilizers may also be used for maintenance therapy. Lithium and valproic acid may be combined with an atypical antipsychotic medication for bipolar maintenance therapy. Lithium has a narrow therapeutic index and requires frequent monitoring. Patients taking lithium must avoid dehydration to prevent toxic levels from accumulating. The efficacy of antidepressant use in bipolar disorder is unclear because there is possible risk of precipitating mania.[35]

DISPOSITION

Disposition of the bipolar disorder patient is similar to that of the depressive disorder patient. Lack of insight to the loss of cognitive abilities and delusional ideas may put the patient at risk for self-harm. Bipolar disorder patients who are exhibiting psychotic features or are at risk for harm to self or others need psychiatrist evaluation for admission.

ANXIETY DISORDERS

Anxiety is a very common presenting symptom in the ED. Psychological, physical, or substance abuse disorders may all cause anxiety symptoms,

TABLE 289-4 Medications Used for Bipolar Disorder

Generic Name	Brand Name	Mechanism of Action	Side Effects (BLACK BOX WARNING IN CAPS)	Usual Starting Dose	Comments
Lithium carbonate	Eskalith, Lithonate, Lithotabs	? increase NE function ? increase serotonin function	Initially: nausea, dry mouth, excessive thirst, tremors, polyuria, peripheral edema, cognitive impairment Long-term: polyuria, diabetes insipidus, goiter, hypothyroidism, rashes, leukocytosis	300 milligrams 2 or 3 times a day	Effective for both acute and maintenance therapy Narrow therapeutic window; toxicity common; symptoms may be delayed up to 48 h in acute overdose
Valproic acid	Depakene, Depakote, Depacon	Antiepileptic; enhances transmission of GABA	Weight gain, nausea, vomiting, hair loss, bruising, tremor, thrombocytopenia, hepatic failure	250 milligrams 2 or 3 times a day	Effective for both acute and maintenance therapy Can monitor drug levels Monitor liver and platelet function May be used alone to treat BD, or in combination with antipsychotic or lithium
Carbamazepine	Tegretol	Antiepileptic; stabilizes sodium channels, potentiates GABA receptors	AGRANULOCYTOSIS, nausea, vomiting, hyponatremia, rash, leukopenia	100–200 milligrams 1 or 2 times a day	Effective for acute or maintenance therapy Can monitor drug levels Monitor LFTs May be better in rapid cycling disorder Do not use with antipsychotics Many drug interactions with similarly liver-metabolized medications
Lamotrigine	Lamictal	Antiepileptic; sodium channel blockade	STEVENS-JOHNSON SYNDROME/ TOXIC EPIDERMAL NECROLYSIS—rare complications but potentially fatal; nausea, vomiting, fatigue, dizziness	25 milligrams once a day	Used with more severe depressive symptoms
Olanzapine	Zyprexa	Antipsychotic; muscarinic; dopamine and serotonin antagonist	Sedation, constipation, dry mouth, glucose intolerance, orthostatic hypotension, hyperlipidemia	10–15 milligrams 1 or 2 times a day	May be used in combination with lithium or valproic acid
Quetiapine	Seroquel	Antipsychotic; dopamine, serotonin, and adrenergic antagonist	Headache, dry mouth, weight gain, sedation, dizziness, orthostatic hypotension	100–200 milligrams 1 or 2 times a day	May be used in combination with lithium or valproic acid
Risperidone	Risperdal	Antipsychotic; serotonin and dopamine antagonist	Extrapyramidal side effects, prolactin elevation, sedation, dyspepsia, nausea, weight gain	1–2 milligrams 1 or 2 times a day	May be used with lithium or valproic acid
Aripiprazole	Abilify	Antipsychotic; partial agonist of dopamine/ serotonin receptors; antagonist of other serotonin receptors	Headache, nausea, vomiting, extrapyramidal symptoms	10–30 milligrams once a day	May be used with lithium or valproic acid

Abbreviations: BD = bipolar disorder; GABA = γ-aminobutyric acid; LFTs = liver function tests; NE = norepinephrine.

alone or in combination. Patients with anxiety disorders seek medical care about twice as often as nonanxiety patients and are high users of the ED.[36,37] This is partly due to the fact that anxiety disorders, especially panic disorder, may mimic life-threatening conditions. **Anxiety disorders are characterized by excessive fear or worry about real or imagined events.** Fears often adversely impact both physical and psychological health.

Anxiety disorders are a heterogeneous group. Generalized anxiety disorder, panic disorder, and posttraumatic stress disorder are discussed here.

PATHOPHYSIOLOGY

The pathophysiology of anxiety disorder is multifactorial. Certain neurotransmitters, such as γ-aminobutyric acid, norepinephrine, and serotonin, may play a role, as evidenced by the utility of SSRIs and benzodiazepines to treat anxiety disorder. Areas of the brain that are involved in processing anxiety, such as the limbic system, and specifically the amygdala, have been implicated. There appears to be a genetic role, especially in panic disorder,[6] although it does not seem to be as strong a predictor as in other psychological illnesses. Exposure to stressful events, especially in childhood, is a risk factor for development of anxiety disorder.[38] A specific stressful event precedes the development of posttraumatic stress disorder.

CLINICAL FEATURES

The various types of anxiety disorders share many common somatic and cognitive symptoms (**Table 289-5**). Common physical symptoms include chest pain, palpitations, tachycardia, smothering feeling, shortness of breath, lightheadedness, abdominal pain, fatigue, trembling, numbness or tingling, and generalized vague pain. Psychological symptoms may include fear of impending death, feelings of depersonalization, irritability, inability to concentrate, obsessions and compulsions, and feeling "ill at ease."

Generalized Anxiety Disorder Patients with generalized anxiety disorder have chronic excessive anxiety and worry about real or imagined events, occurring more days than not for at least 6 months.[16] The symptoms cause significant impairment in daily functioning and are generally recognized by the patient as excessive and inappropriate. The anxiety and worry are associated with three or more of the following symptoms: restlessness or being keyed up or on edge, irritability, muscle tension, being easily fatigued, difficulty concentrating or "mind going blank," and sleep disturbance. General anxiety disorder is often accompanied by other psychiatric illness, most commonly mood disorders and other anxiety disorders. Patients may also have interspersed more intense panic attacks.[39]

Panic Disorder Panic disorder is a common, often chronic illness characterized by recurrent, spontaneous panic attacks. **Panic attacks are short-lived episodes of anxiety or intense fear accompanied by a range of somatic symptoms** (commonly cardiac, GI, or neurologic), usually peaking within 10 minutes and lasting up to an hour. The criteria for panic disorder also stipulate that the panic attack must be followed by 1 month of persistent concern about having additional attacks, or worry about the implications of the attack or its consequences, or a significant change in behavior related to the attacks. It cannot be better accounted for by another psychiatric or medical disorder.[16] Panic disorder is closely associated with other anxiety disorders, mood disorders, substance abuse and dependence, and personality disorders. Panic disorder may occur with or without agoraphobia (irrational fear of crowded spaces); panic disorder with agoraphobia may be severely disabling both socially and occupationally. Because of the often debilitating symptoms, panic disorder patients are high users of the ED. In one Canadian study, 25% of patients presenting to the ED with chest pain were ultimately diagnosed with panic disorder.[40] Underrecognition of anxiety disorders, which are treatable, continues the cycle of overutilization of medical resources. Panic disorder may have an association with several medical disorders, including asthma,[41] hypertension,[42] interstitial cystitis,[43] migraine headaches,[44] and cardiovascular disease.[45] The long-held association between mitral valve prolapse is less clear.[46]

Posttraumatic Stress Disorder/Acute Stress Disorder Posttraumatic stress disorder patients have all experienced or witnessed an intense traumatic event, such as rape, combat, natural disaster, child abuse, chronic exposure to an extreme stressor, or even vehicular trauma. The prevalence of posttraumatic stress disorder within the first several months after vehicular trauma is 25% to 40%, and in 15% of patients, posttraumatic stress disorder will persist.[47]

Diagnostic criteria state that the patient has to be exposed to the stressor and that the response involved intense fear, hopelessness, or horror.[16] This is followed by "intrusive recollection," which would include one or more of the following: recurrent distressing dreams of the event, acting or feeling as if the event were recurring ("flashbacks"), and intense psychological distress with or without physiologic reactivity upon exposure to internal or external cues that symbolize the traumatic event. There may also be avoidance of stimuli associated with the trauma and a numbing of general responsiveness. Hyperarousal demonstrated by hypervigilance or exaggerated startle may occur. The symptoms have to be present for at least a month and cause significant impairment in functioning and cannot be better explained by another psychiatric or medical cause.[16] Acute stress disorder is diagnosed when the same symptoms of posttraumatic stress disorder last between 2 days and 1 month. Patients often return to the ED after serious trauma for a variety of reasons (i.e., inadequate follow-up or pain control) and should be questioned about persistent pain, coping strategies, and general well-being, so as to possibly intervene and avert development of acute stress disorder or posttraumatic stress disorder.

TABLE 289-5 Symptoms of Anxiety Disorder

Somatic Symptoms	Cognitive Symptoms
Palpitations, pounding heart, or tachycardia	Fear of losing control Fear of dying
Sweating Sensations of shortness of breath or smothering	Derealization (feeling of unreality) or depersonalization (feeling detached from oneself)
Trembling or shaking	Inability to concentrate
Feeling of choking	Obsessions and compulsions
Chest pain or discomfort	Feeling ill at ease
Nausea or abdominal distress	
Feeling dizzy, unsteady, lightheaded, or faint	
Paresthesias	
Chills or hot flashes	

DIAGNOSIS

Patients with anxiety disorder often go for many years to EDs and primary care settings, experiencing expensive workups and using healthcare resources, before the diagnosis is established.[48] Assess patients with anxiety for life-threatening conditions, self-harm and harm to others, and patient and staff safety. There is about a 10-fold greater suicide risk among patients with anxiety disorders compared with the general population.[49] When a patient has both an anxiety disorder and a mood disorder, suicide risk is greater than for either disease alone.[50]

Through history taking, try to identify current stressful situations that may have precipitated symptoms. First consider serious medical conditions (such as myocardial infarction, pulmonary embolus, hypoglycemia, hypoxia, tachyarrhythmias, thyroid storm, and cerebrovascular accident). Comorbid psychiatric illnesses are common with anxiety; about half of the patients diagnosed with anxiety have comorbid depression.[51]

Anxiety symptoms may also be caused by certain medications or substances of abuse, including corticosteroids, neuroleptics, bronchodilators, decongestants, caffeine, nicotine, cocaine, and amphetamines. Withdrawal from benzodiazepines, opiates, SSRIs/SNRIs, and alcohol

TABLE 289-6 Pharmacotherapy for Anxiety Disorder

	Class of Drug	Drug and Dosage	FDA Approved for Which AD
Acute medication treatment	Benzodiazepines	Lorazepam (Ativan), 0.5–1.0 milligrams 3 times a day	All
		Clonazepam (Klonopin), 0.5–1.0 milligrams twice a day	All
		Alprazolam (Xanax), 0.25–1.0 milligrams 3–4 times a day	All
		Diazepam (Valium) 2–10 milligrams 2–4 times a day	All
Ongoing medication treatment	Selective serotonin reuptake inhibitor	Sertraline (Zoloft), 50–200 milligrams daily (initial dose, 25 milligrams)	PD, PTSD, SAD
		Paroxetine (Paxil), 40–70 milligrams daily (initial dose, 10–20 milligrams)	GAD, PD, PTSD, SAD
		Escitalopram (Lexapro), 10–20 milligrams daily	GAD
		Fluoxetine (Prozac) 20–60 milligrams daily (initial dose 10 milligrams)	PD
	Serotonin norepinephrine reuptake inhibitor	Venlafaxine (Effexor), 75–300 milligrams daily (initial dose, 37.5 milligrams) (Venlafaxine XR preferred in anxiety.)	GAD, PD, SAD
		Duloxetine (Cymbalta) 20–120 milligrams daily (initial dose, 20 milligrams)	GAD

Abbreviations: AD = anxiety disorder; FDA = U.S. Food and Drug Administration; GAD = generalized anxiety disorder; PD = panic disorder; PTSD = posttraumatic stress disorder; SAD = seasonal affective disorder.

may cause agitation and anxiety. One useful screening question is: "Have you experienced brief periods for seconds or minutes of an overwhelming panic or terror that was accompanied by racing heart, shortness of breath, or dizziness?"[52] Take care to identify victims of domestic violence or sexual abuse or assault, because such past or present experiences can provoke panic attacks.

TREATMENT OF ANXIETY DISORDERS

The two main classes of drugs are benzodiazepines for acute treatment and antidepressants for long-term treatment.

Consider initiating short-term benzodiazepine pharmacotherapy in the ED (**Table 289-6**) for acute panic attack, especially for patients who need rapid control of panic symptoms or who are unable to fulfill expected major obligations (e.g., work, school). The limitation of benzodiazepines is their potential for abuse and dependence. Use with caution in patients with a respiratory disorder or a history of substance abuse or dependence. Use caution in the elderly because common concerns include falling, cognitive slowing, paradoxical agitation, and drug interactions due to polypharmacy.

Initiating antidepressants for anxiety is ideally done in conjunction with a primary care or psychiatric practitioner with a follow-up plan in place. SSRIs and SNRIs are the antidepressants of choice. The TCAs and MAOIs are used primarily for treatment failures. Doses tend to be lower than used in treating depression and may take longer to be effective.

DISPOSITION

Once a diagnosis of AD is considered, the next step is to educate patients and provide reassurance that they are not dying or "going crazy." Emphasize that this is an illness that can be treated effectively. Although the different anxiety disorders vary somewhat in their specific treatments, generally, cognitive behavioral therapy and pharmacotherapy are effective. Choice of treatment is based on an individual assessment of risks, benefits, efficacy, availability, acuity, and patient preference. Although cognitive behavioral therapy is not practiced in the ED, education regarding it is worthwhile. It consists of patient education about a disorder, symptom and thought records, and learning anxiety management skills (e.g., breathing retraining) with the guidance of a trained therapist.

The need for admission is rare, except to exclude a life-threatening condition. Medication changes or initiation of antidepressants should be done in conjunction with the primary care provider or psychiatrist.

CHAPTER 290

Psychoses

Adam Z. Tobias

INTRODUCTION & EPIDEMIOLOGY

Psychosis has been defined as a "fundamental derangement of the mind characterized by defective or lost contact with reality."[1] The *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-V),[2] defines psychotic disorders as those that include abnormalities in one or more of five domains: hallucinations, delusions, disorganized or abnormal motor behavior, disorganized thinking, and negative symptoms. The hallmark of these psychoses, schizophrenia, has a worldwide prevalence of 0.5% to 1%[3] and affects approximately 2.4 million adults in the United States.[4] Considered one of the leading causes of chronic incapacity, the term schizophrenia, meaning "split mind," was coined by Eugene Bleuler in 1911.[5] The economic burden of schizophrenia in the United States in 2002 was estimated at $62.7 billion[6] and typically accounts for 1.5% to 3% of the total national healthcare expenditure, with a high incidence of ED utilization.[7]

The assessment of the psychotic patient presenting to the ED can be challenging, because patients may be agitated, combative, uncooperative, or unable to provide any history. The goals of evaluation are multiple. First, minimize any potential harm to the patient and ensure the safety of the ED staff and other patients. In the case of an aggressive or violent patient, this may require the use of verbal de-escalation techniques or physical or chemical restraints. Second, assess for any coexisting or confounding medical or traumatic conditions. Emergency physicians are gatekeepers to the psychiatric world, because once the patient is funneled into the psychiatric treatment realm, organic conditions may become more difficult to identify and treat. Psychiatric conditions contribute to increased mortality from comorbid medical conditions as compared to the general population.[8] Finally, aim to optimize the treatment of the patient's underlying psychiatric illness, either by connecting him or her with the appropriate inpatient or outpatient resources, or, when possible, by contacting his or her psychiatrist.

PATHOPHYSIOLOGY

Both environmental and genetic factors contribute to the schizophrenia spectrum of disorders. The incidence of schizophrenia is higher in those growing up in urban areas[9] and in certain minority ethnic groups,[10] and the disorders have been linked to a spectrum of risk alleles. There is also overlap between the alleles associated with schizophrenia and those associated with other disorders such as autism and bipolar disorder.[11]

Traditionally, the *dopamine hypothesis*, wherein excessive dopamine leads to the pathophysiology of schizophrenia, has been the dominant theory.[12] Now, it is thought that dopamine acts as the common final pathway of a wide variety of predisposing factors, either environmental, genetic, or both, that lead to the disease. Other neurotransmitters, such as glutamate and adenosine, may also collaborate with dopamine to give rise to the entire picture of schizophrenia.[13]

CLINICAL FEATURES

HISTORY

Features of psychoses include hallucinations, delusions, disorganized thinking, and negative symptoms.

A **hallucination** is an "apparent, often strong subjective perception of an external object or event when no such stimulus or situation is present."[2] Although hallucinations may occur in any sensory modality, they are most commonly auditory in schizophrenia and other psychotic disorders. Typically these are experienced as voices distinct from the individual's own thoughts. Not all hallucinations are considered to be pathologic; they may be a normal part of certain religious and cultural experiences.

A **delusion** is "a false belief or wrong judgment, sometimes associated with hallucinations, held with conviction despite evidence to the contrary."[14] Delusions may be classified based on various themes, including *grandiose* (i.e., "when an individual believes that he or she has exceptional abilities, wealth, or fame"), *persecutory*, *erotomanic* (i.e., "when an individual believes falsely that another person is in love with him or her"), and *referential* (i.e., "belief that certain gestures, comments, environmental cues, and so forth are directed at oneself"). Delusions are considered bizarre if they are clearly implausible. In the ED, a nonbizarre delusion may be difficult to distinguish from a strongly held idea.[2]

Typically, **disorganized thinking** is inferred from a patient's speech. Commonly encountered patterns may include *derailment or loose associations*, wherein the individual switches from one topic to another; *tangentiality*, wherein answers to questions may be unrelated or loosely related; and *word salad*, wherein the individual's speech becomes so disorganized that it becomes nearly incomprehensible.[2]

Negative symptoms associated with psychotic disorders include *avolition* (decreased motivation), *diminished emotional expression*, *anhedonia* (decreased ability to experience pleasure), *asociality* (decreased interest in social interaction), and *alogia* (decreased speech).

PHYSICAL EXAMINATION

Aside from grossly disorganized or abnormal motor behavior (discussed below), there are no specific physical findings associated with the psychotic disorders. The goal of physical examination is the exclusion of coexisting medical or traumatic conditions. For agitated patients, be particularly vigilant to assess for any self-inflicted injuries, environmental injuries such as frostbite, or injuries occurring during the restraint process.

Grossly disorganized or abnormal motor behavior may take on various forms, although it is likely most familiar to emergency practitioners as unpredictable agitation. Catatonia, a "marked decrease in reactivity to the environment" is not frequently encountered in the ED. Catatonic features may range from *negativism*, which is a resistance to instructions, to maintenance of a rigid or inappropriate posture, to complete lack of motor or verbal response. Catatonic behavior may occur in association with a variety of psychiatric and medical conditions.[2]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Psychotic symptoms may be caused by numerous medical conditions, including infections such as encephalitis, meningitis, or cystitis; CNS conditions such as stroke, seizure, Parkinson's disease,[15] or brain tumor; and metabolic derangements such as hypoglycemia or hepatic encephalopathy. Additionally, various medications and illicit substances may give rise to psychotic symptoms (**Table 290-1**).[16-19]

The DSM-V, delineates specific diagnostic criteria for the schizophrenia spectrum and other psychotic disorders (see discussion below). However, such granular distinctions are typically not necessary or relevant for emergency assessment and treatment. Rather than making a specific psychiatric diagnosis, the ED provider's focus should be on emergency treatment and stabilization, identification of comorbid conditions, and appropriate disposition. Assignment of a specific diagnosis should be left to the purview of those with specialized psychiatric training. Diagnostic testing is directed by the history and physical examination. Routine laboratory testing for otherwise stable and cooperative psychiatric patients is of low yield and need not be performed in most cases. Similarly, urine toxicologic screening rarely affects ED management and need not be routinely obtained.[20]

TABLE 290-1 Common Medications and Drugs of Abuse Causing Psychosis

Medications	Drugs of Abuse
Corticosteroids	Ethanol*
Fluoroquinolones	Cocaine
Atropine and other anticholinergics	Amphetamines and other stimulants (including "bath salts")
Dextromethorphan	LSD and other hallucinogens
Benzodiazepines*	Marijuana
	Phencyclidine (PCP)
	MDMA (ecstasy)

*Psychosis is more commonly seen in benzodiazepine withdrawal; can occur with ethanol intoxication or withdrawal

Many psychotic patients presenting to the ED have been previously diagnosed with a psychiatric condition. In such cases, determine whether there has been an acute change from the patient's baseline and whether the current presentation is confounded by another condition that requires medical treatment. In cases where the patient is unable to aid with providing history, use other resources, including past medical records, medication lists, family members, and case workers.

For patients with new-onset psychosis, the ED is a common point of first contact with the healthcare system.[21] It is then incumbent on the provider to determine whether the patient's psychosis is the by-product of an acute medical condition, a reaction to a medication or illicit substance, or truly the new onset of a primary psychiatric illness. Newly symptomatic patients often warrant a more extensive medical evaluation than those with known underlying psychotic disorders.

DISPOSITION AND FOLLOW-UP

Psychotic patients may present anywhere along a spectrum ranging from high functioning to completely disabled. Guide disposition decisions by considerations of patient safety and optimization of treatment. Patients thought to be violent, at risk of self-harm, or unable to care for themselves typically require emergent psychiatric evaluation and possible inpatient psychiatric care. Patients with new-onset psychosis (not thought to be due to a medical cause) or those with worsening of underlying psychotic symptoms should have psychiatric consultation in the ED, if available, or be transferred to a psychiatric facility. Patients with known psychoses under apparent good control may be referred for outpatient management. Ideally, such referrals should be made in consultation with the patient's treating psychiatric provider.

Finally, patients with psychosis secondary to a medical condition or those with comorbid illness should be managed accordingly. Give special consideration to a patient's functional level and ability to manage the medical condition as an outpatient. For example, a schizophrenic patient with an infection that might otherwise be treated with oral antibiotics at home might benefit from hospitalization if there is doubt about the patient's ability to comply with treatment and follow-up instructions.

PHARMACOTHERAPY

Antipsychotic (neuroleptic) medications are typically used in the treatment of schizophrenia and the other psychoses. The exact mechanism of

TABLE 290-2 Typical Antipsychotics

Generic Name	Brand Name	Relative Potency	U.S. Food and Drug Administration Warnings
Phenothiazines			
Chlorpromazine	Thorazine	Low	
Mesoridazine	Serentil	Intermediate	QT_c prolongation
Thioridazine	Mellaril	Intermediate	QT_c prolongation
Perphenazine	Trilafon	Intermediate	
Trifluoperazine	Stelazine	High	
Fluphenazine	Prolixin	High	
Thioxanthenes			
Loxapine	Loxitane	Intermediate	
Thiothixene	Navane	High	
Dihydroindolones			
Molindone	Moban	Intermediate	
Butyrophenones			
Haloperidol	Haldol	High	QT_c prolongation and torsades de pointes
Droperidol	Inapsine	High	QT_c prolongation and torsades de pointes

TABLE 290-3 Atypical Antipsychotics

Drug	U.S. Food and Drug Administration–Approved Indications	Warnings and Common Side Effects (BLACK BOX WARNINGS IN CAPS)
Clozapin (Clozaril)	Treatment-resistant schizophrenia Reduction in the risk of recurrent suicidal behavior in schizophrenic or schizoaffective disorders	Sedation, dizziness, hypotension, tachycardia, salivation, weight gain, hyperthermia.
		AGRANULOCYTOSIS, SEIZURES, MYOCARDITIS, OTHER ADVERSE CARDIOVASCULAR AND RESPIRATORY EFFECTS
Olanzapine (Zyprexa)	Schizophrenia Bipolar disorder Agitation associated with schizophrenia and bipolar I mania	CVAE, sedation, postural hypotension, hyperglycemia, weight gain, dizziness
Quetiapine (Seroquel)	Bipolar mania Schizophrenia	NMS, hyperglycemia, sedation, hypotension, headache, weight gain
		CATARACT FORMATION
Risperidone (Risperdal)	Schizophrenia Bipolar mania	Extrapyramidal effects, hyperglycemia, hypotension, hyperprolactinemia, weight gain
Ziprasidone (Geodon)	Schizophrenia Bipolar mania Acute agitation in schizophrenic patients	Sedation, rash, dizziness, hypotension, hyperglycemia, extrapyramidal effects
		QT PROLONGATION AND RISK OF SUDDEN DEATH
Aripiprazole (Abilify)	Schizophrenia Bipolar disorder	NMS, CVAE, hyperglycemia, seizure, hypotension, headache, akathisia
Asenapine (Saphris, Sycrest)	Schizophrenia Bipolar mania	Blood dyscrasias, cerebrovascular effects, dyslipidemia, extrapyramidal symptoms, NMS, hyperglycemia, QT_c prolongation, orthostatic hypotension, increased mortality with chronic use in dementia patients
Iloperidone (Fanapt)	Schizophrenia	
Paliperidone (Invega, Sustenna)	Schizophrenia Schizoaffective disorder	

Abbreviations: CVAE = cerebrovascular adverse event; NMS = neuroleptic malignant syndrome.

action of the antipsychotics is not known. The majority of antipsychotics block the D_2 dopamine receptors and 5-HT_{2A} serotonin receptors in the brain to a varying degree. Antipsychotics are classified as either *typical* or *atypical*.

The typical antipsychotic medications are often categorized as being of low, medium, or high potency. The "potency" of these drugs does not refer to their effectiveness, but rather to the dosing of the drug for effective clinical response. In general, **low-potency medications** tend to be more sedating and are more often associated with hypotension, dizziness, and anticholinergic symptoms. **High-potency medications** are generally less sedating, but are more frequently associated with extrapyramidal effects such as tremors, rigidity, muscle spasms, and akathisia. **Table 290-2** reviews the common typical antipsychotics.

The U.S. Food and Drug Administration (FDA) has placed black box warnings on a number of the typical antipsychotics, due to concerns about possible cardiac dysrhythmias associated with their use. In particular, several of these medications have been associated with QT_c prolongation and the FDA recommends evaluation of the QT_c interval prior their use. In clinical situations in which rapid tranquilization is necessary, a priori determination of the QT_c interval is impractical and usually impossible. If ECG data are available from the ED visit, these should be reviewed for evidence of QT_c prolongation. Similarly, if prior ECG data are available, incorporate them into clinical decision making. Haloperidol remains a popular and effective agent for rapid tranquilization, and despite aggressive marketing claims to the contrary, its effectiveness is better supported by evidence than newer agents such as aripiprazole or ziprasidone.[22] Unfortunately, QT_c prolongation does not directly correlate with the clinical risk of dysrhythmias or the development of the malignant arrhythmia torsades de pointes. The black box warnings have led to apprehension in the use of highly effective medications.

The atypical antipsychotics (**Table 290-3**) are generally newer medications that more specifically target the dopamine receptors or inhibit the reuptake of serotonin. They also offer increased efficacy in the treatment of the negative symptoms of psychosis. Based on this improved receptor specificity, adverse effects such as sedation, extrapyramidal effects, QT_c prolongation, and tardive dyskinesia are generally reduced but are not completely eliminated. The incidence of hypotension does not appear to have been significantly altered. The FDA has placed a black box warning on both typical and atypical psychotics for their off-label use in managing agitation and psychosis in elderly patients with dementia. Increased rates of cerebrovascular accidents, cardiovascular events, and mortality have been associated with chronic use.[23,24]

ADVERSE EFFECTS

The following side effects are more commonly associated with the typical antipsychotics but may also occur with medications in the atypical class: acute dystonia, akathisia or restlessness, parkinsonism, anticholinergic effects, cardiovascular effects, and neuroleptic malignant syndrome.

Acute Dystonia Acute dystonias are probably the most common side effect of antipsychotic medications seen in the ED. Muscle spasms of the neck, face, and back are the most common dystonias, but oculogyric crisis and even laryngospasm may also occur. Treatment with either benztropine, 1 to 2 milligrams IV, or diphenhydramine, 25 to 50 milligrams IV, rapidly corrects the dystonia. For persistent reactions, both medications may be used, and benzodiazepines may be added for treatment failures. Dystonias often recur despite dosage reduction or discontinuation of the offending antipsychotic.

Akathisia (Motor Restlessness) Akathisia, a sensation of motor restlessness with a subjective desire to move, can begin several days to several weeks after initiation of antipsychotic treatment. Management can be difficult. If possible, decrease the dosage of the antipsychotic after

psychiatric consultation. The best treatment is probably administration of β-blockers such as propranolol.

Antiparkinsonian or anticholinergic drugs such as benztropine, 1 milligram PO two to four times daily, may also afford some relief. In refractory cases, the antipsychotic may need to be changed to an atypical agent.

Antipsychotic-Induced Parkinson's Syndrome A complete Parkinson's syndrome, including bradykinesia, resting tremor, cogwheel rigidity, shuffling gait, masked facies, and drooling, can occur, but often only one or two features of the syndrome are obvious. Antipsychotic dosage reduction and/or anticholinergic medication is usually effective.

Anticholinergic Effects Anticholinergic effects range from mild sedation to delirium. Peripheral manifestations may include dry mouth and skin, blurred vision, urinary retention, constipation, paralytic ileus, cardiac dysrhythmias, and exacerbation of angle-closure glaucoma. The central anticholinergic syndrome is characterized by dilated pupils, dysarthria, and an agitated delirium. Treatment is discontinuation of the antipsychotic and supportive measures.

Cardiovascular Effects Cardiovascular side effects, such as orthostatic hypotension and tachycardia, are commonly encountered with use of the antipsychotics. These effects are likely related to anticholinergic and adrenergic blockade and occur at therapeutic dosages. Typically, hypotension can be easily managed with IV fluids. In severe cases, vasopressor support may be required. Additional effects caused by blockade of sodium, calcium, and potassium channels in the central nervous and cardiac systems are less well delineated. However, effects on specific potassium channels in the myocardium have been linked to the drug-induced prolongation of the QT_c interval associated with several of the antipsychotics.[25,26] It is this mechanism of action by which the antipsychotics are believed to induce torsades de pointes.

Neuroleptic Malignant Syndrome Neuroleptic malignant syndrome is an uncommon idiosyncratic reaction to neuroleptic drugs manifested by rigidity, fever, autonomic instability (tachycardia, diaphoresis, and blood pressure abnormalities), and a confusional state. Although high-potency antipsychotics may be more likely to cause the disorder, all antipsychotics are potential offenders. Neuroleptic malignant syndrome is a medical emergency and has a mortality rate as high as 20%. Management includes immediate discontinuation of the antipsychotic medication, hydration, and meticulous supportive treatment in an intensive care setting. Anticholinergic medications are not helpful and may worsen the condition by further impairing centrally mediated temperature regulation. Medications such as dantrolene sodium or bromocriptine are sometimes used to relieve the rigidity.

SCHIZOPHRENIA SPECTRUM OF DISORDERS

The schizophrenia spectrum of disorders is listed in **Table 290-4**. Some of the more commonly encountered conditions are discussed in detail below.

Schizophrenia is the most common form of psychosis. It typically involves a wide range of impairments in functioning and may affect all areas of a patient's life, including occupational and social aspects. It usually begins to manifest between the late teens and the mid-30s and is often preceded by a prodromal phase. Its course is characterized by acute episodes and periods of partial or full remission. There is a male-to-female rate ratio of 1.4, and the incidence varies significantly based on socioeconomic, racial, and geographic factors, with a higher incidence among migrants, urban populations, and ethnic minorities.[27-29] Patients with schizophrenia have high rates of medical comorbidity and concomitant substance abuse.[30,31]

TABLE 290-4 The Schizophrenia Spectrum of Disorders

Schizophrenia
Brief psychotic disorder
Substance/medication-induced psychotic disorder
Schizotypal personality disorder
Unspecified catatonia
Unspecified schizophrenia spectrum and other psychotic disorder
Catatonia associated with another mental disorder
Delusional disorder
Schizoaffective disorder
Schizophreniform disorder
Psychotic disorder due to another medical condition
Catatonic disorder due to another medical condition
Other specified schizophrenia spectrum and other psychotic disorder

TABLE 290-5 Diagnostic Criteria for Schizophrenia[2]

Criterion A*	Other Selected Criteria
Hallucinations	Disturbance present for at least 6 months
Disorganized speech	Significant deficiencies in major areas of function (work, self-care, interpersonal relations)
Delusions	Depression, bipolar disorder, schizoaffective disorder ruled out
Negative symptoms	Not attributable to another medical condition or substance
Grossly disorganized or catatonic behavior	

*Must have two or more criteria and at least one must be delusions or disorganized speech.

Signs of the disturbance must be present for at least 6 months for a formal diagnosis, and symptoms cannot be attributable to another medical condition or the effects of a substance. Diagnostic criteria are listed in **Table 290-5**.

Schizophreniform disorder differs from schizophrenia only in its duration of symptoms (1 to 6 months) and in the absence of impaired social and occupational functioning as a diagnostic criterion. In contrast, **brief psychotic disorder** lasts between 1 day and 1 month and involves the sudden onset of at least one of the following: delusions, hallucinations, disorganized speech, or grossly disorganized or catatonic behavior.[2]

Schizotypal (personality) disorder is considered part of the schizophrenia spectrum but is classified as a personality disorder, and its treatment is generally more similar to that of other personality disorders than to that of the other psychoses. The disorder is characterized by eccentricities of behavior, a reduced capacity for close relationships, and a pattern of social and interpersonal deficits.

Delusional disorder is diagnosed in the absence of schizophrenia and involves the presence of one or more delusions for at least 1 month. Risk factors include low socioeconomic status, family history of psychiatric disorders, older age, immigration, and exposure to stressful events, with persecutory delusions being the most common.[32] The central theme of the *somatic type,* and a potential trigger for an ED visit, is a preoccupation with health and organ function. For example, individuals may be convinced that they have an infestation of insects on their skin or that a part of their body is not functioning.[2]

Schizoaffective disorder is about one-third as prevalent as schizophrenia.[33] It is characterized by Criterion A of schizophrenia (see **Table 290-5**) occurring concurrently with a major mood episode (major depressive or manic). Furthermore, delusions or hallucinations must be present for at least 2 weeks in the absence of the mood symptoms. Patients may have problems with self-care, restricted social contact, and poor insight.[34,35] Patients with schizophrenia and schizoaffective disorder have a 5% lifetime risk of suicide, with higher risk in patients with depressive symptoms.[36]

Catatonia may occur in the context of various conditions and is categorized as either *catatonia associated with another mental disorder*, *catatonic disorder due to another medical condition*, or *unspecified catatonia*. Medical conditions associated with catatonia include encephalitis, head trauma, hepatic encephalopathy, and neoplasms. The acute presentation of catatonia often includes stupor, and therefore patients often have their first clinical contact in the ED. **It is therefore important to recognize that catatonia is frequently associated with an organic cause.**[37]

CHAPTER 291

Eating Disorders

Gemma C. Lewis

INTRODUCTION AND EPIDEMIOLOGY

Eating disorders, such as anorexia nervosa, bulimia nervosa, and binge-eating disorder, are psychological pathologies characterized by disordered relationships with food. Eating disorders are challenging to diagnose in the ED because physical manifestations may be subtle and historical features may not be elicited unless the disorder is suspected from medical complications or comorbidities. It is important for the emergency physician to recognize these conditions, however, because they are among the most deadly of psychiatric illnesses.[1] The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* refines the diagnostic criteria of eating disorders from the previous edition (**Table 291-1**).[2]

There are two subtypes of anorexia, restrictive and binge/purge, with crossover between the two subtypes.[3] Patients with a predominantly restrictive pattern simply minimize their food intake. Patients with a predominantly binging/purging subtype make up for unacceptable food intake with diuretics, laxatives, enemas, or vomiting. There are also two subtypes of bulimia: purging and nonpurging. Those who purge do so by the above methods; those classified as nonpurging may use compensatory methods such as fasting or excessive exercise. There is a moderate amount of crossover between anorexia and bulimia, with up to 50% of anorexia patients eventually developing bulimia.[4] Binge eating disorder is characterized by habitual, recurrent binge consumptions that cause significant distress and is distinct from simple episodic overeating.

Anorexia nervosa has an overall incidence rate of 8 per 100,000 person-years,[5] with an estimated lifetime prevalence of 0.9% in women and 0.3% in men.[6] There is no significant difference in prevalence of anorexia between different races or ethnicities.[7] **Bulimia nervosa** has an overall incidence rate of 12 per 100,000 person-years,[5] with an estimated lifetime prevalence of 1.5% in women and 0.5% in men.[6] Bulimia is more common in Latinos (lifetime prevalence of 2.03%) and African Americans (1.31%) than in whites (0.51%).[7] **Binge eating disorder** is relatively more common in older individuals and males than both anorexia and bulimia.[5] It is also more prevalent in minority groups than in non-Latino whites.[7] In the United States, the incidence rate for those ≥14 years old is 1010 per 100,000 person-years in females and 660 per 100,000 person-years in males,[8] with a lifetime prevalence of 3.5% in women and 2.0% among men.[6] Although it is often associated with obesity, binge eating disorder is a distinct disorder.[9]

PATHOPHYSIOLOGY

There are several biologic and psychosocial factors that predispose toward disordered eating. There is evidence that eating disorders run in families,[10] possibly related to both genetic influences and similar underlying temperaments and behaviors.[11] Development of eating disorders has historically been associated with dysfunctional reward processing in relation to food,[12] but the pathogenesis of this abnormal response is not well understood.[13] MRI studies detect altered subcortical and cortical brain behavior as well as structural brain differences in patients with eating disorders compared to normal controls. Some of these studies implicate differences in brain regions involved in reward processing, but results are inconsistent.[14-16] Patients with eating disorders also demonstrate differences in certain peripheral and central chemical modulators involved in eating behavior and energy homeostasis compared to controls, but it is not known if such changes are causal or correlative.[17]

CLINICAL FEATURES

HISTORY

Patients with eating disorders often present to the ED with vague signs and symptoms, such as weakness, fatigue, pallor, dizziness, syncope, confusion, bloating, edema, or persistent nausea.[18] Alternatively complaints may be due to medical complications, such as chest pain and hematemesis caused by a Mallory-Weiss tear from purging; palpitations from electrolyte-induced dysrhythmias; dysmenorrhea from disruption of the hypothalamic-pituitary axis; or fractures from osteoporosis or extreme exercise. Depression, anxiety, substance abuse, self-injurious behavior, or suicidality may coexist.[19,20] A meta-analysis of 36 studies reviewing mortality rates for patients with eating disorders reported that one in five individuals with anorexia who died had committed suicide.[21] Data on patients with bulimia or binge eating disorder are confounded

TABLE 291-1 *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, Criteria for Eating Disorders

Anorexia Nervosa	Bulimia Nervosa	Binge Eating Disorder
Restriction of caloric intake relative to requirements, leading to a lower than expected body weight in the context of age, sex, development, and physical health (<85% predicted)	Recurrent episodes of binge eating characterized by both: 1. Eating in a discrete time period an amount of food that is larger than most people would eat in the same period under the same circumstance 2. A feeling of lack of control over eating during an episode	Recurrent episodes of binge eating characterized by both: 1. Eating in a discrete time period an amount of food that is larger than most people would eat in the same period of time under the same circumstance 2. A feeling of lack of control over eating during an episode
Fear of weight gain or becoming fat, despite lower than predicted body weight	Recurrent, inappropriate compensatory behaviors to prevent weight gain including self-induced emesis; abuse of laxatives, diuretics, or other medications; caloric restriction; or excessive exercise	The episodes are associated with three of the following: 1. Eating much more quickly than normal 2. Eating until feeling uncomfortably full or overfull 3. Eating large amounts of food even when not feeling hungry 4. Eating alone because of embarrassment about how much one is eating 5. Feeling disgusted, depressed, or guilty afterward
Derangement in the way the patient's body weight or appearance is experienced, undue effects of body weight on self-evaluation, or denial of the dangerousness of the current low body weight	Binging and purging at least 1 time a week for 3 weeks	The patient exhibits marked distress regarding binge eating.
	Self-evaluation is unduly influenced by body weight and appearance	The binge eating occurs at least 1 time a week for 3 months.
	The disturbance does not occur exclusively during episodes of anorexia	The binge eating is not associated with inappropriate compensatory behavior and does not occur exclusively during the course of anorexia, bulimia, or avoidant/restrictive food intake disorder.

by crossover diagnoses. **Therefore, if an eating disorder is suspected, consider screening for depression and suicidality.**

If clinical suspicion is raised for an eating disorder based on complaint cluster, physical examination, or family report, explore a more focused history. Important data points to elicit include eating and dieting behavior; desire for weight loss; typical daily dietary intake; presence or absence of calorie counting; compensatory exercise behavior; guilt patterns following eating; menstruation pattern; and use of over-the-counter dietary supplements or laxative agents. Certain sensitive history points may be difficult to elicit in the ED, such as early childhood GI issues or picky eating or obesity, self-esteem issues, societal thinness pressures, teasing, propensity toward perfectionism, or sexual abuse. Certain physical activities raise risk for eating disorders, such as gymnastics, ballet and other dance, wrestling, swimming, and cross-country running.[22-24] Because eating disorders are characterized by denial of symptoms and behaviors, when eliciting history, take a nonjudgmental approach to encourage trust and truthful disclosure.[19]

PHYSICAL EXAMINATION

Patients with **anorexia** are typically easily identifiable based on a very thin body habitus. Other possible signs include hypotension (resting or orthostatic); bradycardia or tachydysrhythmia; or hypothermia. Patients may also exhibit signs of vitamin deficiencies such as brittle, flaking, or ridged nails (nonspecific malnutrition); stomatitis or cheilitis (B vitamin deficiency); or perifollicular petechiae (scurvy). They may also develop fine, long hair on the arms and face, acral cyanosis (impaired thermoregulation), and/or pretibial edema secondary to malnutrition.[19]

Patients with **bulimia or binge eating disorder** can be difficult to detect in the ED because they tend to be normal weight or even slightly overweight. **Consider eating disorder diagnoses in the presence of other physical indicators, even in normal weight or overweight patients.** Self-induced vomiting can cause painless hypertrophy of the parotid glands, dental erosion, and trauma or callous formation to the dorsal hands (**Russell's sign**),[25] as well as pharyngeal erythema or abrasions, gingivitis, facial petechiae or subconjunctival hemorrhage, and halitosis. Laxative abuse may cause peripheral edema, anal fissures, hemorrhoids, perianal dermatitis, and rectal bleeding. Binge eating disorder may have no abnormalities apparent on physical examination.

DIAGNOSIS

The **SCOFF questionnaire** (**Table 291-2**) is useful for screening for anorexia and bulimia in a brief ED encounter and can be remembered by its acronym: Sick, Control, One stone, Fat, Food.[26] Other screening tools are more extensive and are more useful in a primary care setting. For reference, the Eating Disorder Diagnostic Scale is a 22-point questionnaire that is self-administered and can identify risk for all three major eating disorders.[27] The Eating Attitudes Test is nonspecific and can identify need for referral to a mental health professional for further evaluation.[28] The Questionnaire on Eating and Weight Patterns-Revised is specific for binge eating disorder and displays a reasonable level of concordance between its scores and diagnostic interviews.[29]

DIFFERENTIAL DIAGNOSIS

Consider organic pathology in the assessment of a patient with a potential eating disorder (**Table 291-3**).

TABLE 291-2 SCOFF Questionnaire

Do you make yourself sick because you feel uncomfortably full?
Do you worry you have lost control over how much you eat?
Have you recently lost more than 1 stone (14 lb) in a 3-month period?
Do you believe yourself to be fat when others say you are too thin?
Would you say that food dominates your life?

Note: A score of 2 or more indicates probable anorexia or bulimia nervosa with sensitivity of 88% and specificity of 88%.

TABLE 291-3 Differential Diagnosis of New-Onset Eating Disorders

Endocrine	Adrenal insufficiency
	Hyperthyroidism
	Diabetes
GI	Hepatitis
	Pancreatitis
	Celiac disease
	Inflammatory bowel disease
	Superior mesenteric artery syndrome
Infectious disease	Mononucleosis
	Human immunodeficiency virus
	Tuberculosis
Cancer	Nervous system malignancy
	Ovarian malignancy
	Intra-abdominal malignancy
Pregnancy	Hyperemesis gravidarum
Psychiatric	Substance abuse
	Major depressive disorder
	Bipolar disorder
	Schizophrenia
Inborn error of metabolism	Mitochondrial disorders
	Enzyme deficiency

LABORATORY TESTING

Initial testing should include a full chemistry panel including magnesium, calcium, and phosphorus, CBC, blood glucose, urinalysis, pregnancy test, hepatic function panel, serum albumin, lipase and amylase, and thyroid-stimulating hormone. Electrolyte derangements and other lab abnormalities are more common in purging-type eating disorders. Patients with restrictive-type anorexia may not demonstrate any laboratory abnormalities. Purging results in a metabolic alkalosis and may cause hypokalemia and hypochloremia. Purging and binge eating both may cause elevation of liver and pancreatic enzymes. Habitual vomiting can result in hyperamylasemia. Hyponatremia and hypochloremia are often seen in patients who vomit. Laxative and diuretic abuse and vomiting can lead to potassium depletion. Hyponatremia may develop in patients who abuse diuretics. Laxative abuse may cause a positive fecal occult blood test. Dehydration can lead to hemoconcentration. Malnutrition can cause low albumin. Starvation ketosis may cause spilling of ketones in the urine, and dehydration may cause increased urine specific gravity and urea concentration. In patients with very severe anorexia, anemia, leukopenia, hypoglycemia, and hypophosphatemia can develop.[19,30,31]

IMAGING

Obtain imaging to rule out an underlying organic cause of presenting symptoms or to exclude medical complications; for example, obtain chest films to exclude Boerhaave's syndrome or abdominal radiographs to diagnose paralytic ileus or acute gastric dilatation. Radiographic findings in anorexia include decreased muscle mass, paucity of subcutaneous fat, mild small bowel dilatation,[32] and osteoporosis.[33] These findings are reversed upon refeeding and appropriate weight gain. There are no specific radiographic findings diagnostic of binge eating disorder or bulimia, but a swallowed toothbrush or similar item suggests purging by induced vomiting.[34]

DISEASE COMPLICATIONS

Medical complications of eating disorders are many and varied. Medical complications of anorexia are typically more severe than bulimia or binge eating and are directly related to the starvation state. Bulimia medical complications are usually related to purging behaviors and are often the

result of chemical derangements or structural damage to the GI tract.[35] The most common medical complication of binge eating is obesity, but acute structural complications such as gastric dilatation may also be seen.

CARDIOPULMONARY COMPLICATIONS

Among the most deadly of the eating disorder complications are changes to the cardiovascular system. Malnutrition in eating disorders leads to decreased muscle mass, including cardiac muscle mass, specifically in the interventricular septum and the left ventricle, as well as increased vagal tone. These effects lead to decreased contractility and cardiac output, and therefore result in hypotension, bradycardia, and orthostasis. Relative decreases in cardiac muscle mass compared to valve cross-sectional area can lead to the development of mitral valve prolapse.[36] Rarely, patients with anorexia nervosa can develop pericardial effusion, which in a few cases has led to cardiac tamponade requiring urgent pericardiocentesis.[37] Purging behavior leading to electrolyte abnormalities can cause cardiac arrhythmias. Syrup of ipecac, used as an emetogenic, is directly cardiotoxic and can cause an irreversible cardiomyopathy.[38] Prolongation of the QT interval on ECG has been described in patients with all types of eating disorders relative to controls. QT prolongation is a marker for risk of ventricular tachyarrhythmia, specifically *torsades de pointes*, and risk of sudden death. QT prolongation as a result of eating disorders is reversed by adequate refeeding and is associated with normalization of heart rate, heart rate variability, and exercise tolerance.[39] Therefore, QT normalization has been used as a marker to guide refeeding and rehabilitation.[40] Most cardiac sequelae are reversible with appropriate weight gain, but there is increased risk of cardiac complications during the first week of refeeding after severe nutrient depletion.[39,41] There are also case reports of pneumothorax and pneumomediastinum as complications of severe anorexia.[42]

NUTRITIONAL COMPLICATIONS

The proportion of eating disorder patients with vitamin deficiencies is difficult to determine, because many patients take supplementary vitamins. Decreased bone mineral density was reported in 18% of patients age 15 to 54 years old admitted to a specialized eating disorders unit but was not associated with decreased vitamin D levels.[43] Deficiencies of other vitamins are rare, and typically merit case reports. Iron and vitamin B_{12} deficiency can lead to anemia in severely food-restrictive patients. Skin erythema and pruritus with sun exposure, glossitis, epidermal desquamation, and diarrhea should raise suspicion of pellagra.[44] Confusion, confabulation, ataxia, ophthalmoplegia, and/or nystagmus suggest Wernicke-Korsakoff encephalopathy. Other vitamin deficiencies reported in association with eating disorders include wet beriberi and scurvy, although these are extremely rare.[45,46]

Refeeding following prolonged nutrient depletion can cause electrolyte abnormalities, most commonly hypokalemia, hypophosphatemia, and hypomagnesemia, due to redistribution of electrolytes from the extracellular to the intracellular space triggered by insulin release and from depletion of phosphorus during protein synthesis. This can lead to arrhythmias, congestive heart failure, pericardial effusions, and cardiac arrest.[41]

GI COMPLICATIONS

Patients with anorexia are at increased risk of constipation, gastroparesis, gastric dilatation, and gastroesophageal reflux.[19,47] Gastroesophageal reflux and laryngopharyngeal reflux commonly occur in patients with bulimia and may result in hoarseness or dysphagia.[19,48] Chronic stimulant laxative abuse can lead to development of rectal prolapse, melanosis coli, or the cathartic colon syndrome.[49-51] Other very rare GI complications include superior mesenteric artery syndrome; gastric dilatation, necrosis, and rupture; necrotizing colitis; and gastric bezoar.[42,52-55]

ENDOCRINE COMPLICATIONS

Profound food restriction affects the hypothalamic-pituitary axis. Low levels of gonadotropins, loss of the normal pulsatile waves of luteinizing hormone, and estrogen deficiency lead to hypothalamic amenorrhea.[56]

TABLE 291-4 Society of Adolescent Medicine Criteria for Hospital Admission

Anorexia Nervosa	Bulimia Nervosa
Body weight <75% of ideal for age, sex, and height	Potassium <3.2 mmol/L
Daytime heart rate <50 beats/min or nighttime heart rate <45 beats/min	Chloride <88 mmol/L
Body fat <10% of body weight	Esophageal trauma and hematemesis
Dehydration	Vomiting unresponsive to antiemetics
Cardiac arrhythmia including QT prolongation	Dehydration
Temperature <96°F	Cardiac arrhythmia including QT prolongation
Orthostasis and syncope	Temperature <96°F
Acute psychiatric emergencies such as hallucinations or suicidality	Orthostasis and syncope
Systolic blood pressure <90 mm Hg	Acute psychiatric emergencies such as hallucinations or suicidality
Ongoing weight loss despite outpatient treatment	Ongoing purging despite outpatient treatment

Anorexia is also associated with the **"euthyroid sick syndrome"** in which thyroid-stimulating hormone is normal or slightly low, T_3 is low, and sometimes T_4 levels are also decreased. Thyroid deficiencies likely contribute to the bradycardia, orthostasis, and hypothermia in anorexia. High cortisol levels and low levels of insulin-like growth factor 1 (somatomedin C), T_3, estradiol, and testosterone contribute to loss of bone mass.[57] Refeeding and recovery from illness do not fully return bone mass to normal levels, and patients with anorexia remain at an increased risk of fracture for as many as 40 years following initial diagnosis.[58] The endocrine effects of bulimia and binge eating disorder are less well studied, more variable, and less predictable. Endocrine abnormalities in these disorders may be more related to comorbid obesity than to the eating disorder itself.

TREATMENT AND DISPOSITION

The ED treatment of eating disorders is limited to stabilization of urgent medical complications, followed by hospital admission or outpatient referral to a mental health specialist. **Tables 291-4 and 291-5** list guidelines for hospital admission.[59,60] Treatment requires a multidisciplinary approach, including medical management with pharmacotherapy, dietary interventions, and psychotherapy.[59] If pharmacotherapy is indicated, it should be initiated by a psychiatrist or primary care provider. Selective serotonin reuptake inhibitors may alleviate comorbid psychiatric symptoms including depression and anxiety, but are not associated with improved weight gain or longer times to relapse in patients with anorexia.[61] Fluoxetine is approved by the U.S. Food and Drug Administration for use in bulimia, and other antidepressants show some benefit in bulimia.[62] Avoid bupropion in all patients with eating disorders

TABLE 291-5 American Psychiatric Association Criteria for Hospital Admission

Medical instability (bradycardia or tachycardia, orthostatic hypotension, hypothermia, metabolic or electrolyte abnormality, dehydration, or evidence of organ compromise)
Weight <85% of ideal or acute decline despite outpatient or partial hospitalization treatment
Acute decline in oral intake despite outpatient or partial hospitalization treatment
Comorbid psychiatric conditions or acute stressors including suicidality
Poor motivation or high resistance to treatment interventions unless highly structured
Absence of treatment options of medium intensity, i.e., partial hospitalization treatment programs

because it can potentiate weight loss and reduce seizure threshold in patients with electrolyte abnormalities.

SPECIAL POPULATIONS

PREGNANT WOMEN

Pregnancy can be a particularly stressful time for a woman with an eating disorder, particularly with respect to maintaining adequate and appropriate weight gain for the pregnancy. There are conflicting data on whether the presence of eating disorders increases the risk of complications of pregnancy; certain studies have documented increased risk of miscarriage, lower birth weights, and lower Apgar scores, whereas others have reported no increase in medical complications and normal birth weights. However, the broadest study of its kind to date revealed that the majority of patients with anorexia and bulimia have normal pregnancies and healthy babies. There is, however, an increased risk of birth by cesarean section and an increased risk of postpartum depression following delivery, and these differences remained between groups who had active symptoms of their disease and those with a history of an eating disorder who were asymptomatic during pregnancy.[63]

MEN

Do not neglect the possibility of eating disorders in males. Men may account for between 10% and 25% of cases of anorexia and bulimia,[64] but the exact proportion of men with eating disorders is unknown, because men are less likely to be diagnosed and appropriately treated than women. Of the eating disorders, binge eating disorder is more common in men than is anorexia or bulimia. Excessive exercise is a common compensation in men for overeating. Eating disorders in males are typically characterized by the drive to add muscle bulk and increase lean mass. Eating disorders in men are often associated with antecedent obesity, athletic performance concerns, bullying, and occasionally, but not always, sexual abuse. Men with eating disorders are also more likely to abuse steroids and growth hormones, particularly when muscle dysmorphia is present.[65]

CHAPTER 292

Substance Use Disorders

Edward Bernstein
Judith A. Bernstein
Scott G. Weiner
Gail D'Onofrio

INTRODUCTION AND EPIDEMIOLOGY

In EDs around the world, on every shift, patients present for medical conditions related to the consequences of unhealthy drinking or drug use. Sometimes the cause of the presenting problem is obvious, but just as often, the connection of substance use with its medical consequences remains undiscovered. Emergency physicians are experts in stabilization, rapid diagnosis, and treatment of *acute* alcohol and drug emergencies and their secondary complications but often fail to identify and discuss drinking and drug use as a component of medical care. Factors that often accompany unhealthy alcohol and drug use, such as psychiatric illness, trauma, homelessness, low level of health literacy, inability to pay for medications, criminal justice involvement, absence of family support, and limited availability of treatment and recovery support services, make patient management and disposition difficult.

The scope of substance use disorders includes unhealthy use of alcohol, use of illicit drugs, and nonmedical use of prescription drugs. Severe substance use disorders (addictions) resemble asthma, diabetes, hypertension, and other chronic diseases in that they have genetic components and patients have problems with adherence to medication, loss to follow-up, repeat visits to the ED, and hospital admissions, yet only a small fraction of those needing alcohol or drug treatment are actually receiving indicated therapy, compared with a much higher fraction of patients with chronic medical conditions.[1]

Substance use is a significant global problem. The World Health Organization reports worldwide 185 million illicit drug users, 2 billion alcohol users, and 1.3 billion smokers. In 2000, tobacco, alcohol, and illicit drugs accounted for about 12% of all deaths worldwide.[2]

Those who begin drinking before age 15 have a fourfold increased risk of developing dependence than those who begin drinking later.[3] Underage drinking and drug use have a profound impact on the developing nervous system, so early intervention is needed to mitigate life-altering consequences.[4]

UNHEALTHY ALCOHOL USE

The term *unhealthy alcohol use* describes a spectrum of alcohol consumption ranging from "risky" or hazardous use (no consequences experienced), to harmful use (experience of consequences), to what was previously called *alcohol dependence* but is now termed *alcohol use disorders*.[5] The National Institute on Alcohol Abuse and Alcoholism defines low-risk drinking as follows[6]: for men, no more than 14 drinks per week and no more than four drinks over a 2-hour occasion. Women of all ages and men >65 years old are advised to drink no more than seven drinks per week and no more than three drinks over a 2-hour occasion because of gender and age differences in volume distribution and concentrations of alcohol dehydrogenase in the liver. Binge drinking (drinking too much too fast) is alcohol consumption that results in a blood alcohol level over the U.S. legal limit of 0.08 gram/dL, which for the average male is the result of more than four drinks in 2 hours and for the average female is more than three drinks in 2 hours. Abstinence is advised for pregnant women and underage drinkers, and a lower limit or abstinence is advised for patients with chronic conditions exacerbated by alcohol or who are taking medications with an alcohol interaction.[6]

SUBSTANCE USE DISORDERS

The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, groups *substance abuse* and *dependence* into categories from mild to severe substance use disorders.[7] The diagnosis of substance use disorder requires two or more of the following 11 criteria: (1) tolerance; (2) withdrawal; (3) recurrent use in greater quantities or for a greater duration than intended; (4) failed attempts to cut back or quit substance use; (5) spending a great deal of time obtaining, using, or recovering from the substance; (6) persistent or recurrent use despite physical and or psychological consequences; (7) giving up important activities in order to use; (8) failure to fulfill responsibilities in work, school, and/or home because of recurrent use; (9) recurrent use resulting in physically hazardous behavior, such as driving under the influence; (10) persistent use despite social or interpersonal problems; and (11) craving alcohol or other drugs. Severity is based on the number of criteria: two or three of the criteria constitute mild substance use disorder, four to five constitute moderate, and six or more constitute severe.[7]

ALCOHOL WITHDRAWAL SYNDROMES

ALCOHOL WITHDRAWAL

Alcohol withdrawal symptoms develop in individuals with a history of heavy and prolonged consumption of alcohol who abruptly stop or reduce their drinking. The spectrum of alcohol withdrawal symptoms includes hand tremors, headache, loss of appetite, nausea and vomiting, diaphoresis, insomnia, tachycardia, hypertension, fever, psychomotor agitation, hyperarousal, craving, and anxiety, as well as the more serious manifestations of seizures, hallucinations, and delirium. The abrupt

withdrawal of alcohol from the brain of chronic heavy drinkers is thought to reduce inhibitory neurotransmission through γ-aminobutyric acid and enhance excitatory neurotransmission through glutamate, but not all heavy drinkers experience withdrawal when stopping or cutting back their consumption.[8-10]

Alcohol withdrawal symptoms exist on a continuum from uncomplicated to moderate and severe, may begin as early as 2 to 6 hours after reduction in alcohol consumption, and can persist for up to 2 weeks. Up to 5% of patients in withdrawal progress to delirium tremens; those with a prior history are at greatest risk. Convulsions occur in 5% to 15%, and delirium tremens occurs in less than 5%. Deaths from delirium tremens among patients receiving early and aggressive treatment have declined from 35% in the early twentieth century to 5% in the current period.[8-10]

The first step in successful treatment is to identify alcohol withdrawal early and distinguish withdrawal from mimics. The most common mimics include toxic-metabolic abnormalities (hyponatremia, hypoglycemia, hypomagnesemia, diabetic ketoacidosis, Wernicke's encephalopathy), toxic alcohol ingestions (ethylene glycol, methanol), prescription or illicit drug ingestions (opioids, sedative-hypnotics, antihistamines), neurologic abnormalities (primary generalized seizures, withdrawal seizures), subdural or epidural hematoma, hypovolemic trauma, infection, and sepsis.

Gastritis, peptic ulcer disease, and pancreatitis are comorbidities with symptoms that often require abrupt cessation of alcohol consumption, leading to withdrawal. The gathering of collateral history, thorough serial examinations of the undressed patient, repeated monitoring of vital signs, measurement of oxygen saturation and bedside finger stick for blood glucose, laboratory assessment of metabolic conditions, and imaging as clinically indicated can detect most comorbidities.

ALCOHOL WITHDRAWAL SEIZURES

Alcohol withdrawal seizures are diffuse tonic-clonic seizures. According to the landmark observations by Victor and Brausch,[11] alcohol withdrawal seizures occur as early as 6 hours after the decrease in intake or the last drink, and 90% occur within 48 hours. Approximately 40% of patients have a single seizure, and 60% have multiple generalized seizures. Victor and Brausch reported that one-third of patients with alcohol withdrawal seizures develop delirium tremens, with the seizures terminating before the development of delirium. An alcohol withdrawal seizure may be brief, with a short or no postictal period.[10] The diagnosis of alcohol withdrawal seizures requires the exclusion of traumatic brain injury, hypoxia, hypoglycemia, structural lesions, infections, use of illicit drugs, idiopathic epilepsy, withdrawal from other recreational drugs, and withdrawal from prescription medications. Focal seizures suggest a focal cerebral lesion. Also consider noncompliance with antiseizure medications (in those with idiopathic or posttraumatic seizures).[12]

ALCOHOL WITHDRAWAL HALLUCINATIONS (ALCOHOL-INDUCED PSYCHOTIC DISORDER)

Alcohol-induced withdrawal hallucinations or alcohol-induced psychotic disorder may develop as an isolated finding 12 to 48 hours after decreasing or abstaining from alcohol. Auditory hallucinations predominate over visual and tactile hallucinations. Psychosis, paranoia, and agitation may last from days to weeks. Alcohol-induced psychotic disorder has a high risk for suicide and co-occurs with other psychiatric diagnoses. Patients with hallucinations lasting for >6 months have the worst prognosis; however, the prognosis is more favorable if abstinence can be maintained.[13]

ALCOHOL WITHDRAWAL DELIRIUM TREMENS

Alcohol withdrawal delirium tremens is characterized by acute and fluctuating disturbances in consciousness, confusion, psychomotor agitation, inattention and impairment in cognitive and perceptual function (hallucinations) unrelated to preexisting or established dementia.[8-10] Patients often develop life-threatening fluid, metabolic, and electrolyte imbalances. Among the risk factors associated with alcohol withdrawal delirium are past withdrawal seizure and delirium, severe dependence and prior detoxification history, high and long duration of alcohol intake, older age, use of other drugs, genetic polymorphism, and comorbidity.[8-10]

TREATMENT OF ALCOHOL WITHDRAWAL SYNDROMES

The goals of therapy for alcohol withdrawal are to alleviate autonomic hyperactivity and agitation, halt progression to delirium tremens, and if possible, provide motivation for and access to detoxification to promote long-term abstinence.[5,8-10] General therapy is the substitution of a benzodiazepine for alcohol (**Table 292-1**).[5,8-10] **Benzodiazepine equivalents are lorazepam 1 milligram = midazolam 2 milligrams = diazepam 5 milligrams = chlordiazepoxide 25 milligrams.** Oral diazepam has a rapid onset of action, and the onset of action of IV diazepam is almost immediate. IM diazepam absorption is erratic, so do not give it IM. Duration of action of diazepam is 20 to 50 hours, and metabolism is hepatic, with the major metabolite (desmethyldiazepam) having a half-life of 20 to 50 hours. Chlordiazepoxide is only available as an oral medication, has a long half-life of up to 28 hours, and has extensive hepatic metabolism with its major active long-acting metabolite, desmethyldiazepam. Lorazepam can be given PO, IM, or IV. Onset of action when given IV is within minutes, and duration of action is 8 hours.

TABLE 292-1 Treatment of Alcohol Withdrawal Syndromes

Condition	Treatment
Uncomplicated alcohol withdrawal (no seizures, no hallucinations, no delirium)	Lorazepam 2 milligrams PO *or* Diazepam 10–20 milligrams PO (hepatic metabolism with long-acting metabolite) *or* Chlordiazepoxide 50–100 milligrams PO (hepatic metabolism with long-acting metabolite) to maximum of 300 milligrams/day *or if vomiting* Diazepam 5–10 milligrams IV every 2–4 h *or* Lorazepam 1–2 milligrams IV every 1–2 h *and* Ondansetron 4 milligrams IV
Alcohol withdrawal seizures	Lorazepam 2 milligrams IV
Alcohol-induced psychotic disorder	Abstinence from alcohol Antipsychotics until symptoms remit
Alcohol withdrawal delirium tremens	Lorazepam 1–4 milligrams IV every 5–15 min PRN[9] *or* Midazolam 0.02–0.1 milligram/kg/h[14] *or* Diazepam 5 milligrams IV, @ 2.5 milligrams/min; repeat in 5–10 min, then 10 milligrams for third and fourth dose; 20 milligrams for fifth and subsequent doses until light somnolence, then 5–20 milligrams every hour PRN[9] *or if refractory to benzodiazepines* Phenobarbital 65 milligrams IV every 15–30 min to maximum 260 milligrams[10] (respiratory depression more common than with benzodiazepines, typically requires intubation) *or if refractory to benzodiazepines* Propofol 5 micrograms/kg/min (or 0.3 milligram/kg/h) titrated to effect; typically requires intubation (unlabeled use, primarily case reports of effectiveness)[10] Haloperidol 0.5–5.0 milligrams IV or IM every 30–60 min for severe agitation[9]

Lorazepam is metabolized rapidly by the liver with inactive metabolites excreted by the kidneys and recognized as the benzodiazepine most tolerated by patients with advanced liver disease.[8-10] Midazolam can be given IV or IM, but for delirium tremens, it is typically given IV. IV onset of action is 3 to 5 minutes.

Give individualized symptom-triggered therapy rather than fixed-schedule dosing. Symptom-triggered regimens result in less drug and shorter duration of treatment than fixed-drug dosing.[15] The Clinical Institute Withdrawal Assessment for Alcohol–Revised (CIWA) is the most commonly used validated, structured instrument for guiding continuing treatment once a diagnosis of alcohol withdrawal is established.[16] It has not been validated specifically for ED use, and comorbid conditions and medications make it difficult to score the Clinical Institute Withdrawal Assessment accurately. The CIWA score ranges from 0 to 67 and tracks 10 variables, with a 0 to 7 ranking for nine variables and a 0 to 4 ranking for the last variable (orientation and clouding of sensorium), where 0 is none and 7 (or 4) is the most severe manifestation of the variable. The variables are nausea/vomiting; tremor; paroxysmal sweats; anxiety; agitation; tactile disturbance; auditory disturbance; visual disturbance; headache; and orientation and clouding of sensorium (0 to 4 rank). A score <8 represents mild withdrawal; score of 9 to 15 moderate withdrawal, and score >15 severe withdrawal.[17]

Drug Therapy for Uncomplicated Alcohol Withdrawal For patients meeting criteria for uncomplicated alcohol withdrawal without seizures, hallucination, or delirium, the recommended first-line treatment is a benzodiazepine (**Table 292-1**).[8-10] Because no specific benzodiazepine is more effective than the others, physician choice, institutional availability, cost, and patient factors are taken into consideration.[10]

Drug Therapy for Alcohol Withdrawal Seizures Benzodiazepines are effective in protecting against seizures and reducing recurrent seizures in alcohol withdrawal.[18,19] A prospective randomized ED trial demonstrated a 3% seizure recurrence rate with a single dose of IV lorazepam, 2 milligrams, compared with 24% among patients receiving placebo.[20] Phenytoin is not recommended for prevention of further alcohol-related seizures and should not be used unless the patient has an underlying structural lesion. Repeated loading of phenytoin may, in fact, lower the seizure threshold.[20,21]

Drug Therapy for Alcohol Withdrawal Hallucinosis (Alcohol-Induced Psychotic Disorder) Antipsychotic therapy with alcohol abstinence is the recommended treatment. There is no long-term need for antipsychotic medication for abstinent patients once symptoms remit. Because patients with alcohol-induced psychotic disorder could be at risk for suicide, admission is recommended.[13]

Drug Therapy for Alcohol Withdrawal Delirium Alcohol withdrawal delirium develops within 3 to 5 days of the last drink and generally lasts 48 to 72 hours, but may last longer. The current practice guideline published by the American Society of Addiction Medicine recommends the use of sedative-hypnotics in high enough doses to quickly control agitation, minimize adverse events, and achieve light somnolence with arousal when stimulated.[9] A benzodiazepine is the initial treatment of choice (**Table 292-1**). If symptoms are unresponsive to adequate doses of benzodiazepines, additional agents include phenobarbital, propofol, or haloperidol.[22-24] Phenobarbital or propofol typically requires intubation. Propofol's central nervous system mechanism of action is thought to be similar to that of ethanol. Adverse effects of propofol include hypotension, and prolonged use >48 h and >5 milligrams/kg/h can cause propofol infusion syndrome,[25,26] with dysrhythmias, heart failure, hyperkalemia, lipemia, metabolic acidosis, and rhabdomyolysis. Antipsychotics such as haloperidol, droperidol, or ziprasidone should be reserved for psychosis or continued agitation (see chapter 287, "Acute Agitation") only after adequate benzodiazepines are administered.

Patients with delirium require thorough diagnostic assessment, aggressive treatment of co-occurring illnesses, supportive care, prevention of aspiration, and treatment of hyperthermia, dehydration, hypoglycemia, and electrolyte imbalance. Thiamine, 100 milligrams, and folate, 1 milligram, should be considered. Treat hypomagnesemia with IV magnesium. A benefit from magnesium therapy in the absence of hypomagnesemia is not established.[27] Physical restraints may be temporarily needed until chemical restraint is achieved; a quiet, calm, supportive environment with low stimuli contributes to successful management.[8-10]

DISPOSITION

Patients with mild or moderate uncomplicated alcohol withdrawal that responds well to initial ED treatment, without trauma or major medical comorbidities, with no suicidal or homicidal ideation, and without a seizure disorder can be managed successfully in a detoxification unit or discharged to a supportive family with referral to an outpatient program. Indications for admission include advanced age, mild or moderate withdrawal that does not respond well to ED treatment, the presence of active medical comorbidities, a prior history of delirium tremens, and alcohol withdrawal seizures. Consider intensive care unit admission for moderate withdrawal with comorbid conditions or severe withdrawal in which sedative requirements necessitate intubation or close monitoring to prevent respiratory compromise.

OPIOID WITHDRAWAL

Symptoms of opioid withdrawal include dilated pupils and tearing, sneezing and running nose, nausea, vomiting, diarrhea and abdominal cramps, yawning, piloerection (goose bumps), and myalgias. **Heroin** or short-acting opioid withdrawal symptoms appear within 36 to 72 hours after decreasing or stopping the agent and may last for 7 to 10 days.[8] Of the opioids, **withdrawal symptoms are most severe with heroin but most prolonged with methadone**.[9] Oxycodone or crushed and injected OxyContin® withdrawal resembles heroin in this regard. **OxyContin® (long-acting oxycodone) and buprenorphine are intermediate-acting opioids, and peak withdrawal symptoms occur in a time frame between heroin and methadone.** Methadone is used for pain control and also to transition patients from other narcotics as medication-assisted treatment for opioid addiction. Methadone has been associated with QT prolongation on the ECG and possibly torsade de pointes, so review the ECG prior to initiating the medication.[28,29] However, methadone withdrawal symptoms can be protracted, because methadone is firmly bound to tissue protein and there is slow release over time from tissue-binding sites. Methadone withdrawal symptoms appear at 72 to 96 hours and may last for 2 weeks or more. For methadone cessation, typically 10% of the maintenance dose is reduced every 2 weeks.

Buprenorphine is a partial opioid agonist and a weak antagonist. It has a high affinity for μ-receptors, displacing other opioids from the receptor, causing acute withdrawal in patients who have recently used opioids. The antagonist effects of buprenorphine block respiratory depression and provide a good margin of safety to treat withdrawal or to provide opioid substitution therapy. The U.S. Food and Drug Administration approved two sublingual formulations of buprenorphine in 2002 for the treatment of opioid dependence. The preferred preparation is a combination of buprenorphine combined with naloxone in a ratio of 4:1, as a sublingual tablet or film (brand name Suboxone® or Zubsolv®) to prevent diversion and overdoses.[30,31] The naloxone component is rapidly bioavailable and will precipitate withdrawal symptoms in opioid users. Overdoses can be managed with naloxone.[30]

OPIOID WITHDRAWAL TREATMENT

There are few options for treating opioid withdrawal. Clonidine in doses of 0.2 milligram three times a day can reduce autonomic symptoms to some degree, but it is not very effective with other symptoms. Patients who stop clonidine abruptly may develop severe rebound hypertension. Symptomatic relief of anxiety and muscle spasms can be achieved with muscle relaxants or benzodiazepines, and GI symptoms can be managed with antispasmodics, antiemetics, and antidiarrheals.[8]

Buprenorphine/naloxone can be used to treat mild withdrawal, but when symptoms are moderate or severe, the high affinity of the drug for the μ-receptor will displace the other opioid and precipitate severe withdrawal. It can be given approximately 12 hours after short-acting opioid use, 24 hours after long-acting opioid use, and up to 48 to 96 hours after high-dose methadone use (30 to 60 milligrams/d). Patient on methadone

ideally should be tapered to <30 milligrams/d, and at this low dose, patients can be transitioned to buprenorphine/naloxone in 24 hours.

The starting dose for treatment of opioid withdrawal is sublingual buprenorphine/naloxone, 4 to 8 milligrams buprenorphine/2 milligrams naloxone, with a first-day maximum of 8 milligrams.[32] In an outpatient setting, the dose is titrated to control symptoms, usually 16 to 32 milligrams/d. Buprenorphine withdrawal is slower in onset and milder than withdrawal from opioids.[31] Patients taking buprenorphine who develop conditions associated with severe pain, may require large doses of potent opioids such as fentanyl to override buprenorphine's antagonist properties, with close observation for respiratory depression.

OPIOID ADDICTION MANAGEMENT

The Drug Addiction Treatment Act of 2000 established office-based opioid treatment in an effort to integrate treatment options into comprehensive clinical care practice and reduce stigmatization of medication-assisted treatment. The prescription of methadone for treatment of addiction is limited by the Federal Narcotics Act to inpatient units or outpatient facilities licensed by the U.S. Drug Enforcement Administration, and buprenorphine is limited to certified clinicians in office- or clinic-based practices. However, there is a "3-day rule" (Title 21, Code of Federal Regulations, Part 1306.07b) that allows a practitioner who is not separately registered as a narcotic treatment program or certified as a "waivered Drug Addiction Treatment Act of 2000" physician to administer (but not prescribe) narcotic drugs to a patient to relieve acute withdrawal symptoms while arranging for referral to treatment (http://www.buprenorphine.samhsa.gov/faq.html). Only one day's supply may be administered or given to a patient, and this may be done for 72 hours only, which cannot be extended. The intent of Title 21, Code of Federal Regulations, Part 1306.07b is to provide flexibility in emergency situations and is especially relevant to emergency physicians. This offers patients options for relief of withdrawal symptoms to bridge the patient for follow-up to either a specialized treatment program or an office-based physician program in the community.

The rise in opioid overdose hospitalizations and deaths has contributed to the White House Office of National Drug Control Policy[33] partnering with the Substance Abuse and Mental Health Services Administration and Centers for Disease Control and Prevention to address the epidemic. The four pillars of their national strategy are to (1) educate prescribers about opioid painkiller prescribing[34]; (2) expand prescription drug monitoring programs and promote links among state systems and to electronic health records[35]; (3) increase prescription return/take-back and disposal programs; and (4) assist states to address doctor shopping and pill mills via law enforcement. Additional national strategies include reducing social stigma and expanding access to medication-assisted treatment,[33,36] and implementing innovative policies to increase availability of naloxone to first responders and the lay public together with ED and community-based programs to train the public in overdose prevention education, calling 911, rescue breathing, and the proper use of bystander naloxone.[33,37,38]

BENZODIAZEPINE WITHDRAWAL

Symptoms of withdrawal may develop up to 7 to 10 days after stopping chronic benzodiazepine use. Patients may develop withdrawal seizures. The clinical picture resembles alcohol withdrawal with symptoms of hypertension, tachycardia and tachypnea, tremulousness, anxiety, agoraphobia, insomnia, altered mental status, delirium, and hallucinations. Mild withdrawal can be managed by a gradual taper over 10 weeks of the benzodiazepine that has been abused.[39]

COCAINE AND OTHER STIMULANT WITHDRAWAL

Stimulant withdrawal can produce symptoms often associated with depression such as disturbances in sleep, appetite, and mood. The duration is from 8 to 48 hours. Co-occurring opioid and sedative dependency may complicate withdrawal. There is no effective evidence-supported treatment currently available for cocaine and stimulant withdrawal.

MARIJUANA/CANNABIS WITHDRAWAL

Marijuana dependence has been associated with low energy, sleep and memory disturbances, deterioration in job and family function, and financial difficulties, but dependence is less likely than for other drugs. Marijuana withdrawal begins after 24 to 48 hours, usually lasts for 1 to 3 weeks after abstinence, and peaks within 4 to 6 days. Among the symptoms associated with withdrawal are difficulty sleeping, cravings, mood swings, depression and irritability, and decreased appetite. Withdrawal symptoms are considerably less severe than for heroin or alcohol, but nevertheless, like other drugs, withdrawal symptoms can interfere with efforts to quit or seriously cut back on use.[40]

ED SCREENING, BRIEF INTERVENTION, AND REFERRAL TO TREATMENT

Alcohol Screening in the ED (Revised and approved by the American College of Emergency Physicians [ACEP] Board of Directors April 2011)

ACEP believes alcohol abuse is a significant public health problem. Further, ACEP believes emergency medical professionals are positioned and qualified to mitigate the consequences of alcohol abuse through screening programs, brief intervention, and referral to treatment. ACEP encourages wide availability of resources necessary to address the needs of patients with alcohol-related problems and those at risk for them

Screening, brief intervention, and referral to treatment were established in 2003 by the U.S. Substance Abuse and Mental Health Services Administration to address the gap in preventive services for unhealthy alcohol and drug use, to stem the progression to addiction by early intervention, and to address the treatment gap by promoting help seeking and facilitating access to addiction treatment and recovery support services. Screening, brief intervention, and referral to treatment in the ED setting may have short-term benefits.[41-49]

SCREENING FOR UNHEALTHY DRINKING AND DRUG USE

Brief standardized screening questions have a higher sensitivity for identifying heavy and dependent drinkers and illicit drug–using patients than smell of alcohol on breath, patient self-report, or profiling based on demographics or presenting complaint. Brief screening instruments are easy to administer and may help match an individual to the most appropriate treatment resource. Validated brief screening questions useful for ED providers include the National Institute on Alcohol Abuse and Alcoholism Quantity/Frequency/Questions[6] and the Single Screening Questions for Alcohol[50] and Drug Use (**Table 292-2**).[51] Questions can be integrated into the triage electronic medical record.[52] Screening for heavy smoking is also important since there is an association between heavy smoking and poly drug use.[52]

As part of the social history, physicians can integrate questions that reflect their concern for the patient's overall health and safety. Substance use disorder screening questions could be embedded among other preventive health

TABLE 292-2 Single Screening Questions

"Would it be okay with you if I ask you some very personal questions that I ask all my patients to improve the care I give? You do not have to answer them if you are uncomfortable."

1. Single Screening Question for Alcohol: "Do you drink beer, wine, liquor, or distilled spirits? How many times in the past year have you had 5 or more (for men)/4 or more (for women) drinks in a day?"[6,50] Clarify that a standard drink is 1.5 oz of spirits, 6 oz of wine, and 12 oz of beer.[6]
2. Single Screening Question for Drug Use: "How many times in the past year have you used an illegal drug or used a prescription medication for nonmedical reasons?" You can add something like ". . . for instance, for the experience or feeling it gives you?"[51]

TABLE 292-3 Identifying Substance Abuse Risk

When assessing a prescription drug monitoring program (PDMP) profile, it is important to look at the following factors:

1. From how many providers did the patient receive prescriptions?
   — Patients who used 4 or more prescribers or 4 or more pharmacies in 6 months may have risk of death from overdose.[59,60]
2. Is the patient taking both opioids and benzodiazepines?
   — Patients who use combinations of medications may be at increased risk for overdose.[61]
3. How many morphine milligram equivalents of opioids is the patient taking per day?
   — Patients who take 50 to 100 morphine milligram equivalents per day are at greater risk of overdose death.[62-64]
4. Is the patient taking long-acting/extended-release (LA/ER) opioids?
   — Patients taking LA/ER may be at increased risk for overdose.[65]
5. How often did the patient fill another prescription before the previous one was scheduled to finish?
   — Early refills indicate nonmedical use or noncompliance with treatment plan.[65]
6. Is the patient taking buprenorphine?
   — Patients taking buprenorphine are likely under the care of a pain specialist who should be contacted prior to prescribing a scheduled medication.
7. Is the patient taking psychiatric medications, such as methylphenidate?
   — Psychiatric comorbidities are associated with increased risk of overdose.
8. If reported by the PDMP, how often did the patient self-pay?
   — Patients may pay out of pocket for a prescription without involving an insurer to avoid detection of nonmedical use.

issues to reduce stigma and patient resistance and encourage veracity and trust. Questions asked in a nonjudgmental, matter-of-fact fashion are well accepted by patients.[53]

Patients who are above the "low-risk" drinking guidelines could benefit from a brief intervention and primary care referral to motivate reducing consumption. For moderate to severe alcohol use, provide referral to a specialized treatment center.

The Centers for Disease Control and Prevention recommends screening for illicit drug use or nonmedical use of prescription drugs before writing an opioid prescription.[54] Screening may not detect all patients with an abuse problem. As an additional tool, nearly all states have implemented prescription drug monitoring programs,[55] which track the prescribing and dispensing of controlled substances at the retail pharmacy level. States with prescription drug monitoring programs appear to have lower rates of substance abuse treatment admission and lower rates of increase in abuse/misuse compared to states that do not have them.[56] Prescription drug monitoring program data can change prescribing behavior, because providers do not have a very good sensitivity (63%) or positive predictive value (41%) in determining drug-seeking behavior without the aid of a prescription drug monitoring programs.[57,58] There are still no evidence-based consensus guidelines for identifying possible drug-seeking activity or patients at risk for prescription drug abuse. Prescription drug monitoring programs do not detect medications that are diverted or purchased illegally, report prescriptions filled in another state (unless there is a data-sharing program in place), or identify residents writing prescriptions under a hospital's Drug Enforcement Administration number. Use prescription drug monitoring program data along with history, physical examination, and clinical impression. Do not use prescription drug monitoring program data as a reason to withhold adequate and necessary analgesia. Several factors from prescription drug monitoring program data may suggest concerning substance abuse risk (**Table 292-3**).

THE BRIEF NEGOTIATED INTERVIEW FOR SUBSTANCE USE INTERVENTION

The *brief negotiated interview*[41,43,48,49,66,67] has four key elements: establish rapport, provide feedback, enhance motivation, and negotiate plan of action. The first principle of promoting health behavior change is that the argument for change needs to come from the patient, not the healthcare provider. Begin a respectful, nonjudgmental conversation by recognizing the patient as the decision maker and asking the patient's permission to talk about alcohol or drug use and health concerns. The best time for early intervention may be during a medical, social, or criminal justice crisis.[69] The entire interaction often can be accomplished in 5 to 7 minutes,[66] and the conversation can take place at any point in care, such as at discharge or while suturing or casting or performing an incision and drainage of an abscess.

The brief negotiated interview algorithm incorporates key elements of motivational interviewing: open-ended questions, affirmations, reflective listening, and summaries (**Figure 292-1**) (see SBIRT for drug use).

Establish rapport *and ask the patient's permission to discuss his or her use of alcohol and drugs.* Establish an atmosphere of trust through respect. The patient is not the problem but is a person who has a problem.

Provide feedback. Elicit patient's thoughts on low-risk or safe alcohol and drug use. Provide information by reviewing current drinking and drug use and guidelines. Express concern that by drinking in excess of safe limits, the patient is at risk for injury or illness. Elicit/solicit the reaction to the guidelines. Ask patients to make a connection between alcohol and/or drug use and quality of life; possible negative consequences related to health, family, legal system, and employment; and, if applicable, the current ED visit or injury. If appropriate, discuss physical dependence, withdrawal, and the cycle of behaviors to obtain more alcohol and/or drugs.

Enhance motivation. *Assess readiness to change on a readiness ruler.* Ask patients to mark on a drawing of a ruler, with a scale of 1 to 10, how ready they are to change, cut back, or quit their alcohol and/or drug use. If they say 5, give affirmation and say that "You are 50% on the way," and ask, "Tell me why you didn't mark a 2 or 3, a lesser number?" Here is when we try to elicit change talk/reasons and motivation for change. Repeat what the patient has shared with you and follow up with, "It sounds like you have some important reasons to change, so what small steps can you take to stay healthy and safe?" If the patient shows resistance to the readiness ruler or the score is <2, then *explore the pros and cons of current use. A discussion of the pros and cons* promotes self-questioning and draws attention to the patient's own reasons for tipping the scale toward change. Use open-ended questions such as, "Help me to understand (or see it through your eyes) what you like and dislike about your use of alcohol?" Explore the importance to the patient of the issues that emerge. *Use reflective listening* to summarize what you think the patient said to verify your interpretation, for example: "On the one hand, you like the taste, how it helps you to loosen up and forget your problems, and it is something to do when you're bored. On the other hand, you said you don't like how you feel the next day and that wrecking your car in a crash and ending up in the ED is no fun. You also told me you are spending a lot of money on drinking and are concerned about not meeting some responsibilities. So then, in the balance, where does that leave you?"

Negotiate and advise. Negotiate an action plan. Explore with patients what life might be like if they made these changes. What would be the benefits of change, and what would be the challenges? Add the steps they would need to take to address challenges and explore and support confidence in ability to make a change. *Offer a menu of options and resources* to assist with the change plan, including, if appropriate, referrals to primary care providers and substance use disorder treatment. *Document the plan.* Ask the patient to state in her or his own words the agreed-on steps and document them on a piece of paper or discharge instructions as a reminder of goals (a prescription for change). Reflect back to the patient and reinforce reasons for, and steps toward, change. End the conversation by thanking the patient for being honest and spending time talking with you.

Afterward, take a minute for self-assessment. To what degree did you provide *f*eedback? Did you *l*isten carefully? Did you ask *o*pen-ended questions? Did you offer *a*ffirmations and *a*lternatives? (FLOAT) Did the patient have enough *t*ime to talk, or did you do the majority of talking? Did you negotiate a concrete action plan?

BNI Steps	Dialogue/Procedures
1. Raise subject	Hello, I am _____. Would you mind taking a few minutes to talk with me about your alcohol use? <<PAUSE and LISTEN>>
2. Provide feedback	
• Review screen	From what I understand you are drinking [insert screening data]… We know that drinking above certain levels can cause problems, such as [insert facts]…I am concerned about your drinking.
• Make connection	What connection (if any) do you see between your drinking and this ED visit? *If pt sees connection:* reiterate what pt has said *If pt does not see connection:* make one using facts
• Show NIAAA guidelines and norms	These are what we consider the upper limits of low risk drinking for your age and sex. By low risk we mean that you would be less likely to experience illness or injury if you stayed within these guidelines.
3. Enhance motivation	
• Readiness to change	[Show readiness ruler] On a scale from 1–10, how ready are you to change any aspect of your drinking?
• Develop discrepancy	*If patient says:* ≥*2 ask* Why did you choose that number and not a lower one?
• Explore pros and cons	*<2 or resistance ask pros and cons* Help me to understand what you enjoy about drinking? <<PAUSE AND LISTEN>> Now tell me what you enjoy less about drinking. <<PAUSE AND LISTEN>>
• Use reflective listening	On the one hand you said, <<RESTATE PROS>> On the other hand you said, <<RESTATE CONS>> So tell me, where does this leave you?
4. Negotiate and advise	
• Negotiate goal	What's the next step?
• Give advice	What do you think you can do to stay within the safe drinking guidelines? If you can stay within these limits you will be less likely to experience [further] illness or injury related to alcohol use.
• Summarize	This is what I've heard you say…Here is a drinking agreement I would like you to fill out, reinforcing your new drinking goals. This is really an agreement between you and yourself. Provide drinking agreement [pt keeps 1 copy]
• Provide handouts and suggest PC f/u	Suggest Primary Care f/u to discuss drinking level/pattern
• Thank patient	Thank patient for his/her time

FIGURE 292-1. Screening, brief intervention, and referral to treatment algorithm as taught in the standardized ED curriculum.[43,66] BNI = brief negotiated interview; f/u = follow-up; NIAAA = National Institute on Alcohol Abuse and Alcoholism; PC = primary care; pt = patient. Copyright John Wiley & Sons.[43,66,70]]

REFERRALS FOR TREATMENT

Train ED staff in screening, brief intervention, and referral to treatment. Develop an ED collaborative team with staff such as social workers, care managers, psychologists, nurse specialists, peer alcohol and drug counselors, volunteers from Alcoholics Anonymous or Narcotics Anonymous, or health promotion advocates to enhance the efforts of existing staff and motivate and assist patients with identifying and accessing treatment options.[45,67,68]

Build and maintain a referral/resource service network.[45,67,68] Current practice in most EDs is to provide patient and family members with a list of detoxification or treatment resources in the community (see "Useful Web Resources" below). The Center for Substance Abuse Treatment at the U.S. Department of Health and Human Services also has an online resource locator (http://dasis3.samhsa.gov). The resource list includes specialized treatment facilities for patients with co-occurring medical, traumatic, and psychiatric illnesses; inpatient and outpatient detoxification, acupuncture, and medication-assisted treatment such as methadone maintenance programs, buprenorphine, and naltrexone for opioid and alcohol addiction; outpatient individual and group counseling; intensive outpatient or partial hospitalization; recovery residents; residential communities; Alcoholics and Narcotics Anonymous meetings; and programs focused on the needs of women, culture-specific programs, and programs designed for gay, lesbian, and transgender clients.

If patients are not ready to enter specialized treatment or attend Alcoholics Anonymous or Narcotics Anonymous, then try to provide information and negotiate a safety plan such as the identification of a designated driver or use of a taxicab when drinking heavily, or avoiding drinking while taking medications. The injecting drug user who is not ready to accept a treatment referral may accept a referral to a syringe exchange program or overdose education, a nasal naloxone rescue kit program, or a prescription for naloxone.

THE MEDICAL CLEARANCE EXAMINATION

EDs often function as sources for the medical clearance examination before patient transfer to a substance or psychiatric treatment facility. There is considerable variability in the levels of medical care provided in such facilities, ranging from facilities that manage an array of chronic health problems to those with minimal nursing support only for very stable patients. Medical clearance does not mean that the patient has no medical problems, but it does mean that "within reasonable medical certainty there is no medical emergency."[71] Criteria include the following: patients are stable for transfer (in the short term rather than long term), are ambulatory, can take oral medications, and are not suicidal or likely to seize. Patients on medications should bring them to the treatment facility or be given prescriptions or provided with several doses. Psychiatrically stable patients with dual diagnoses who are not suicidal or acutely psychotic can be medically cleared for transfer, as long as they have a supply of necessary nonpsychiatric medications and can be expected to be reliable in taking their medications correctly.

CHAPTER 293

Female and Male Sexual Assault

Lisa Moreno-Walton

INTRODUCTION AND EPIDEMIOLOGY

Sexual assault is a crime of violence, intended to dominate and humiliate the victim through the use of intimidation and fear.[1] In many parts of the world, sexual assault is a tool for oppression, a weapon of war, and an act of genocide. Psychological trauma is a universal consequence of rape and sexual assault, but the absence of physical injury does not indicate that an assault did not take place. Sexual assault remains a major public health problem throughout the world, with case rates of police-recorded incidents as high as 92.9 per 100,000 in Botswana to a first time record of 0.0 in Liechtenstein in 2010.[2] In the United States, the case rate is 27.3 per 100,000,[2] with nearly one in five (18.3%) women reporting being raped at some time during their lives.[3]

Although males are less commonly victimized, studies estimate that between 0.6% and 22.2% of males have experienced sexual assaults.[4-6] According to the National Electronic Injury Surveillance System (NEISS), sexual assaults accounted for over 150,000 ED visits in 2001 in the United States.[7] However, many sexual assault survivors do not report the assault to police or seek medical care.[8] Women are likely to seek treatment earlier for more severe assaults and injuries, and they are more likely to delay seeking assistance if assaulted by a known perpetrator.[8]

In most cases of rape in the United States, a single assailant is involved, and most often the perpetrator is known to the victim.[9] Force or coercion is used in most assaults, but a weapon is reported in only 11% of cases.[3]

About half of female[10] and male[11] assault survivors have genital or rectal trauma on examination, and about two thirds have some evidence of bruising elsewhere.[10] Injuries are more often found in female patients <20 years old or >49 years old, those who have experienced anal assault, and those who present within 24 hours of assault. Survivors age 12 to 17 years were more likely to have anogenital injuries than those age 18 to 49 years.[12]

HEALTHCARE RESPONSIBILITIES

Care of the sexual assault victim is complex and can be time-consuming. Responsibilities include obtaining the medical and forensic history; performing and documenting results of the medical examination; collecting forensic evidence and ensuring that material follows the proper chain of custody; treating potential sexually transmitted infections; treating other acute medical problems and injuries; assessing pregnancy risk and providing treatment options; providing referral for crisis intervention and medical follow-up; coordinating care with sexual assault advocates; and testifying in court if needed.[13] Although some hospitals provide **sexual assault nurse examiners** (see below) to aid in medical and forensic evaluation, in many institutions, emergency physicians will be expected to provide most of the care for sexual assault victims.

Sexual assault nurse examiners (SANEs) provide expert assistance for sexual assault evaluation. SANEs are certified by examination through the Commission for Forensic Nursing Certification. Requirements before examination include an unrestricted RN license, 2 years of nursing experience, 40 hours of coursework, and competency in supervised sexual assault examination.[14] Physicians, physician assistants, and nurses can also complete a separate course of training and receive certification as a **sexual assault forensic examiner (SAFE)**. The Department of Justice established national training standards for SAFEs in 2006.[15] Individuals, most often physicians and physician assistants, who complete the proscribed training and pass a standardized exam receive certification as a SAFE. There is little difference between SANE and SAFE training, but only registered nurses are eligible to train as SANEs, and the Commission for Forensic Nursing maintains authority over the certification of SANEs.

Because SAFEs and SANEs are specially trained to perform the precise and sensitive history, physical, and forensic examination, and preserve evidence in a chain of custody, many U.S. hospitals have designated these individuals as part of **sexual assault treatment teams (SARTs)**. Local EMS personnel can transport survivors of sexual assault to SARTs as a matter of protocol.

CULTURAL DIFFERENCES AND MINORITIES

Appropriate cultural competency skills often set the tone for the first steps toward healing. Some cultures consider rape a punishment or a consequence of aberrant sexual behavior.[16] Societies characterized by gender-based power disparities are often less likely to define sexual coercion and threats of violence as rape. Women from such cultures often present for care with other chief complaints or will give inconsistent histories if they feel they are culpable or could have offered more resistance.[17] In countries with a history of slavery, indentured servitude, human property laws, and rigid caste or class systems, policies, traditions, and biases affect the treatment and adjudication of sexual assault. Survivors may be reluctant to report victimization if they fear a biased criminal justice system, do not think police will help, or anticipate being blamed by their family or community.[9,18,19]

Fear of deportation may impact the decision of illegal aliens regarding evidence collection, police reporting, and testifying in court. Before encouraging patients to make a police report, learn your state's laws about illegal aliens who are crime victims.

Women of color face more challenges than white women obtaining assistance after rape. Services for victims of diverse backgrounds are limited, and minority victims are often reluctant to contact rape crisis centers.[9] Although most large cities have good referral services and resources for providers, smaller communities may not have support services for minority and ethnically diverse patients. For black women survivors of sexual assault, poverty is a positive predictor of increased life-long risk of depression and posttraumatic stress disorder.[9,20,21] **The Substance Abuse and Mental Health Services Administration National Council for Trauma-Informed Care** provides excellent resources for institutions, providers, and patients,[22] especially for referrals for continuing care.

THE SEXUAL ASSAULT EVALUATION

TRIAGE

Triage sexual assault patients as a high priority, in accordance with Department of Justice recommendations.[13] Notify the SAFE or SANE on call, and place the patient in a private room, ideally one reserved for the care of sexual assault victims. If a SAFE or SANE examiner is not in-house or if the hospital does not have a SART program, the triage

nurse should notify the emergency physician of the patient's presence in the department. Make sure the patient does not undress or change into a hospital gown, as all clothing must be properly removed and stored for forensic evaluation. Tell the patient not to wash, drink, or rinse the mouth. Provide appropriate medical care whether or not patients agree to evidence collection, police reporting, or assisting with criminal prosecution.

HISTORY

Begin the interview with introductions, express regret about the assault, and provide reassurance that medical and psychological needs will be addressed. Maintain a professional, caring attitude. A patient's response is affected by the physician's attitude. A physician's shock or outrage may increase the patient's concern about physical injuries or cause her to feel marginalized. Questions perceived as critical or judgmental result in feelings of guilt and shame and interfere with the survivor's ability to provide a thorough history. Calm reassurance will facilitate the history, examination, and collection of evidence.

Ask open-ended questions about sexual history. For some women, sexual assault is the first sexual encounter, and for some lesbian patients, it may be the first sexual encounter with a male.

Obtain a thorough past medical history and general assault description, and ask the patient about injuries. In some instances, the triage nurse will have obtained the past medical history. In EDs with SANE services, a detailed assault history, to help guide the evidentiary examination, will be obtained by the SANE. If there are no SANE services, but a sexual assault advocate, police representative, or social worker is available, have those individuals in the room during the history taking so that the patient does not have to repeat information.

Details to gather about the assault and medical history are listed in **Tables 293-1 and 293-2**. Most authorities caution that the chances of finding forensic evidence >72 hours after the assault are slim, so **a forensic examination is not necessary if >72 hours have elapsed since the assault, unless the specific state allows evidence collection up to 96 hours after the assault**. Verify the policy in your state well in advance of the need to know.

TABLE 293-1 Assault History

Who?
Did the assault survivor know the assailant?
Was it a single assailant or multiple assailants?
Can the survivor recall any identifying features of the assailant (height, build, age, race, tattoos, scars, birthmarks, etc.)? (Document in the medical records.)
What happened?
Was the patient physically assaulted?
With what (e.g., gun, bat, or fist) and to what part of the body?
Was there actual or attempted vaginal, anal, or oral penetration?
Did ejaculation occur? If so, where?
Was a foreign object used?
Was a condom used?
When?
When did the assault occur?
(Emergency contraception is most effective when started within 72 h of the assault.)
Where?
Where did the assault occur?
(Corroborating evidence may be found based on the location of the assault.)
Suspicion of drug-facilitated rape?
Was there a period of amnesia?
Is there a history of being out drinking and then suddenly feeling very intoxicated?
Is there a history of waking up naked or with genital soreness?
Douche, shower, or change of clothing?
Did the patient douche, shower, or change clothing after the assault? (Performing any of these activities prior to seeking medical attention may decrease the probability of sperm or acid phosphatase recovery, as well as recovery of other bits of trace evidence.)

TABLE 293-2 Medical History

Last menstrual period? Birth control method?
Last consensual intercourse?
If the patient has had consensual intercourse within the last 3 to 4 days, it may confuse laboratory analysis for sperm and acid phosphatase and genetic typing.
Allergies, medication history, and possible pregnancy?

CONSENT FOR FORENSIC EXAMINATION

Have the patient sign the consent form for the forensic examination, collection of evidence, photography, and transfer of evidence to law enforcement authorities. Most hospitals have a prepackaged rape kit with equipment and directions. However, check with the police if you are unsure about the utility of your hospital's kit, because some police departments may require use of a specific kit for their precincts. Hospitals will usually allow the storage of a rape kit for a specified period of time while the patient decides whether or not she wishes to make a police report. In such a case, encourage the patient to consent to the forensic exam. **Not every part of the forensic evidence kit needs to be used every time. Tailor the collection of evidence to the specifics of the assault.**

If >72 hours (or 96 hours, according to your hospital's policy) have elapsed or the patient does not want an evidentiary examination, still perform a full history and physical examination, provide pregnancy and sexually transmitted disease prophylaxis, and refer for follow-up medical care and rape crisis counseling.

PHYSICAL EXAMINATION

General Examination Record general information such as vital sign values and alertness and orientation. After clothing is properly removed and stored, perform a head-to-toe inspection, and look for injuries. Focus on defensive injury areas such as the extremities, and carefully check potential areas of injury such as the oral cavity, strangulation signs at the neck, breasts, thighs, and buttocks. Describe all injuries, and record all areas of tenderness, even if there is no outward sign of injury. Injuries, predominantly bruises, are often located on limbs (32%), face (23%), and torso (7%), with most assault survivors sustaining light (44%) or moderate (18%) injuries.[23] Other nongenital injuries include abrasions (40%), lacerations (4%), and bites and burns (1%).[10]

FORENSIC EXAMINATION

The forensic examination includes collection of head and pubic hair and buccal swabs for DNA comparison, photographs of injuries, and vaginal and perineal examination, often with colposcopy. Tell the patient what the examiner is doing at each stage of the process. Tell the patient she can take a break at any point during the examination.

Assemble all of the needed equipment for forensic examination. Throughout the examination, keep the patient's body covered as much as possible. Have several pairs of gloves available for different parts of the examination—change gloves between the physical and the genital exam, and again between the genital and the anal exam. A detailed list of equipment and a demonstration of the examination and evidence collection is available. Take photographs of abrasions, bruises, contusions, lacerations, bite marks, burns, areas of erythema, hematomas, incisions, petechiae, and swelling. Document location, position of patient, and position of injury, using a clock face reference. Traditionally, when the patient is in lithotomy position, the pubic bone is at 12 o'clock, the left hip is at 3 o'clock, and the right hip is at 9 o'clock. Begin the photographic series with a photograph of the patient's face and end with a photograph of the patient's hospital wrist band. If photography is not available, describe signs of trauma and areas of tenderness in detail using a body map.

Begin the genital exam with combing of the pubic hair and extraction of hair samples. Patients can pluck their own hair, but make sure that the hair root is included. Examine the genital and rectal areas for injuries and signs of trauma. Note any vaginal discharge, vaginal abrasions, cervical abrasions, and cervical lacerations. In some institutions, a topical application of **toluidine blue dye** is used to highlight microtrauma. Toluidine is a dye with affinity for DNA and RNA.[24] When placed on an area where the topical nonnuclear layer has been removed (as by abrading by injury), toluidine dye will be taken up by underlying cellular tissue. It is typically mixed for use by the hospital pharmacy. Toluidine is applied to the external vulva, especially the posterior fourchette, but not onto mucous membranes. If toluidine dye is used, do not perform a speculum examination until after the toluidine dye examination is completed, because the speculum examination itself may induce small abrasions that can be confused with injuries from the assault.[25] After examination, remove excess dye with a water-soluble lubricant. If the solution is not used soon after it is mixed, cover the bottle with aluminum foil, store at 4°C (39.2°F), and bring to room temperature before use.[26] An alternative to bottles of toluidine blue dye is the commercially available **Forensic Blue Swabs®**.

Colposcopy detects injuries not visible to the naked eye.[11] In one study, only 34% of genital lesions were seen with the naked eye, 49% were seen with a colonoscopy, and 52% were seen with toluidine blue dye.[25] If the colposcope is used to photograph injuries, document magnification. If the patient reports anal penetration, examine the anus and rectum for abrasions or lacerations.

Finally, darken the room and scan the entire body surface with a **Woods lamp** to detect traces of semen. Swab areas where the perpetrator made any oral contact, and swab areas that illuminate with the Woods lamp. Dry and label all swabs and add to the rape kit.

After all evidence is collected, make sure to maintain chain of custody. Do not leave the kit unattended. Each party that releases and accepts the evidence kit must sign, date, and time the chain of evidence form. If the police are not present to receive the evidence, store the kit in a locked cabinet specifically designated for this purpose. Many rape kits contain elements which require refrigeration. In this case, when police are not available to accept the kit, store the entire kit in a locked refrigerator only used to store rape kits.

LABORATORY TESTING

Obtain ancillary tests as clinically indicated. If there is high suspicion of **drug-facilitated rape**, a urine sample can be sent to a laboratory for toxicologic testing. Drugs that are typically thought of as "date rape" drugs, such as ketamine, Rohypnol, and gamma hydroxybutyric acid (GHB), are not detected on routine ED toxicology screening tests, and special "send out" tests must be ordered. Rohypnol can be detected in the urine for up to 72 hours, and GHB can be detected for 12 hours. Results, however, are not available for days.[27] Most SANEs typically send these tests when indicated and assume responsibility for checking the results. In some hospitals with SART programs, consent forms give the right to the prosecuting attorney in the Special Victims Unit to receive the results. If these "send out" tests are ordered by the ED physician, develop a protocol for checking results and documenting results in the patient's record. Guidance for appropriate ordering can be obtained from womenshealth.gov or by calling 800-994-9662.

Obtain a urine or serum pregnancy test before giving emergency contraception. Testing for gonorrhea, chlamydia, and bacterial vaginosis is not necessary, because treatment is provided at the ED encounter. However, **do test for syphilis, hepatitis B and C, and human immunodeficiency virus (HIV)**. Obtain serum chemistry, liver function studies, and CBC for patients who will receive HIV postexposure prophylaxis (PEP).[28] Follow baseline HIV testing with repeat testing at 6 weeks and 3 and 6 months.

TREATMENT

Follow standard care protocols and also individually assess the needs of the survivor.[29,30] Treat physical injuries and provide immediate crisis intervention if needed. Offer emergency contraception, sexually transmitted disease prophylaxis, tetanus and hepatitis B vaccination if needed, and prophylaxis against HIV infection (**Table 293-3**).[28]

TABLE 293-3 Centers for Disease Control and Prevention Guidelines for Postassault Prophylaxis

Postexposure hepatitis B vaccination, if not previously vaccinated. Subsequent doses at 1–2 months and 4–6 months after first dose[28]; no hepatitis B immune globulin
Empiric antibiotics for chlamydia, gonorrhea, and trichomoniasis (see Table 4)
Tetanus prophylaxis if needed
Offer emergency contraception if the assault could result in pregnancy[28]
Baseline testing for syphilis, hepatitis C, and HIV
Obtain serum chemistries and liver function studies if HIV postexposure prophylaxis given

SEXUALLY TRANSMITTED INFECTION PROPHYLAXIS

The prevalence of sexually transmitted infections in an adolescent urban population varies as follows by causative organism: *Neisseria gonorrhoeae*, 0.0% to 26.3%; *Chlamydia trachomatis*, 3.9% to 17%; *Treponema pallidum*, 0.0% to 5.6%; *Trichomonas vaginalis*, 0.0% to 19.0%; and human papillomavirus, 0.6% to 2.3%.[31] The regimens currently recommended by the Centers for Disease Control and Prevention are provided in **Table 293-4**.

EMERGENCY CONTRACEPTION

Obtain a pregnancy test on all women unless there is a history of hysterectomy. Offer pregnancy prevention to those who are not pregnant.[32-37] Also prescribe an antiemetic for nausea and vomiting.[36,37] Offer meclizine 50 milligrams, metoclopramide 10 milligrams, or ondansetron 4 milligrams.[37] **Three common emergency contraceptive regimens are listed in Table 293-5.** A fourth method of emergency contraception recommended by the Centers for Disease Control and Prevention but not commonly used after sexual assault or in the ED is the insertion of a copper intrauterine device. Provide emergency contraception as soon as possible following exposure; the Centers for Disease Control and Prevention states it can be provided within 5 days of unprotected intercourse.[38] Pregnancy after emergency contraception is 3.6 times more likely for obese women than for women with a normal body mass index. Failure of emergency contraception is more likely to occur with levonorgestrel than with ulipristal acetate; however, in all women, regardless of body mass index, the most significant factor predicting failure is the cycle day of intercourse.[39] Because rape poses a risk of sexual disease transmission and because rape may have resulted in trauma, oral contraceptive pills are the preferred form of ongoing contraception.

Breastfeeding is not contraindicated following emergency contraception. Advise women that emergency contraception does not protect against HIV infection, other sexually transmitted infections, or subsequent unprotected intercourse. Recommend follow-up with a healthcare provider for all women and especially those with abnormal bleeding after cessation of emergency contraception.[37] Advise women who use emergency contraception to follow up with a regular provider to begin use of ongoing contraception in the form of oral contraception pills or

TABLE 293-4 Centers for Disease Control and Prevention Recommended Regimens for Infection Prophylaxis

Ceftriaxone, 250 milligrams IM, single dose; *or* cefixime 400 milligrams PO, single dose
Plus
Metronidazole, 2 grams PO, single dose
Plus
Azithromycin, 1 gram PO, single dose
Or
Doxycycline, 100 milligrams PO, twice a day for 7 d

TABLE 293-5 Emergency Contraception

Drug	Dose	Comments
Levonorgestrel (Plan B)	1.5 milligrams once *or* 0.75 milligrams at 1 and 12 h	Prescribe antiemetics; less nausea than combined estrogen-progestin
Combined estrogen-progestin[40]	100 micrograms ethinyl estradiol *plus* 0.50 milligrams levonorgestrel, at 1 and 12 h	Prescribe antiemetics
Ulipristal acetate (Ella/Fibristal)	30 milligrams PO in a single dose	Prescribe antiemetics

copper intrauterine device to ensure successful prevention of pregnancy from subsequent unprotected intercourse.[38,39]

HIV POSTEXPOSURE PROPHYLAXIS

Viral load in the assailant is the most significant factor determining infectivity.[41] HIV seroconversion has occurred in persons whose only known risk factor was sexual assault or sexual abuse.[42] HIV transmission risk increases when bleeding occurs with vaginal, anal, or oral penetration; if viral load in the ejaculate is high; and if genital lesions are present in the assailant or the survivor.[28] Assistance in determining the advisability for PEP can be obtained by calling the toll-free 24-hour National HIV/AIDS Post Exposure Hotline at 1-888-448-4911 or by accessing their website at www.nccc.ucsf.edu/home. The Centers for Disease Control and Prevention recommendations for postexposure assessment of adolescents and adults are listed in **Table 293-6**.

If PEP is administered, follow the standard protocol recommended by your hospital's infectious disease specialists. When prescribing HIV PEP, ask about sulfa allergy. Truvada includes tenofovir which has a sulfa moiety.

DISPOSITION AND FOLLOW-UP

Excellent care for survivors of sexual assault requires the coordination of clinical medicine with forensic science, law enforcement, and survivor advocacy. Once injuries are assessed and managed, offer counseling. This can be done by a dedicated rape counselor or trained social worker. If injuries are not severe, a rape counselor may be present prior to the physician's assessment. Gaps in service and patient care have largely involved lack of treatment of sexually transmitted infections and lack of availability of pregnancy-related services.[43]

TABLE 293-6 Recommendations for Postexposure Assessment of Human Immunodeficiency Virus (HIV) Infection Risk for Adolescent and Adult Survivors within 72 Hours of Sexual Assault

Assess risk for HIV infection in the assailant.
Evaluate characteristics of the assault event that might increase risk for HIV transmission.
Because recommendations vary with time and between institutions, consult with a specialist in HIV treatment for specific postexposure prophylaxis (PEP).
If the survivor appears to be at risk for HIV transmission from the assault, discuss antiretroviral prophylaxis, including toxicity and lack of proven benefit.
If the survivor chooses to start antiretroviral PEP, provide enough medication to last until the next return visit. Reevaluate the survivor 3–7 d after initial assessment and assess tolerance of medications.
If PEP is started, perform CBC and serum chemistry panel at baseline. Do not delay PEP while awaiting laboratory results.
Perform HIV antibody test at original assessment; repeat at 6 weeks, 3 months, and 6 months. Repeat serologic assessment for syphilis can also be repeated at these times.[28]

Source: From Centers for Disease Control and Prevention: Sexually transmitted diseases: treatment guidelines 2010: sexual assault and STDs. http://www.cdc.gov/std/treatment/2010/sexual-assault.htm#adults. Accessed April 10, 2013.

Prior to discharge, make sure that the patient has a safe place to go, a safe way to get there, and a plan for addressing absence from home or work. This conversation should include a discussion of if, to whom, and how she will reveal her assault for the present time. Cultural competency of the caregivers is essential throughout the delivery of healthcare services to the survivors of sexual assault, but is critical at this juncture. If the team is not familiar with the cultural attitudes and practices surrounding sexual assault in the survivor's religious, ethnic, or social group, ask the patient how his or her family, religious community, or social network may respond.

Prior to discharge, provide the opportunity for bathing and oral care. Because clothing has been sequestered as part of the evidence kit, hospitals should provide fresh, packaged underwear and outerwear for the patient. Sweat suits are customarily provided at most SART hospitals. This is an appropriate time to raise the issue of returning to the home environment, since the patient will return in clothing that is not customary dress. Provide a headscarf for women who customarily wear head coverings in public.

Arrange follow-up appointments according to Centers for Disease Control and Prevention recommendations. Patients receiving PEP should be seen in 3 to 7 days following initial assessment, and all patients should be seen in 1 to 2 weeks.[28] This ensures the effectiveness of pregnancy prophylaxis and sexually transmitted infection treatment.

Male sexual assault survivors should follow up with a urologist or proctologist. Special populations, such as children, should be referred to a pediatrician or a pediatric abuse clinic.

SPECIAL POPULATIONS

ADOLESCENTS AND CHILDREN

Consider sexual abuse in children if no definitive explanation for nonsexual transmission of a sexually transmitted infection can be identified.[28] For extensive discussion, see chapter 148, "Child Abuse and Neglect." The most experienced examiner available should examine children to minimize pain or further trauma. Today, there are over 600 pediatric SANE programs in the United States.[44-46]

ELDERLY PATIENTS

Most elder assaults take place at the patient's home, and most assaults are by an unknown assailant.[47] In the case of an elderly assault survivor, the forensic interview and examination present unique challenges. The patient not only may resist the pelvic examination because of injury or pain, but the pelvic area may be difficult to visualize because of hip contractures or vaginal atrophy. It is also difficult to explain the examination to a patient with dementia or cognitive impairment. Further challenges include obtaining an accurate and reliable history of the details of the assault, the injuries sustained, and regions of pain or discomfort.[47,48] Special adjustments may be needed for the interview and sexual assault examination.[47,48]

TRANSGENDER AND LESBIAN PATIENTS

Information about sexual assault of lesbian and transgendered women has mostly relied on data from informal surveys.[49] A London clinic reported that transgender sex workers self-reported higher rates of violence and sexual assault than did biological female sex workers, but that rate was not specified.[50] **FORGE** (www.forge-forward.org) is a Wisconsin-based group for the support of the transgender population. The group has a Web site with printable handouts for lesbian and transgendered patients who are sexual assault survivors, survivor first-person narratives, and resource links for both patients and providers.

MEN

Male sexual assault is less common than sexual assault of women.[51] Assaults on males generally result in more severe injuries,[52,53] with 40% to 60% of males sustaining anogenital injuries,[53,54] and assaults on men are likely to involve multiple assailants.[55] At least a third of males who are sexually assaulted have a history of psychiatric or cognitive disability.[54] One major factor that complicates the care of male survivors is the fact

Global Issues in Sexual Assault

Lisa Moreno-Walton

In the 1990s, during the conflicts in Bosnia, Rwanda, the Democratic Republic of the Congo, and Liberia, rape became weaponized as a form of torture,[1] genocide,[2] and a means of humiliating and demoralizing the opponent.[3] Although women are subjected to sexual torture far more often than men,[4] sexual assault is calculated to destroy not only the man or woman who is raped, but entire families and communities. Rape of men is meant to be the ultimate humiliation of conquest, and the rape of women highlights the inability of men to perform their role as protectors of women and children. In the Congo, for example, over half of the victims of military rapes are children, 10% of them less than 10 years of age. In the ultimate depravity, fathers are forced to rape their daughters and sons their mothers in the presence of the entire community as a means of achieving total submission through fear.[5]

Systematic, repeated rape is now an adjunct to genocidal extermination camps and has been used in Sudan, Guatemala, the Congo, Rwanda, and Bosnia.[2] During the Bosnian War (1992 to 1995), the Serbian paramilitary created rape camps to imprison women and adolescent girls, and torture and gang rape them over months with the "assistance" and compliance of the local authorities.[6] There are reports, out of Liberia specifically, describing the dual role of combatants who are commanded to torture, rape, and murder and then to gratify the sexual desires of their superior officers in order to keep their jobs.[7] Societies demoralized by war, fearful of torture and death, hungry and poor, and knowing that there are no consequences for their assailants, often come to regard violence and the expectation of violence as customary and acceptable.[2,4-8]

Plagued by both poverty and concerns for their daughters, many parents coerce young girls into early marriages as a way of fetching a good bride price for a virgin daughter, who has not yet been raped by the military or paramilitary combatants. Instances of girls as young as 11 or 12 years being given in marriage to men in their 60s have been reported.[8,9] Girls who run away are beaten by their families and returned to their husbands either to protect the family's reputation or because some of the money from the bride price has already been spent. In many such traditional cultures, victims of rape are blamed for their assault and bring shame upon their families. Women may not access medical care without the permission of their husbands, increasing the likelihood that rape will never be reported.[9] And although sexual assaults by strangers are widely acknowledged as crimes, rape in marriage, sexual coercion in schools, demands for sex in return for a job, and forced marriage are tolerated or socially condoned in many countries. Women are expected to be submissive and sexually available to their husbands at all times, and it is considered both a right and an obligation for men to use violence in order to "correct" or chastise women for perceived transgressions.[10]

When rape is used as a weapon of war, the consequences to women are severe. Many women suffer fistulas, incontinence, infertility, depression, suicidal ideation, suicide, abandonment by family, and exile by the community.[2,4,5,11,12] Women who have been raped are more likely to be sexually abused again[2] and are more likely to engage in high-risk sexual behavior, such as exchanging sex for food and money, having sex with military personnel for perceived benefits of association with the powerful, and having unprotected sex with individuals known to be human immunodeficiency virus positive.[13] Both rape and high-risk sexual behavior in exchange for food, money, and/or cosmetics are reported to be frequent among internally displaced persons living in refugee camps.[12-14]

However disturbing these reports may be, investigation of the literature reveals that physicians and scientists still do not have a comprehensive understanding of the dynamics of sexual violence, that methods of data collection remain understandably flawed, and that methodology, including single-site studies of self-reports by small populations, may indeed not represent the scope of the actual problem. Although some countries' medical associations have issued guidelines to clinicians, global clinical standards of care need further development.[15] Journalists with an incomplete understanding of biostatistics often report inaccurate information that remains as fact in the minds of the general public, as evidenced by a media report that 75% of Liberian women were raped during the country's civil war. Peer-reviewed studies have set the estimated number at 9.2% to 15%, with 77% of women who were assaulted reporting sexual violence.[16] Overreporting of such sensitive data may make good news, but ultimately, it damages the credibility of future reports. Underreporting may trivialize a major human rights violation and the suffering of its victims.

Human rights organizations, national governments, physicians, and physician organizations must continue to take firm steps to ensure sanctions against governments, societies, and individuals who tolerate such practices.

that physiologically, the stimulation of anal penetration can lead to involuntary erection and sometimes to ejaculation. Furthermore, many assailants manually stimulate their victims to cause ejaculation. Numerous cases of male sexual assault have been determined to be consensual by judges and defense attorneys who fail to understand the involuntary nature of this physiologic response.[55] The survivors themselves can be confused and distressed by this response and may hesitate to offer this information. Use a short, simple explanation of the physiology using lay language to assist in history taking.

Hospitals have male rape kits available, and the same guidelines should be followed for history, physical exam, collection of forensic evidence, and maintaining chain of custody as have already been described. SANEs and SAFEs are all trained in the sexual assault forensic examination of males. Resources for counseling may be more difficult to find for the male survivor, especially in small communities. The **Rape, Abuse & Incest National Network** does have special resources for men. Their victim hotline can be reached at 1-800-656-HOPE, and their Web site can be accessed at www.rainn.org

PRACTICE GUIDELINES AND SOCIETY POSITION STATEMENTS

The American Academy of Pediatrics, American College of Obstetrics and Gynecology, American College of Emergency Physicians, and Centers for Disease Control and Prevention all have issued recommendations regarding the acute management of rape survivors.[28,56-59] The American College of Emergency Physicians issued a policy statement on the treatment of the patient with a complaint of sexual assault.[58] As an adjunct to this policy, the American College of Emergency Physicians Emergency

Medicine Practice Committee prepared a handbook, *Evaluation and Management of the Sexually Assaulted or Sexually Abused Patient*, to assist in developing a community or ED plan.[59]

Acknowledgment: The author would like to thank Sheryl L. Heron, MD, and Debra E. Houry, MD, for writing the prior edition of this chapter, which has been updated and revised for this edition.

CHAPTER 294

Intimate Partner Violence and Abuse

Mary Hancock

INTRODUCTION AND EPIDEMIOLOGY

Intimate partner violence is defined as a pattern of assaultive, coercive behaviors that may include inflicted physical injury, psychological abuse, sexual assault, progressive social isolation, stalking, deprivation, intimidation, and threats. Such behaviors are perpetrated by someone who is, was, or wishes to be involved in an intimate or dating relationship with an adult or adolescent individual and are aimed at establishing control by one partner over the other.[1]

Intimate partner violence and abuse is the preferred alternative for previously used terms such as *spousal abuse*, *wife battering*, and *domestic violence*. This term more accurately reflects the fact that this type of abuse occurs not only in adult heterosexual married relationships but also in relationships between cohabiting, separated, gay and lesbian, bisexual, and transgendered individuals as well as in adolescent dating relationships.[2,3]

Intimate partner violence and abuse occurs in every racial, ethnic, cultural, geographic, and religious group, and it affects individuals of all socioeconomic and educational backgrounds worldwide. Men are affected, but the overwhelming burden of victimization from intimate partner violence is borne by women.[2,4,5] Risk factors for intimate partner violence and abuse include female sex, age between 18 and 24 years, low income level of the household, and relationship status of separated rather than divorced or married.[2] Sexual and/or physical abuse during childhood and adolescence is a frequent predictor of future victimization.[2,6] Presence of weapons in the home and threats of murder are associated with increased risk of homicide.

Effects extend to family members, friends, coworkers, other witnesses, and the community at large.[2] Children who grow up in violent homes may be physically or emotionally abused or neglected, and witnessing violence can have short- and long-term adverse health consequences.[7] In families in which *either* child maltreatment or spousal abuse is identified, it is likely that both forms of abuse exist. Children may be incidentally injured or killed when they try to intervene in a struggle.[7] Children exposed to violence in the home may develop behavioral difficulties, including depression, abusive behaviors, and drug abuse. Frequent exposure to violence in the home may teach children that violence is a normal way of life. Perpetrators of violence, in particular severe violence, may be at risk for suicide, committing murder, or being murdered by a family member.[7,8]

Ask about a history of intimate partner violence or abuse during healthcare encounters. Failure to recognize and intervene in situations of intimate partner violence may have serious consequences for the survivor and family. Such consequences may include continued violence, physical and psychological health problems, and injury or even death.[2,9,10]

CLINICAL FEATURES

Intimate partner violence is most often cyclical in nature. The cycle begins with a period of tension building, which may include arguing, blaming, or controlling behaviors or jealousy. The next phase is escalation and may include verbal threats, physical and sexual abuse, or assault. Weapons may be used at this point. Subsequently, there is a "honeymoon" phase in which the perpetrator may apologize or make excuses for inappropriate behavior. Over time, the abusive behavior tends to increase in severity, and the intervals between abusive episodes become shorter.

There are no "usual" features by which a person who has experienced intimate partner violence may be identified in the ED. Often it is one of a number of health-related consequences of violence or abuse that causes persons who have experienced intimate partner violence to seek medical attention (**Table 294-1**). Therefore, screening and assessment for elements of the history and physical examination suggestive of intimate partner violence are needed to identify victims. Signs suggestive of intimate partner violence and abuse are summarized in **Table 294-2**.[1,2,4,11]

TABLE 294-1 Consequences of Intimate Partner Violence

Adults	Adolescents	Children
Injuries	Same as for adults	Low birth weight
Alcohol and substance abuse	*plus*	Prematurity and associated complications
Sexually transmitted infections	Victimization as an adult	Failure to thrive
Human immunodeficiency virus infection	Fertility problems	Parental neglect syndrome
Unplanned/unwanted pregnancy	Poor school performance and school dropout	Speech disorders
Headaches	Unwanted pregnancy and associated complications of pregnancy, frequent pregnancies	Bedwetting
Chronic pelvic pain		Headaches
Urinary tract infections	Eating disorders	Cognitive functioning problems—lower verbal and quantitative skills
Vaginal bleeding	Behavioral disorders	Psychological and emotional problems—aggression, hostility, withdrawal, acting out
Back pain	Involvement with the legal system and courts	
Eating disorders	Prostitution	
GI disorders	Increased suicide risk	
Depression	Smoking and substance abuse	
Panic disorders		
Suicide		
Posttraumatic stress disorder		
Homelessness		
Social isolation		

TABLE 294-2 Signs Suggestive of Intimate Partner Violence

Findings	Comments
Injuries characteristic of violence	Fingernail scratches, broken fingernails, bite marks, dental injuries, cigarette burns, bruises suggesting strangulation or restraint, and rope burns or ligature marks may be seen.
Injuries suggesting a defensive posture	Forearm bruises or fractures may be sustained when individuals try to fend off blows to the face or chest.
Injuries during pregnancy	Up to 45% of women report abuse or assault during pregnancy.[12] Preterm labor, placental abruption, direct fetal injury, and stillbirth can occur.
Central pattern of injury	Injuries to the head, neck, face, and thorax and abdominal injuries in pregnant women may suggest violence.
Extent or type of injury inconsistent with the patient's explanation	Multiple injuries at different anatomic sites inconsistent with the described mechanism of injury. The most common explanation of injury is a "fall." Embarrassment, evasiveness, or lack of concern with the injuries may be noted.
Multiple injuries in various stages of healing	These may be reported as "accidents" or "clumsiness."
Delay between the time of injury and the presentation for treatment	Victims may wait several days before seeking medical care for injuries. Victims may seek care for minor or resolving injuries.
Visits for vague or minor complaints without evidence of physiologic abnormality	Frequent ED visits for a variety of injuries or illnesses, including chronic pelvic pain and other chronic pain syndromes.
Suicide attempts	Women who attempt or commit suicide often have a history of intimate partner violence.[12]

A defensive, hostile, or aggressive partner accompanying the patient may provide clues to the diagnosis by exhibiting controlling or abusive behavior. Overly solicitous behavior by the partner may occur. The patient may appear frightened of the partner or refuse to answer questions and instead defer all responses to the partner. In situations raising concern, and if the patient agrees, hospital police can prevent the alleged perpetrator from visiting the patient in the ED and hospital. **Ask abused individuals if they have suicidal or homicidal ideation. Such ideation, particularly if accompanied by a concrete plan of action, should trigger immediate consultation with a mental health provider.**

SCREENING AND ASSESSMENT

Many experts, including the American Medical Association and The Joint Commission, recommend routine screening for intimate partner violence for all adolescent and adult women who present to the ED and for mothers of children brought to the ED. National screening consensus guidelines are available online at http://www.futureswithoutviolence.org.[13] Because of the known adverse long-term impacts of intimate personal violence on health, when time permits, consider screening for lifetime exposure.

The responsibilities of the ED team include identification of intimate partner violence; validation of the abused individual's experience; assessment of immediate risk and safety planning; referral to experts for care; and documentation in the medical record.[12]

Screening should be conducted by providers educated about the dynamics of intimate partner violence. Provide a safe and private environment for the interview. Take into account cultural differences and expectations. If translators are required, use individuals who have no connection to the patient and, if possible, who have education in the dynamics of abuse. Document screening results, safety assessment, and any interventions, including referrals and required reporting. Screening guidelines for adolescent and adult patients are summarized in **Table 294-3**.[13] Sample verbal screening questions are listed in **Table 294-4**.

Abused individuals want providers to be nonjudgmental, sensitive, and direct. They also want to be assured of confidentiality. They want the provider to have an understanding of the complexity of intimate partner violence and the difficulty of achieving a "quick fix." Women value the reassurance that their experiences with intimate partner violence and abuse are unacceptable and undeserved (it is not their fault). They also value a nonpressured encounter and a provider who respects their decisions and works with them to determine an appropriate course of action.[14]

TREATMENT AND DISPOSITION

Ensuring the safety of the abused individual and children is the foremost goal. "Placing the patient in a shelter" or "having the attacker arrested" may not be congruent with the individual's goals. Ultimately, the abused individual must make the determination of whether it is safe to return home. By providing information about intimate violence, risks, and options, the physician can help the patient decide what is best for themselves and their family members. The patient's decision making may be very complex, because depression, lack of self-esteem, lack of support, social isolation, financial dependence on the perpetrator, and fear make it difficult to leave the relationship.

Patients must be told that violence, abuse, and intimidation are not a part of normal, healthy relationships. For some, this may be the first

TABLE 294-3 Summary of National Consensus Guidelines for Screening for Intimate Partner Violence and Abuse in the ED[13]

Screening	Assessment	Intervention	Documentation	Referral and Follow-Up
Routinely screen at every visit. Screen for current abuse, and if time allows, screen for history of abuse. Screen privately (one on one) or with nonrelated trained interpreter. Ask: What happened? When did it happen? Where did it happen? Who did this? Respect patient decision to disclose or not. Discuss any required reporting. Include screening questions on intake forms.	Assess immediate safety. Assess health impact of abuse. Assess pattern of abuse. Assess for danger and potential lethality. If the danger assessment findings are positive, assess potential for suicide and homicide.	Listen carefully and provide support. "I'm concerned for your health and safety." "You are not alone." "Help is available." "It is not your fault." "You don't deserve it." "What happened to you can affect your health." Provide information and materials. "What can I do for you?" Provide a safety plan. Offer services, including an advocate, social worker, police, shelter, etc.	Legible, full signature; maintain confidentiality of records Abuse history: Subjective information: patient states… Objective information: detailed description of patient's appearance, behavioral indicators, injuries, and health complaints Use of rape kits where appropriate Results of physical examination Use of body maps Photographs (with patient's consent) Radiologic, laboratory findings, collection of forensic evidence: clothes, debris, etc. Any materials and referrals offered Results of health and safety assessments	Refer to primary care physician, mental health provider, social worker, or intimate partner abuse advocate. Obtain permission to notify provider. Know current phone numbers for: Abuse and assault prevention programs Legal services Children's programs Mental health services Law enforcement Substance abuse programs Transportation Local clergy or other community organizations

TABLE 294-4 Sample of Domestic Violence Screening Questions

The healthcare worker should explain the following in his or her own words:

We are concerned about your health and safety, so we ask all women the same questions about violence at home.

Violence is very common, and we want to improve our response to families experiencing violence.

The healthcare worker may ask the following questions of ALL patients:

1. Are you ever afraid of your partner?
2. In the last year, has your partner hit, kicked, punched, or otherwise hurt you?
3. In the last year, has your partner put you down, humiliated you, or tried to control what you can do?
4. In the last year, has your partner threatened to hurt you?

If domestic violence has been identified in any of the above questions, ask if the individual would like assistance today. Be prepared to offer resources, assess for safety, and discuss a safety plan with the individual.

time they have heard such information. The abused individual's reports and experiences should be acknowledged and believed. Let the patient know that you take the situation seriously and that you are concerned about the health and safety of her (or him) and the children. Emphasize that he or she has done nothing to warrant violence and abuse. It is the perpetrator whose behavior is unacceptable. Clarify that ED personnel can help patients contact trained social workers or intimate violence advocates, who can then help develop logistical plans either for safety or for ending the relationship. Respect the abused individual's wishes about the future of the relationship. Screening and validation may be the stimulus needed by the patient to begin planning for change.

Indicators of a high-risk and potentially lethal situation include escalation in the frequency or severity of violence; the threat or actual use of weapons, in particular firearms; obsession with the abused individuals; hostage taking; stalking; and homicide or suicide threats or attempts and evidence of violent behavior outside the home. Another risk factor for serious injury or death is substance abuse by the perpetrator, which can increase violent behaviors.[2,11]

The most dangerous periods for abused individuals are during the time of abuse disclosure and during attempts to leave the relationship. Some patients feel safer remaining in the violent relationship than leaving without adequate planning for a safe departure.[13]

Refer survivors to intimate violence experts, such as hospital social workers or community-based advocates, who can help the victim assess the situation, understand options, plan for safety, and arrange safe shelter. Community advocates are typically on call or available by telephone. If the patient can be safely discharged from the ED and personal contact with an advocate cannot be made before discharge, give the patient up-to-date information about available services in the community. **Intimate personal violence advocates should not be asked to call the patient directly unless the patient agrees, because calls to the home could jeopardize the patient's safety.**

Resources for healthcare providers to assist in preparing their practices for optimal response to victims of intimate personal violence are available from a number of organizations (**Table 294-5**).

If lethality risk is high, consult with experts before ED discharge. Hospital admission of the abused individual or children is an option in high-risk situations in which there is no other way to ensure safety. Use of a 24-hour safe room, a location established by some hospitals and communities to provide a safe place for the patient to stay while arrangements for safe disposition of the patient and family members are made, is another option. Use of an alias name on admission and screening of incoming phone calls may also be of benefit.

TABLE 294-5 Resources for Healthcare Providers

Futures Without Violence (formerly Family Violence Prevention Fund)	http://www.futureswithoutviolence.org
National Domestic Violence Hotline	800-799-SAFE (7233)
National Coalition Against Domestic Violence	http://www.ncadv.org

ED RECORD DOCUMENTATION

Documentation in the ED should be clear and legible. Voluntary descriptions of intimate personal violence should be quoted and described in the patient's own words. Do not use the word *alleged* because it implies that the person recording the incident does not believe the complaint. A complaint of "sexual assault" is no more alleged than is a complaint of "ear pain" or a "sore throat."

Record past and current abuse, with details of date, time, location, witnesses, and specific injury. Describe the patient's health complaints, injuries, appearance, and demeanor. Annotated body maps and photographs can supplement written notes.

Obtain relevant forensic evidence, and follow the appropriate chain of custody of evidence. If sexual assault has occurred, document ED testing and treatment.

Record safety assessment and disposition. A safety assessment form or referral notes from an expert are helpful adjuncts. Discussion of a safety plan with the patient is an important discharge function and also requires documentation.

LEGAL CONSIDERATIONS

Most states in the United States have laws that require healthcare providers to report injuries resulting from firearms, knives, or other weapons. Twenty-three states have reporting requirements for injuries resulting from crimes (intimate personal violence is a crime in all 50 states); seven states have statutes that specifically require health providers to report injuries resulting from intimate personal violence. The specifics of the reporting requirements vary from state to state, and the adequacy of response by the police to reporting varies by jurisdiction.[15] Inadequate or inappropriate response to the reports (e.g., informing the perpetrator of the report without providing for the safety of the abused individual) can increase the risk of harm to abused individuals. ED personnel should be aware of reporting requirements and police response in their area. Patients must be informed if there is an obligation to make a police report and should also be told about possible ramifications.

ED PREPARATION FOR OPTIMAL RESPONSE

The Joint Commission requires, and the Institute of Medicine recommends, that staff receive initial and ongoing training about intimate partner violence and abuse. This should include education related to cultural competency, victim perspective, and consequences of violence, as well as how to assess, intervene in, support, and document care. Employees should also be informed of their options for assistance if they or someone they know is in an abusive relationship.

A routine screening protocol should be implemented that addresses training of ED personnel, confidential interviewing, and appropriate interventions, including validation and referral.

Multicultural and multilingual information about interpersonal violence and effects on abused individuals and family members should be made available to the public and employees. This may consist of posters and/or brochures in areas of the hospital such as public areas, examination rooms, and restrooms. Community resources that provide services to victims should be a part of the shared information.

Implement a continuous quality improvement program that assesses adherence to recommended screening and intervention strategies.

Form professional relationships with hospital- and/or community-based experts to ensure appropriate referral practices.

SPECIAL POPULATIONS

PREGNANCY

Prevalence during pregnancy ranges from 6% to 22%.[5,11] Women who report intimate partner violence and abuse during pregnancy are at increased risk of postnatal abuse. Approximately half of female murder

TABLE 294-6 Strategies for Violence Prevention—World Health Organization

Increase safe, stable, and nurturing environments between children and their parents or caregivers.
Reduce availability and misuse of alcohol.
Reduce access to lethal means.
Improve life skills and enhance opportunities for youth.
Promote gender equality and empower women.
Change cultural norms that support violence.
Improve criminal justice systems.
Improve social welfare systems.
Reduce social distance between conflicting groups.
Reduce economic inequality and concentrated poverty.

National Domestic Violence Hotline: 24 h; links caller to help in her (or his) area—emergency shelter, domestic violence shelters, legal advocacy and assistance programs, social services	800-799-SAFE (7233) 800-787-3224 (TTY)
Rape, Abuse, and Incest National Network: 24 h; automatically transfers caller to nearest rape crisis center anywhere in the nation	800-656-HOPE (4673) http://www.rainn.org

victims are killed by a current or previous intimate.[2,11] Women assaulted during pregnancy are three times more likely to be admitted to the hospital than nonpregnant women.[11]

GLOBAL ISSUES

Globally, death from interpersonal violence is ranked as the 20th most common cause of death.[16] The World Health Organization's Violence Against Women Survey demonstrates that intimate partner violence and abuse not only are substantial health problems due to direct injury and mortality, but also contribute to other serious health problems because of an increased burden of disease. The associations between reported ill health in women and intimate partner violence and abuse are consistent within and across countries.[8,16] This effect persists even if the violence was in the past.[16]

In May 2014, the 67th World Health Assembly requested that the World Health Organization prepare a global plan of action to strengthen the health system to address interpersonal violence, especially against women, girls, and children (http://www.who.int/violence_injury_prevention).

Ten key strategies for violence prevention have been developed for international use[17] (**Table 294-6**).

For resources for patients (hotlines), see **Table 294-7**.

PRACTICE GUIDELINES

The *National Consensus Guidelines on Identifying and Responding to Domestic Violence Victimization in Health Care Settings*, revised in 2004, is available from Futures Without Violence (formerly Family Violence Prevention Fund) (http://www.futureswithoutviolence.org). Preparation of this report was funded by the Conrad N. Hilton Foundation and the U.S. Department of Health and Human Services.

CHAPTER 295

Abuse of the Elderly and Impaired

Jonathan Glauser
Frederic M. Hustey

INTRODUCTION

Elder abuse is an act or omission resulting in harm to the health or welfare of an elderly person. Three key groups have published definitions of elder abuse.[1-3] Although the incidence of elder neglect and abuse is unknown and widely felt to be underreported, the rate of different types of abuse among the elderly has been estimated to be in the mid-single digits, or between 500,000 and 1 million U.S. adults.[4,5] **Table 295-1** summarizes the categories of elder abuse.

CLINICAL FEATURES

PHYSICAL ABUSE

Physical abuse is the most easily recognized form of elder abuse. It is defined as the use of physical force that might result in bodily injury, physical pain, or impairment. Pushing, slapping, burning, striking with objects, and improper use of restraint are all examples of physical abuse. Chemical restraint (such as intentional overmedication or administration of tranquilizers) is a more subtle form. Regardless of mechanism, physical abuse is carried out with the intention of causing suffering, pain, or other physical impairment to the abused person.

CAREGIVER NEGLECT

Elder neglect is the most common form of elder maltreatment, accounting for more than half of all elder maltreatment cases reported to adult protective services agencies annually.[6] Elder neglect is defined as the failure of a caregiver to provide basic care to a patient and to provide goods and services necessary to prevent physical harm or emotional discomfort.[7,8] Examples of neglect include deprivation of food, clothing, hygiene, medical care, shelter, or supervision that a prudent person would consider essential for the well-being of another.[7,8]

Elder neglect is both underrecognized and potentially lethal. It likely accounts for the majority of cases of unreported abuse.[9] It is also an independent risk factor for mortality, even taking into account that the

TABLE 295-1 Categories of Elder Abuse

Categories of Abuse	Example
Physical abuse	Pushing, slapping, burning, striking with objects, improper use of restraint (physical or chemical)
Caregiver neglect	Deprivation of food, clothing, hygiene, medical care, shelter, or supervision
Sexual abuse	Unwanted touching, indecent exposure, unwanted innuendo, rape
Financial or material exploitation	Forcible transfer of property or other assets, including changing elderly person's will
Emotional or psychological abuse	Verbal threats (such as threats of violence, institutionalization, or deprivation), humiliation, intimidation, harassment, social neglect, and isolation
Abandonment	Desertion of an elder in the home or a hospital, nursing facility, shopping mall, or other public location by a caregiver or caretaker
Self-neglect	Failure or unwillingness to provide adequate food, clothing, shelter, medical care, hygiene, or social stimulation to self in individuals with diminished capacity to perform essential self-care tasks

Source: Reproduced from U.S. Department of Health and Human Services, Administration on Aging and Administration for Children and Families: *The National Elder Abuse Incidence Study*. Washington, DC: National Center on Elder Abuse, 1998.

deaths themselves may not be immediately ascribed to injury.[6] Elder neglect may be difficult to diagnose. Although some cases may be obvious (such as in a patient with multiple deep pressure ulcers), it is often more subtle and difficult to detect.

SEXUAL ABUSE

Sexual abuse is broadly defined as nonconsensual sexual contact of any kind with an elderly person. The spectrum of sexual abuse ranges from unwanted touching, indecent exposure, or unwanted innuendo, to rape itself. Although sexual abuse is underreported across all age groups, in the elderly, sexual abuse is even less likely to be reported. Fear of retaliation and shame on the part of patients, as well as stereotyping of older patients as asexual or not sexually desirable by clinicians, police, and others, may be factors in underrecognition and underreporting of sexual abuse.[10]

FINANCIAL OR MATERIAL EXPLOITATION

Financial abuse is estimated to be the second most common form of elder abuse, accounting for approximately 20% to 30% of abuse cases.[11] Financial or material exploitation is the illegal or improper use of an elder's funds, property, or assets.[12] It occurs when family members, caregivers, or friends take control of the elder person's resources. Coercion or outright theft may occur, with or without the awareness of the elder person experiencing abuse. An elderly person may unwittingly sign over access to savings accounts and other assets when he or she is in an incapacitated state. Social Security checks or pensions may be used by caregivers for personal gain. Theft may be blatant or coerced, with forcible transfer of property, including changing of the elder's will. Abuse may result in a decrease in the standard of living and an inability to pay bills, purchase food, or obtain medications.

EMOTIONAL OR PSYCHOLOGICAL ABUSE

Emotional or psychological abuse is defined as the infliction of anguish, emotional pain, or distress. Examples of psychological and emotional abuse include verbal threats (such as threats of violence, institutionalization, or deprivation), humiliation, intimidation, and harassment. Social neglect and isolation are also forms of abuse. Psychological and emotional abuse can contribute to the development and worsening of mental health problems such as depression, which is common in many older victims.[12]

ABANDONMENT

Abandonment constitutes the desertion of an elderly person by an individual who is that person's custodian or who has assumed responsibility for providing care to the elder. Desertion of an elder in the home, hospital, nursing facility, shopping mall, or other public location may occur.

SELF-NEGLECT

Self-neglect includes those behaviors of an elderly person that threaten his or her own safety. Such behaviors include failure or unwillingness to provide adequate food, clothing, shelter, medical care, hygiene, or social stimulation for oneself. It is the result of an adult's inability, due to diminished capacity, to perform essential self-care tasks. By definition, this applies to one who understands the consequences of his or her choices and makes a conscious decision to engage in acts that threaten his or her own health or safety.[13] Patients who have cognitive impairment or who are living in poverty are at greater risk of self-neglect and may have increased mortality.[9]

DIAGNOSIS

RISK FACTORS

An awareness of risk factors is important for the recognition of potential victims of elder abuse or neglect. Risk factors can be divided into two categories: factors associated with the elders and factors associated with the perpetrators (**Table 295-2**).[7,13-17]

TABLE 295-2 Risk Factors for the Occurrence of Elder Abuse

Risk Factors for Elders	Risk Factors for Perpetrators
Cognitive impairment	History of mental illness
Physical dependency	History of substance abuse
Lack of social support	Excessive dependence on elder for financial support
Alcohol abuse	History of violence within or outside the family
History of domestic violence	
Female gender	
Developmental disability	
Difficult behavior (such as aggression or verbal outbursts)	
Special medical or psychiatric needs	
Limited experience managing finances	
Institutionalization	

Patient characteristics associated with a higher risk for elder mistreatment are cognitive impairment, physical dependency, lack of social support, alcohol abuse, female sex, and a history of domestic violence.[14] In addition, developmental disabilities, special medical or psychiatric needs, and difficult behavior (such as aggression or verbal outbursts) also increase the risk for abuse. Individuals with limited experience in managing finances are at increased risk for financial or material exploitation. Although elder abuse is more common in residential than institutional settings, institutionalization is also recognized as a risk factor for neglect and abuse.[7,16]

Three characteristics of perpetrators have been identified as risk factors: a history of mental illness and/or substance abuse, excessive dependence on the elder for financial support, and a history of violence within or outside of the family.[17] Abusers are most often the primary caregiver. Adult children tend to be more inclined to abuse than are spouses, and males engage in abuse more often than females.[13] Caregivers may be well intentioned but simply overwhelmed by the amount of care required. They may themselves be impaired by mental or physical problems that serve as barriers to the provision of adequate care.

HISTORY

The approach to the patient interview is important. Potential sufferers of abuse should be interviewed in private. The presence of caregivers, family, or friends may cause the patient to feel intimidated or embarrassed, which limits the amount and accuracy of information obtained. Try to put the patient at ease by making the assessment seem like a routine part of the evaluation.[12] Separately interview individuals accompanying the patient. Screening tools are available to aid in the detection of elder abuse.[18-20] The use of lengthier tools is not feasible in a busy ED, but the American Medical Association has proposed a list of nine screening questions that may be more practical to implement (**Table 295-3**). An affirmative answer to any of the questions in this screening tool raises concern and mandates further exploration.

TABLE 295-3 Screening Questions for Elder Abuse

1. Has anyone ever touched you without your consent?
2. Has anyone ever made you do things you didn't want to do?
3. Has anyone taken anything that was yours without asking?
4. Has anyone ever hurt you?
5. Has anyone ever scolded or threatened you?
6. Have you ever signed any documents you didn't understand?
7. Are you afraid of anyone at home?
8. Are you alone a lot?
9. Has anyone ever failed to help you take care of yourself when you needed help?

TABLE 295-4 Clues during the Medical Interview That May Suggest Elder Abuse

The patient appears fearful of his or her companion.
There are conflicting accounts of an injury or illness from the patient and caregiver.
The caregiver displays an attitude of indifference or anger toward the patient.
The caregiver is overly concerned with the costs of treatment needed by the patient.
The caregiver denies the patient the chance to interact privately with the physician.
The caregiver appears overly concerned and attentive.

During the interview, be prepared to recognize behavioral signs and symptoms that suggest elder abuse. These include depression, fear, withdrawal, confusion, anxiety, low self-esteem, and helplessness. Other history-related indicators that suggest abuse or neglect include a pattern of "physician shopping," unexplained injuries inconsistent with medical findings, and recurrent visits for similar injuries. Additional history taking should explore risk factors for abuse as outlined earlier in "Risk Factors."

Information can be obtained by the physician prior to conducting the private interview or by other members of the healthcare team, such as nurses, who are likely to have more frequent interaction with the patient and caregivers. Observing the interaction between the accompanying individuals can yield valuable clues (**Table 295-4**).

PHYSICAL EXAMINATION

Physical examination findings range from subtle and nondiagnostic to highly suspicious. Abuse is often detected when examination findings prompt further history taking with results suggesting elder mistreatment. Psychological abuse and financial abuse are especially hard to diagnose in the ED setting because physical examination findings are uncommon. Nonetheless, it is important to perform a detailed evaluation, including obtaining adequate exposure of the body to evaluate for trauma and pressure ulcers. Common physical findings in sufferers of elder abuse are bruising or trauma, poor general appearance and hygiene, malnutrition, and dehydration.[19]

Although not the most common form of elder abuse, physical abuse is the most easily recognized. Evidence of injury to normally protected areas of the body is highly suspicious for physical abuse.[14] Examples include contusions or lacerations on the inner arms or inner thighs and injury to the mastoid area. It is important to expose these areas when examining the patient to avoid missing significant findings. Contusions on the palms, soles of the feet, and buttocks also raise concern for elder abuse.[14] Multiple injuries in various stages of healing can suggest abuse, but may also be seen in patients with recurrent falls. Taking a thorough history is especially important in differentiating these two causes. Although older patients may sustain burns through accidental injury (such as coming too close to an open flame while cooking), unusual burns or multiple burns in various stages of healing should also raise concern. Traumatic alopecia is highly suspicious, although not necessarily diagnostic (because it may be seen in patients with some psychiatric conditions). Rope or restraint marks on wrists or ankles[13] occur when elders are inappropriately restrained. Midshaft ulnar fractures (nightstick fractures) can occur from attempts to shield blows by raising the forearm. Fractures of the head, spine, and trunk may be more indicative of abuse, although these can occur by other mechanisms.[21] Spiral fractures of long bones and fractures with rotational components also raise suspicion of abuse.[21]

Findings resulting from caregiver neglect or self-neglect are less specific. Perhaps the most identifiable finding is that of multiple or deep pressure ulcers. Ulcers that are uncared for (such as open ulcers lacking appropriate dressings or packing) or those not in lumbar or sacral areas raise suspicion even further. Incapacitated patients should be turned as part of the examination to evaluate for skin breakdown. Poor personal hygiene, inappropriate or soiled clothing, dehydration, malnutrition, contractures, fecal impaction, and excoriations suggest neglect.[8]

Sexually transmitted diseases or findings of genital trauma, especially in an incapacitated patient, raise concern for sexual abuse. Patients may complain of genital or anal pain, itching, bruising, or bleeding. Torn or stained underwear, with unexplained difficulty walking or sitting, may be present. Oral trauma can also be a manifestation of sexual abuse.

Depression, anxiety, and fear can be manifestations of psychological abuse, although they are nondiagnostic. Observation of interactions with caregivers and companions can provide further important clues to this type of abuse.

Although elder abuse is widely underrecognized and underreported, remember that underlying medical disorders are often associated with findings that could otherwise be identified with abuse. Advanced neurologic disorders such as multiple sclerosis, amyotrophic lateral sclerosis, and Parkinson's disease may lead to immobilization and severe disability. Individuals with such conditions are at risk for pressure ulcers, pneumonia, or venous thromboembolism, even with adequate care.[13]

TREATMENT, DISPOSITION, AND FOLLOW-UP

Treatment of elder abuse in the ED involves three key components:

1. Addressing associated medical and psychological needs
2. Ensuring patient safety
3. Complying with local reporting requirements (http://www.ncea.aoa.gov)

Medical problems, including injuries, should be stabilized and treated, and may be best managed through hospital admission. In addition to physical injury, metabolic derangements may be present. Patients with dehydration or malnutrition can have a variety of electrolyte abnormalities and may also have coexisting renal failure. Elders left in the same position for an extended period of time may be at risk for rhabdomyolysis. Additional problems may exist due to failure to administer usual medications at home. These issues should all be addressed during the ED visit, including the ability to conduct activities of daily living, such as meal preparation, housework, bathing, dressing oneself, toileting, and managing finances.

Psychological problems brought on by abuse, as well as preexisting psychiatric conditions and substance abuse, should also be addressed. The severity of the problem and planned disposition can affect the extent to which treatment is completed in the ED. For patients requiring hospitalization, concerns and findings should be communicated to the admitting service and documented in the medical record. For patients who are discharged to home, arrangements should be made for appropriate follow-up. Follow-up must be arranged for the patient's medical and psychiatric needs, and arrangements must also be made for monitoring and assessment of home safety and assessment of caregiver stress or substance abuse. A variety of resources are available to assist with these issues (**Table 295-5**). Social work consultation can be helpful in finding local resources.

Patients in immediate danger should be hospitalized, transferred to the care of a friend or reliable family member, or placed in an emergency shelter. Suspected abuse should be reported to the appropriate state agency (http://www.ncea.aoa.gov) or local adult protective services agency in order to ensure a follow-up investigation and a thorough long-term assessment. Although all 50 states have adult protective services and long-term care ombudsman programs, reporting is not mandated by law in every state. Elderly who live in the community are protected in all states by adult protective services agencies. Elders in institutional settings are protected in all states by long-term care ombudsman programs. Violations specific to nursing home residents might include the following: failure to respond to calls for help, unattended symptoms, injury of unknown origin or falls, physical abuse, poor staff attitudes related to respect or dignity, inappropriate medications or dosages, stolen or lost property, or abuse by other residents. Much long-term facility abuse occurs between residents; many facilities have younger psychiatric patients who are more mobile and aggressive than the older debilitated residents.[22] Become familiar with requirements pertaining to your own practice area (http://www.ncea.aoa.gov).

In cases of unintentional neglect, education of the caregiver may be the only intervention necessary. Other support options include home

TABLE 295-5 Resources for Elder Abuse

Who to Contact	Services Provided
Clinical Justice Services Public Policy Institute American Association of Retired Persons 601 E St., NW Washington, DC 20049 202-434-2222	Provides self-instruction training program, pamphlets, and brochures on elder abuse prevention
National Center of Elder Abuse 1201 15th St., NW, Suite 350 Washington, DC 20005-2842 202-898-2586 http://www.ncea.aoa.gov	One of the main information sites for elder abuse; provides a variety of resources, both nationally and by state
National Organization for Victim Assistance 510 King St., Suite 424 Alexandria, VA 22314 800-TRY-NOVA or 703-535-6682 http://www.trynova.org	Provides referrals, resources in every state
National Coalition Against Domestic Violence P.O. Box 18749 Denver, CO 80218 303-839-1852 http://www.ncadv.org	Provides training and education on domestic violence, publications, and programs
National Domestic Violence Hotline Toll free: 800-799-SAFE TTY: 800-787-3224 (for hearing impaired)	Provides intervention; cannot take reports; confidential; available 24 h
National Long-Term Care Ombudsman Resource Center http://www.ltcombudsman.org	Provides background information on support, technical assistance
National Council on Aging 409 Third St., SW, Suite 200 Washington, DC 20024 800-424-9046 http://www.ncoa.org	Addresses many aging issues through various programs
Commission on Law and Aging American Bar Association 750 N. Lake Shore Dr. Chicago, IL 60611 312-988-5000 http://www.abanet.org/aging	Provides information on laws pertinent to elders; has contact information by state and other law-related services for legal assistance providers; provides mandatory reporting requirements for each state. Makes available Domestic Violence and Sexual Assault in Later Life, a resource packet of information and materials accessible online.
National Training Library for Adult Protective Services National Center on Elder Abuse and Elder Abuse http://www.ncea.aoa.gov/NCEAroot/Main_Site 302-831-3525	An ongoing project that gathers training materials from around the country for loan and referral. The library has >140 holdings, including printed materials, PowerPoint presentations, and CDs. Materials are available on loan at no charge.
Family Caregiver Alliance 690 Market St., Suite 600 San Francisco, CA 94104 415-434-3388 http://www.caregiver.org	Lead agency in Link2Care, a program designed to provide Internet services to caregivers of adults with cognitive impairments
AARP 601 E St., NW Washington, DC 20049 202-434-AARP http://www.aarp.org	Leading organization representing people over age 50. Provides publications on caregiving issues, financial planning, durable power of attorney, trusts, and insurance.
Other resources: Administration on Aging 330 Independence Ave., SW Washington, DC 29201 202-245-0641	
Commission on Legal Problems of the Elderly American Bar Association 1800 M St., NW Washington, DC 20036 202-331-2297

health aide visits, respite services, day programs, accessible transportation, support groups, adult day care, and church activities or pastoral visitations.[16,23] When mistreatment results because the caregiver is overburdened, interventions to decrease stress and anxiety may be welcomed by all parties. Spouses are most likely to be primary caregivers; most of these are women. Lack of sleep and inadequate exercise and nutrition are commonly expressed by caregivers, perhaps leading to anger and risk of abuse. Services for caregivers may be publicly funded or community based with support groups. Some programs provide home-delivered meals, respite care, counseling, and assistance with advance directives and estate planning.[24]

If available, medical case management teams can provide consultation and support by assisting in the multidisciplinary evaluation of suspected abuse cases and developing treatment plans. Team members generally are composed of a physician, nurses, and social workers.[25] Teams may make house calls, arrange physical and occupational therapy, and provide for nutritional improvement and management of disease states. Legal intervention teams can also be used to address financial management, probate and guardianships, and other legal and housing issues. Civil courts can issue protective orders, create guardianships, and issue emergency removal orders.

PRACTICE GUIDELINES

Recommendations for ED management of cases of elder abuse and neglect are provided in **Table 295-6**.

TABLE 295-6 American College of Emergency Physicians Policy on Domestic Family Violence[30]

Emergency personnel assess patients for intimate partner violence, child and elder maltreatment, and neglect.
Emergency physicians are familiar with signs and symptoms of intimate partner violence, child and elder maltreatment, and neglect.
Emergency medical services, medical schools, and emergency medicine residency curricula should include education and training in recognition, assessment, and interventions in intimate partner violence, child and elder maltreatment, and neglect.
Hospitals and EDs encourage clinical and epidemiologic research regarding the incidence and prevalence of family violence as well as best practice approaches to detection, assessment, and intervention for victims of family violence.
Hospitals and EDs are encouraged to participate in collaborative interdisciplinary approaches for the recognition, assessment, and intervention of victims of family violence. These approaches include the development of policies, protocols, and relationships with outside agencies that oversee the management and investigation of family violence.
Hospitals and EDs should maintain appropriate education regarding state legal requirements for reporting intimate partner violence and child and elder maltreatment.

SPECIAL CONSIDERATIONS

BARRIERS TO THE DETECTION OF ELDER ABUSE

Sufferers of elder abuse often have low self-esteem and may blame themselves for the abuse. They may not want to admit vulnerabilities and feel disgraced for having raised a child who would betray them.[23,26]

Elder abuse victims may also be unwilling to press charges against a family member. Abused older adults are frequently unaware of available resources.[26] In addition, they may harbor a fear of being removed from the home or placed in a nursing institution, of implicating family members, or of experiencing further abuse in retaliation for having divulged information. They may worry about not being believed. Abusers may control access to others and prevent encounters with outsiders to ensure that secrecy is maintained. There may also be differing perceptions as to what constitutes abuse based on cultural background.[27]

Physicians may fail to report abuse for a variety of reasons. They may not be familiar with reporting laws or adequately understand reporting mechanisms.[4] They may fear offending patients or their family members. Time constraints in the ED can also be a barrier to recognition and reporting. There are no published studies of physical markers of mistreatment to distinguish preventable injury from intentional, inflicted, or avoidable trauma.[28] In addition, some physicians may have the misperception that the law requires them to obtain the patient's permission before reporting suspected abuse.[29] Hospitals may also lack protocols for identifying or addressing elder abuse.

ABUSE IN LONG-TERM CARE FACILITIES

Elder abuse in nursing homes is well documented. In one study, 36% of nurses and nursing aides working in long-term care facilities reported witnessing at least one act of physical abuse in the previous year.[31] A study of 2400 deaths in Arkansas nursing homes found 50 cases of suspected abuse or neglect, which indicates that forensic studies need to play a larger role in the investigation of unexplained deaths of older adults in long-term care facilities.[32] Abuse in institutional settings manifests in similar ways to abuse in residential settings: theft of money or personal property, unsanitary conditions, poor personal hygiene, sexual assault, physical abuse or unexplained injury, bed sores, physical or chemical restraint, and malnutrition and dehydration. Nursing homes participating in Medicare and Medicaid programs must comply with certain quality-of-care requirements.[33] Suspicion of abuse or neglect among patients in nursing homes should be reported to the state nursing home ombudsman program (http://www.ltcombudsman.org) or to an adult protective services agency.

LEGAL CONSIDERATIONS

Circumstances may occur in which hospital admission is advised, but the patient refuses. If the patient is competent, his or her wishes must be honored, even if those wishes do not appear to be in the patient's self-best interest. Decisional capacity by the patient depends on his/her ability to understand all of the relevant information in order to make a choice, to communicate that choice, and to appreciate the current situation and treatment options. In these cases, it is especially important to interview the patient alone and to explain in detail the concerns of the healthcare provider. The physician should also attempt to explore reasons for the patient's reluctance to stay.

Patients who refuse admission but who lack decision-making capacity should not be discharged back to an unsafe environment. Contact with an adult protective services agency should be initiated. ED social workers can help locate contact information for the local adult protective services agency. If the agency determines that the victim of abuse lacks decision-making capacity, an emergency order for protective services may need to be sought from the courts.

CHAPTER 296

Injection Drug Users

Thomas Grosheider
Suzanne M. Shepherd

INTRODUCTION AND EPIDEMIOLOGY

Illicit drug use is a major health issue globally. It is estimated that in 2011 between 167 and 315 million people worldwide used illicit substances.[1] In 2012, an estimated 23.9 million Americans ≥12 years of age used an illicit drug within the previous month, and of these, 669,000 used heroin, nearly triple the prevalence in 2008.[2] Between 2006 and 2011, heroin-related ED visits increased from 189,780 to 258,482, with the majority of visits made by men (69%) and patients age 35 to 44 years.[2] More recently, ED visits due to severe overdoses have been precipitated by drug distributor substitution of the synthetic opiate fentanyl for heroin as a "super high."[3]

The practice of injection drug use and the lifestyle and culture of the injection drug user place the individual at risk for a wide variety of complications, including human immunodeficiency virus (HIV) infection, hepatitis, tetanus, sexually transmitted diseases, trauma, and intimate partner violence.[4] The high incidence of migration, incarceration, homelessness, nutritional deficiencies, coincident smoking and alcohol use, and mental illness further compromises this population's health.[5]

PATHOPHYSIOLOGY

Injection drug use is associated with immune dysregulation. Exaggerated and atypical lymphocytosis, diminished lymphocyte responsiveness to mitogenic stimulation and depressed chemotaxis, hypergammaglobulinemia, increased opsonin production, decreased T-cell and natural killer cell activity, high levels of circulating immune complexes, and reticuloendothelial abnormalities have been found in injection drug users. False-positive results on nontreponemal syphilis serologic tests, positive results on Coombs tests, low measured antibody response to vaccination, and thrombotic thrombocytopenic purpura are some described abnormalities. HIV-infected patients who inject drugs are found to be less likely to suppress HIV-1 RNA than those who do not inject drugs. Given the immune dysfunction, febrile injection drug users should be suspected of having infections, even when the fever is low grade and WBC counts and erythrocyte sedimentation rates are normal.

CLINICAL FEATURES

To adequately evaluate the histories of injection drug users, be aware of the drugs used locally and regionally, drug street names (e.g., "smack," "H," "Mexican mud," "junk," "bud light," "theraflu"), and drug adulterants. Ask about drug type(s) and amount, preparation of materials for injection (e.g., crushing capsules in the mouth, licking needles, blowing on injection sites or blowing out clots in needles, or using saliva, lemon juice, or tap or toilet water for drug reconstitution), reuse of needles, needle sharing, use of antibiotics, and coincident medical and mental illness. Consider socioeconomic issues, such as the ability to purchase medications and access to outpatient follow-up, in patient disposition.

Complications of injection drug use may be obvious, such as a painful, erythematous, fluctuant skin abscess. However, subtle constitutional symptoms such as weakness, anorexia, body pains, myalgias and arthralgias, weight loss, and fever are common and may be the only signs of serious underlying disease (**Table 296-1**).

FEVER

Fever is associated with infection in more than two thirds of patients. Noninfectious causes of fever include acute toxic reactions to substances of abuse, reactions to injected adulterants, and withdrawal syndromes. Cocaine and amphetamines can cause acute fever, occasionally in excess of 40°C (104°F). Adulterants used to dilute active substances may also cause dramatic febrile reactions accompanied by alteration in mental status and leukocytosis. "**Cotton fever**" is a flulike syndrome developing within hours of injection, after the use of cotton balls as filters for drug suspensions. Physical findings may include tachypnea, tachycardia, abdominal pain, and inflammatory retinal nodules. Chest radiographs typically show normal findings but may demonstrate inflammatory pulmonary granulomata. This syndrome spontaneously resolves within 24 hours.[6] Drug withdrawal from benzodiazepines, barbiturates, or heroin also may cause acute illness with chest and abdominal pain, diaphoresis, tachycardia, and fever.

Because no reliable markers are available to exclude serious illness in the febrile injection drug user, common practice has been to obtain specimens for blood culture and admit such patients for observation while culture results are awaited (also see "Infective Endocarditis" section below). In clinically well patients for whom follow-up can be ensured, outpatient evaluation is reasonable as long as appropriate culture specimens are obtained.

DYSPNEA

A wide range of both infectious and noninfectious entities may produce dyspnea and cough in injection drug users. Pneumonia is typically community acquired (see "Pulmonary Infections" section below). However, dyspnea may have other infectious causes, including infections related to aspiration during drug intoxication, tuberculosis, opportunistic infections, and septic pulmonary emboli complicating right-sided endocarditis. The febrile injection drug user with dyspnea, cough, or abnormal findings on chest radiograph should be placed in respiratory isolation until tuberculosis has been excluded and/or an alternative diagnosis is found.[7]

Noninfectious causes of dyspnea include pneumothorax, hemothorax, toxic reaction to injected substances, and hypersensitivity reaction. Pneumothorax and hemothorax are seen most commonly in association with the practice of "pocket shooting," in which drug users, or their drug-injecting partners, inject into veins in the supraclavicular fossa to access the subclavian, jugular, or brachiocephalic vein. "Talc lung" is a syndrome of progressive respiratory distress and diffuse interstitial infiltrates caused by the injection of adulterant talc. Hypersensitivity reactions, associated with both heroin and cocaine injection, cause cough and wheezing and typically respond to inhaled β-agonist therapy. Noncardiogenic pulmonary edema is associated with both heroin and cocaine use. Signs and symptoms include dyspnea, hypoxia, and diffuse alveolar infiltrates on chest x-ray. Treatment is supportive. Finally, septic, air, or needle fragment emboli can produce dyspnea.

TABLE 296-1 Evaluation of Injection Drug Users in the ED

Presenting Symptom	Potential Findings	Possible Diagnoses	Ancillary Tests
Fever alone	Needle and track marks Heart murmur Rales and rhonchi Hypoxia	Pneumonia Endocarditis Occult bacteremia	Chest radiography Blood cultures Urinalysis Erythrocyte sedimentation rate Echocardiography
Fever with nausea and vomiting, rigors, abdominal pain	Diaphoresis Recent injection	Drug withdrawal "Cotton fever" Hepatitis	CBC count Blood cultures Hepatitis serologic testing Liver panel
Fever with dyspnea and cough	Rales and rhonchi Purulent sputum Hypoxia	Bacterial pneumonia Atypical pneumonia Tuberculosis Pneumonia due to opportunistic organisms Septic pulmonary emboli	Chest radiography Blood cultures Sputum culture and Gram staining Chest CT
Fever with weakness, weight loss, anorexia, night sweats, diarrhea	Cachexia Oral thrush	HIV infection Tuberculosis Hepatitis B and C	HIV serologic testing Blood cultures Chest radiography Sputum staining for acid-fast bacillus, sputum culture Hepatitis serologic testing
Fever with back pain	Heart murmur Focal neurologic signs Flank tenderness	Osteomyelitis Epidural abscess Endocarditis Renal abscess	Blood cultures Erythrocyte sedimentation rate Bone radiography CT or MRI Urinalysis
Dyspnea and cough	Expiratory wheezes Rales and rhonchi Fever Pleuritic chest pain	Hypersensitivity reaction Noncardiogenic pulmonary edema Pneumonia Septic pulmonary emboli Talc reaction	Chest radiography Spirometry Echocardiography Consider blood cultures
Painful limb	Localized erythema Tenderness Localized bruit Muscle pain and swelling Fever	Cellulitis Abscess Pseudoaneurysm Myositis Fasciitis Retained foreign body	Wound specimen cultures Soft tissue radiography CT Doppler US Consider blood cultures
Altered mental status	Obtundation Focal neurologic signs Meningismus Seizure	Drug overdose or intoxication Drug withdrawal CNS lesion Meningitis Tetanus	CT Drug screen Lumbar puncture Consider blood cultures
Eye pain and vision loss	Periorbital vesicles Subconjunctival lesions Keratitis Iridocyclitis Retinitis Poorly reactive pupil Vitreous exudates	Herpes zoster Kaposi sarcoma Keratoconjunctivitis sicca Herpes simplex Cytomegalovirus infection Varicella zoster Toxoplasmosis Syphilis Fungal infection	Viral and fungal cultures Serology for syphilis

Abbreviation: HIV = human immunodeficiency virus.

ALTERED MENTAL STATUS AND NEUROLOGIC ABNORMALITIES

Drug intoxication or withdrawal, stroke syndromes, hypoxia, delayed leukoencephalopathy, infectious diseases, mycotic aneurysms, and secondary trauma from either loss of consciousness and fall or drug-related violence may all produce altered mental status or other neurologic impairment in the injection drug user. CNS infections may result from contiguous spread of overlying soft tissue infection, embolic complications of distant infections (e.g., endocarditis), or extension of local infections (e.g., vertebral osteomyelitis). Infections that affect the nervous system and commonly occur in this population include epidural abscess, bacterial and fungal meningitis, and brain abscess. Meningococcus, pneumococcus, and *Staphylococcus aureus* bacteremia from primary endocarditis are the common causes of bacterial meningitis. Both tetanus and botulism are reported, with cranial nerve involvement, altered mental status, and progressive symmetric paralysis.[8]

Infections caused by opportunistic organisms, such as *Toxoplasma*, are common in patients with coincident HIV infection who have low CD4 counts (especially <100). Stroke syndromes may occur secondary to low-flow states during heroin intoxication; hypertensive hemorrhage from amphetamines, phencyclidine, or cocaine; and embolized vegetations associated with infectious endocarditis. Delayed leukoencephalopathies, both hypoxic and nonhypoxic, have been reported in injection drug users, but are rare.

BACK PAIN

Back pain may result from an epidural abscess, vertebral osteomyelitis, or complications from trauma. In patients with coincident HIV infection, opportunistic infections may present with a more indolent course, and the only symptom may be local pain. Nontraumatic focal back pain usually requires imaging studies such as CT and MRI to evaluate for possible infection.

SPECIFIC INFECTIONS IN INJECTION DRUG USERS

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

The use of IV drugs continues to play a major role in the acquisition and transmission of HIV; however, data from the United States and Central and South America have demonstrated a gradual decline in the prevalence of HIV infection due to injection drug use. From 2003 to 2009, the prevalence decreased from 19% to 16%.[9] See chapter 154, "Human Immunodeficiency Virus Infection" for further management.

INFECTIVE ENDOCARDITIS

The incidence of endocarditis in injection drug users is rising,[10] and this patient group appears to be driving the increased incidence of infective endocarditis in North America.[11] Prior incidence estimates of endocarditis in injection drug users presenting with fever to the ED (13% in general[12,13] and 40% in an inner-city population[14]) were based on data two to three decades old. Two studies published since 2011 based on 485 patients reveal that 7.8% of febrile injection drug users hospitalized with "fever without a source" have evidence of endocarditis on echocardiography.[15,16] Unlike endocarditis in the general population, endocarditis in injection drug users involves the right side of the heart (57% to 86% of cases).[15,17] The most common causative organism for infective endocarditis in injection drug users is *S. aureus* (70%), and one third of those cases involve methicillin-resistant *S. aureus*.[17,18] Licking needles prior to injection has been implicated in infections with *Eikenella corrodens*, *Haemophilus parainfluenzae*, *Bacteroides* species, and *Neisseria* species. Up to 20% of cases of injection drug use–related endocarditis are polymicrobial infections.[8]

Clinical features of endocarditis in injection drug users are dominated by right-side heart involvement with respiratory complaints, including dyspnea, cough, and hemoptysis. Multiple opacities on chest radiograph, consistent with septic pulmonary emboli, are common (**Figures 296-1 and 296-2**). Other findings include pyuria (22%) and hematuria (35%) and are due to glomerulonephritis from immune complex deposition, embolic renal infarction, and perinephric abscess.[16,19] A clinical prediction rule to identify endocarditis in febrile injection drug users has been derived[15] and internally validated[16] and assesses sequentially for the presence of a pulse rate >100, absence of skin infection, and presence of murmur. The rule was 100% sensitive (95% confidence interval, 84% to 100%) in the derivation and validation cohorts, but specificity was only 13%,[16] and the scoring system used is complex, requiring comparison to a nomogram. The prediction rule has not been externally validated and cannot be recommended at this time. For further direction regarding diagnosis of endocarditis, treatment with antibiotics, and management of complications see chapter 155, "Endocarditis."

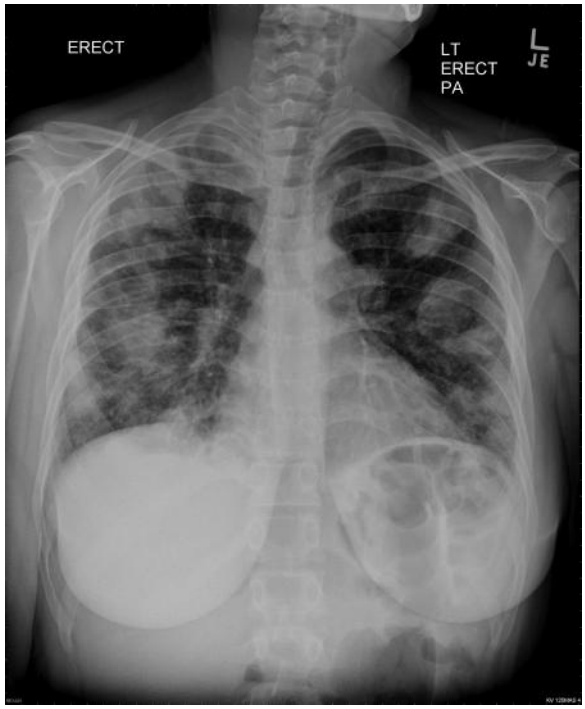

FIGURE 296-1. Chest radiograph showing septic emboli. Multiple opacities are seen in this chest radiograph of an injection drug–using female patient who was found to have bacterial endocarditis.

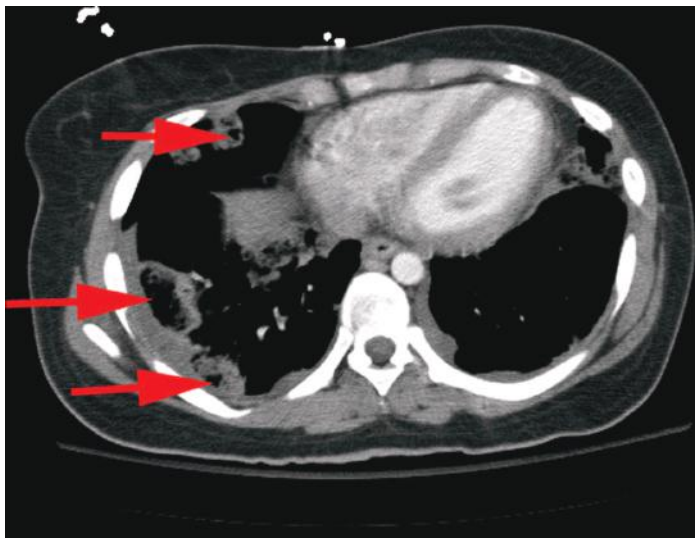

FIGURE 296-2. CT image showing multiple peripheral cavitary lesions (*arrows*) consistent with septic pulmonary emboli.

PULMONARY INFECTIONS

Community-acquired pneumonia caused by *Streptococcus pneumoniae* and *Haemophilus influenzae* remains the most common pulmonary infection in injection drug users, with a 10-fold increased risk for community-acquired pneumonia in the injection drug user population.[8] Patients are also at high risk for pneumonia due to *S. aureus*, including methicillin-resistant *S. aureus*; *Klebsiella pneumoniae* infection; aspiration pneumonia; tuberculosis; and, in HIV-positive patients, opportunistic infections caused by *Pneumocystis jiroveci*, cytomegalovirus, and atypical mycobacteria.[8] Results of the purified protein derivative (tuberculin) skin test may be negative in these patients. Patients may present with atypical clinical and radiographic findings of tuberculosis[20] (see chapter 67, "Tuberculosis").

Because of the risk of atypical infection, coincident bacteremia, and potential for endocarditis in patients with multiple infiltrates on chest radiograph, admission to the hospital is recommended, and respiratory isolation should be maintained until tuberculosis is excluded.[8,14] In patients without risk for *Pseudomonas* infection, IV quinolone and IV ceftriaxone or cefotaxime provide reasonable empiric coverage until culture results are available. In those at risk for *Pseudomonas* infection (structural lung disease, malnutrition, current or recent corticosteroid use or antibiotic use), a preferred regimen is an IV antipseudomonal β-lactamase agent (cefepime, imipenem, meropenem, or piperacillin/tazobactam) and an IV antipseudomonal fluoroquinolone or an antipseudomonal β-lactamase agent, IV aminoglycoside, and fluoroquinolone.[21] For further discussion, see chapter 65, "Pneumonia and Pulmonary Infiltrates."

SKIN AND SOFT TISSUE INFECTIONS

Skin and soft tissue infections are some of the most common infections among injection drug users and include cellulitis, subcutaneous abscesses, septic phlebitis, necrotizing fasciitis, Fournier's gangrene, gas gangrene, and pyomyositis. Most are caused by the user's own commensal flora, with *S. aureus* and streptococcal species remaining the most common pathogens. Because these infections are often self-treated and reporting is not required, the prevalence is difficult to determine but is estimated to be as high as 32%.[22]

Tap water, toilet water, lemon juice, or saliva may be used to dissolve narcotics or cocaine, and each has been implicated as a source of causative organisms, such as *Pseudomonas* and *Candida*, in both skin and blood-borne infections.[8] In 2013, an outbreak (43 individuals, 13 deaths in Scotland) of cutaneous anthrax in heroin users was reported from the United Kingdom.[23] The recent use of desomorphine (street name **Krokodil**), an extremely addictive morphine derivative that typically contains large amounts of toxic synthesis components, including iodine and phosphorus, demonstrates the serious damage to skin, blood vessels, bone, and muscles that illegal drug injection can produce. Many long-term desomorphine users have required limb amputation, which has given this drug the nickname "the flesh-eating drug."[24]

CLINICAL FEATURES AND DIAGNOSIS

Presenting signs and symptoms of cutaneous infections, including pyomyositis, are fever, pain, localized erythema, and edema. Carefully inspect the painful area for fluctuance, crepitus, and lymphangitis. Diagnosis is primarily clinical, except when evaluating an abscess where pulsations are present. Cellulitis and abscesses are typically caused by *S. aureus* (primarily community-acquired methicillin-resistant *S. aureus*) and *Streptococcus* species.[25] Cultures of specimens from cutaneous abscesses may also demonstrate polymicrobial growth, with aerobic gram-negative rods, anaerobic cocci, and bacilli.[8] Increased rates of *Clostridium botulinum* infection have also been found in injection drug users who engage in skin popping, particularly those using Mexican black tar heroin. Mortality rates due to tetanus are highest in older, unvaccinated patients. Other concerns include retained portions of broken needles, which act as a nidus for infection and, in addition, pose an increased risk to the examining healthcare provider. Needles may be identified by radiograph prior to exploration. Individuals may have already attempted to treat abscesses before coming to seek medical care by incision and drainage, illegally purchased antibiotics, or some form of homeopathic care. This is particularly prevalent in Latino populations and those who do not have a usual place of health care.[26]

Infections overlying venipuncture sites may produce thrombophlebitis and infected pseudoaneurysms. Femoral vein injection ("groin hit") has been associated with the development of local gangrene as well as rapidly progressive and fatal Fournier's gangrene. Injection into the jugular vein ("pocket shot") may lead to cutaneous abscess formation involving the carotid triangle and produce airway obstruction, vocal cord paralysis, and laryngeal edema.[8]

IMAGING

For nonpulsatile areas of induration, bedside US can define an underlying abscess. Pulsatile masses, however, must be imaged with Doppler US prior to incision and drainage, because attempts to aspirate or incise and drain an infected pseudoaneurysm can result in severe hemorrhage (see section titled "Vascular Infections" below). CT angiography may identify vasospasm, thrombosis, emboli, or mycotic aneurysms. Plain radiographs can demonstrate air in the soft tissues as well as radiopaque foreign bodies. CT delineates the involvement of other structures and the extent of deep abscesses, especially in complex areas such as the neck.

TREATMENT

Uncomplicated abscesses, large furuncles, and carbuncles should be incised, drained, and packed. Injection drug users with superficial cellulitis without evidence of systemic involvement can be managed as outpatients with oral antibiotics to cover streptococci and methicillin-resistant *S. aureus*. See chapter 152, "Soft Tissue Infections," for discussion of antibiotic choices, abscess drainage, care for the septic patient, and disposition decision making.

VASCULAR INFECTIONS

Distal vascular injury and endovascular infections associated with injection drug use include inadvertent arterial injection with resultant vasospasm or thrombosis, septic thrombophlebitis, venous and arterial pseudoaneurysms, and infected hematomas. Arterial injection rarely results in major vessel occlusion; instead, pain, edema, and patchy mottling of the affected limb occur due to ischemia. Tissue necrosis and gangrene are the consequence of persistent focal ischemia, the cause of which is thought to be a combination of vasospasm, embolization of particulate matter, and endothelial injury leading to thrombosis and vasculitis.[27]

When limb ischemia is suspected, a vascular surgeon should determine whether surgical intervention or intra-arterial thrombolysis is indicated. However, the majority of cases involve distal vessels, and treatment is limited to anticoagulation and supportive care. Limb edema can progress to compartment syndrome, which may require fasciotomy, or may be complicated by rhabdomyolysis.

Infected pseudoaneurysm is a commonly reported vascular complication in injection drug users due to accidental or intentional intra-arterial drug injection and is most often reported in the femoral artery, followed by the radial and brachial arteries.[27] **Figure 296-3** shows a radial artery pseudoaneurysm. Venous pseudoaneurysms are relatively rare and are usually secondary to septic phlebitis, with the femoral vein most often involved. Signs are typically fever and a painful mass. This is a severe complication that can result in life-threatening hemorrhage and sepsis, chronic claudication, chronic skin and soft tissue infections and post-traumatic ulcers, and limb loss. A 23% amputation rate is reported with involvement of the femoral bifurcation. Although the lesion is similar in gross appearance to an abscess, the presence of pulsations and a bruit suggest this diagnosis. Because of the disastrous hemorrhagic consequences of attempted incision and drainage, all painful masses, particularly in the groin, should be expeditiously imaged with US or contrast CT.

In all cases of suspected endovascular infection, antibiotic therapy should be initiated and may be guided by the therapeutic recommendations for endocarditis given above (see "Infective Endocarditis").

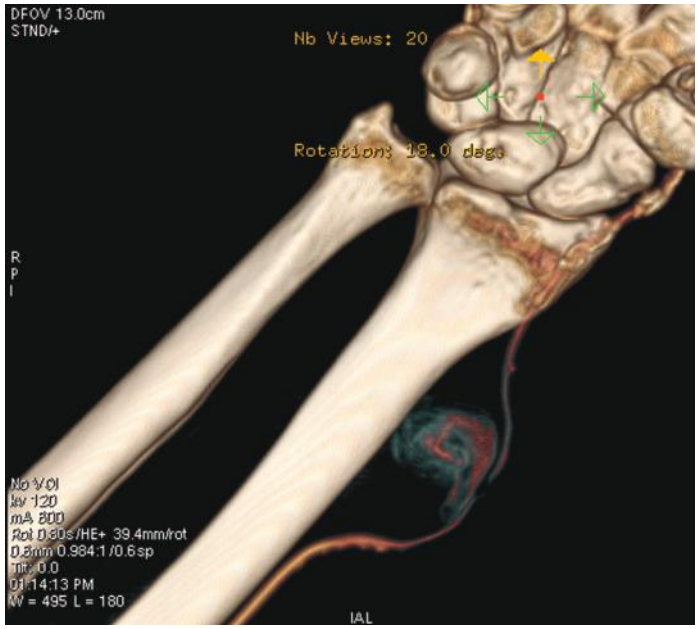

FIGURE 296-3. Volume-rendering CT of the wrist showing a radial artery pseudoaneurysm in the inferior portion of the image. The pseudoaneurysm has displaced the radial artery away from the bony radius.

Surgical treatment options for infected femoral artery pseudoaneurysm are limited due to infection of the surgical field, lack of available autologous graft materials because of deep and superficial venous thromboses from long-term injection, and a high likelihood of continued injection drug use, which increases the risk of postoperative infection and other complications. One therapeutic option is the ligation and resection of the infected pseudoaneurysm without revascularization. Initial outcomes may be favorable; however, long-term morbidity includes claudication, which can become severe, leading to eventual limb amputation.[28,29] A second option is ligation of the common femoral artery without revascularization, accompanied by excision and drainage of the internal femoral artery pseudoaneurysm and routine selective revascularization via either arterial reconstruction with an autologous greater saphenous vein graft or synthetic graft in situ or extra-anatomically.

BONE AND JOINT INFECTIONS

EPIDEMIOLOGY AND PATHOLOGY

Musculoskeletal infections usually occur either through contiguous spread from an overlying skin or soft tissue infection or, more commonly, through hematogenous spread from a distant site. Infecting microorganisms in injection drug users may be unusual, with *Candida* and gram-negative organisms seen, especially *Pseudomonas aeruginosa*. Likely organisms include *S. aureus* (including methicillin-resistant *S. aureus*), *Staphylococcus epidermidis*, *P. aeruginosa*, and *Streptococcus* species.[30] Because of the high incidence of sexually transmitted diseases in this population, also consider gonococcal arthritis and tenosynovitis. *E. corrodens* osteomyelitis is reported in those who lick their needles prior to injection.

CLINICAL FEATURES AND DIAGNOSIS OF OSTEOMYELITIS

Osteomyelitis can develop in the axial skeleton, with another common location being the tibia, often in association with hardware from treatment of a prior fracture.[30] Contiguous septic arthritis can coexist with osteomyelitis.[30] Candidal infections are postulated to be hematogenous in origin and have been related to the use of contaminated reconstituted lemon juice to mix drugs before injection.[8] Some patients report an initial flulike syndrome lasting 3 to 4 days, followed by the appearance of metastatic lesions involving the skin, eye (chorioretinitis and endophthalmitis; see "Ophthalmologic Infections" section below), and the bones and joints several days to weeks later. Rarely, *Aspergillus* species may cause osteomyelitis of the sternum in injection drug users.

Vertebral osteomyelitis usually presents with localized pain and tenderness to palpation over the involved bone, and a soft tissue mass may be palpable. Osteomyelitis may coexist with spinal epidural abscess.[31] Symptoms may be present for days in the case of bacterial infections to weeks in the case of fungal or mycobacterial infections. The presence of both fever and leukocytosis and an elevated erythrocyte sedimentation rate and C-reactive protein level are helpful, if present, but their absence does not exclude these infections. Drainage from contiguous abscesses should be cultured. Biopsy or needle aspiration of joint spaces and bony infections may be necessary, especially in the case of infection with unusual or fastidious organisms, such as *Mycobacterium*, *Candida*, or *Eikenella*.

Imaging for Osteomyelitis Imaging for patients with suspected osteomyelitis varies by institution, but MRI is generally the imaging modality of choice. CT may reveal disk space narrowing and bony lysis suggesting osteomyelitis, but it is neither as sensitive nor as specific as MRI.[31] Patients with osteomyelitis warrant admission, and unless the patient appears septic or has focal neurologic complaints or coincident endocarditis is a concern, antibiotic therapy should be withheld until culture results are obtained.

Treatment of Osteomyelitis Early consultation with the orthopedist or neurosurgeon should guide the timing of antimicrobial coverage, because blood culture results may not be sufficient, and a CT-guided needle biopsy for epidural abscess or a bone sample for culture for osteomyelitis may be required.[25] Antimicrobial choice should be based on culture results (for a biopsy specimen), and therapy is typically required for 4 to 6 weeks. Injection drug use patients in unstable condition who are suspected of having osteomyelitis should receive vancomycin to cover *S. aureus* and ceftazidime to cover *Pseudomonas* (see chapter 281, "Hip and Knee Pain," for further discussion).

SEPTIC ARTHRITIS

Septic arthritis in injection drug users usually involves the knee or hip but may coexist with osteomyelitis in approximately 16% of cases.[30] Sternoclavicular septic arthritis strongly suggests injection drug use.[32] For further discussion of diagnosis and treatment of septic arthritis, see chapter 284, "Joints and Bursae."

OPHTHALMOLOGIC INFECTIONS

Ophthalmologic infections in injection drug users are usually the result of hematogenous seeding from a primary source of infection, such as endocarditis, or of opportunistic infections associated with HIV disease. Bacterial endophthalmitis often presents acutely, with pain, redness, lid swelling, and decrease in visual acuity. Inflammation is usually present in both the anterior and posterior chambers. White-centered, flame-shaped embolic hemorrhages (Roth spots), cotton-wool exudates, and macular holes may be present. *S. aureus* is the most commonly isolated organism, followed by *Streptococcus* species. Treatment involves subconjunctival and systemic antibiotic therapy, most commonly vancomycin and ceftazidime.[33] Surgical intervention may be needed. Visual prognosis is poor.[33]

Fungal organisms, usually *Candida*, are an important cause of endophthalmitis among injection drug users. Such fungal infections were considered rare until Mexican black tar heroin arrived in the 1980s, and lemon juice was used to dissolve this relatively water-insoluble compound.[34] Symptoms include blurred vision, pain, poorly reactive pupil, and decreased visual acuity and can progress over days to weeks. White cotton-like lesions are seen on the choroid retina, with vitreous haziness. Uveitis, papillitis, and vitreitis also have been reported. Presumptive diagnosis is defined as the presence of typical ocular lesions in an injection drug user. Microbiologic diagnosis is made from the results of blood and vitreous culture. Treatment includes amphotericin B and voriconazole.[33] Aspergillosis is the second most common fungal cause of

endophthalmitis in injection drug users, producing ocular symptoms and signs without cutaneous or musculoskeletal involvement. The visual prognosis for fungal endophthalmitis depends on prompt diagnosis and treatment but frequently is poor.[33] Immediate consultation with an ophthalmologist is necessary to ensure appropriate management and a positive outcome. In injection drug users co-infected with HIV, cytomegalovirus infection, toxoplasmosis retinitis, and choroidal *Cryptococcus* and *Mycobacterium avium-intracellulare* complex infections must also be considered.

CHAPTER 297

The Transplant Patient

J. Hayes Calvert

INTRODUCTION

As of the beginning of 2013, there were 76,047 active candidates waiting for solid-organ transplants in the United States, with the kidney transplant waitlist being the largest at 57,903 candidates.[1] The kidney is the most commonly transplanted organ (58%), followed by liver (21%), heart (8%), lung (5%), pancreas (5%), and, less commonly, combined organ transplants and intestine transplants. Annually, there are around 18,000 hematopoietic stem cell transplants in the United States, with about one third of these transplants being allogenic transplants and two thirds being autologous transplants.[2]

Most transplant patients require lifelong immunosuppression. Transplant patients can develop a number of acute to life-threatening emergencies, including (1) transplant-related infection, (2) medication side effects, (3) rejection, (4) graft-versus-host disease, and (5) postoperative complications or complications of altered physiology secondary to the transplanted organ. Transplant patients may also have common medical problems that require unique management. Adverse outcomes often are directly proportional to increasing age of the recipient and the donor organ.[3]

The most common acute disorders prompting ED visits are infection (39%) followed by noninfectious GI/GU pathology (15%), dehydration (15%), electrolyte disturbances (10%), cardiopulmonary pathology (10%) or injury (8%), and rejection (6%).[4-7] Acute graft-versus-host disease is an important complication, especially in those with hematopoietic stem cell transplantation.[8] Coronary artery disease, sudden cardiac death, and heart failure are results of premature cardiovascular disease in solid-organ recipients, due to underlying comorbidities and metabolic effects of immunosuppression.[9] Preoperative and regular postoperative cardiovascular assessment identifies risk factors and enables treatment to mitigate risk effects.[10]

GENERAL APPROACH TO EVALUATION

HISTORY AND COMORBIDITIES

Key historical elements for the management of transplant patients are listed in **Table 297-1**.

PHYSICAL EXAMINATION

Direct the physical examination to the chief complaint, present illness, and evidence of complications of the transplant or immunosuppressive medications (**Table 297-2**).[4-8,11,12]

TABLE 297-1 Key Historical Elements Specific to Transplant Patients

Historical Item	Significance
Recent temperature increase or decrease from baseline	Potential clue to onset of infection or rejection.
Changes from baseline function	Decreased urine may signify rejection in renal transplant patients or acute dehydration. Decreased exercise tolerance may signify rejection in heart transplant patients. Change in skin color (jaundice specifically) may signify rejection in liver transplant patients or graft-versus-host disease.
Date of transplant surgery	The date from transplant helps to predict typical infections and types of posttransplant complications (i.e., graft-versus-host disease).
Graft source for solid-organ transplant, special features of graft if any, prior infections; donor living related vs cadaveric	These details predict the potential for certain infections and rejection.
Graft source for hematopoietic stem cell transplant: autologous, degree of match, related donor	These details predict potential graft-versus-host disease.
Rejection history	May predict current rejection if similar presentation and difficulty in controlling a current episode of rejection.
Recent changes in dosages of antirejection and other medications	Although a planned part of transplant management, rejection is very common when immunosuppression doses are reduced.
Chronic infections (CMV, Epstein-Barr virus, hepatitis B and C, other viruses)	History of chronic infections increases the chances that current presentation is an exacerbation.
Recent exposure to infections (chickenpox, CMV, tuberculosis)	Increases the chance of current infection.
Recent history of compliance with immunosuppressive medications	Noncompliance increases chance of rejection.
Recent travel, exposure to persons arriving from countries with endemic infections, exposure to potential foodborne illness or insect vectors	Exposure may predict unusual infections not commonly considered.
Complete list of all medications, including over-the-counter medication	Complex drug interactions are common causes of symptoms in transplant patients and must be evaluated.
Baseline: blood pressure, body weight, serum creatinine (for renal transplants), and expected levels of immunosuppressive medication	Changes in these parameters may predict rejection or acute illness.

Abbreviation: CMV = cytomegalovirus.

DIFFERENTIAL DIAGNOSIS

Consider complications of immunosuppressive medication, infection, solid-organ rejection, and graft-versus-host disease (**Tables 297-3 and 297-4**). Chronic immunosuppressant medications, including corticosteroids, cause a wide range of physical changes evident on physical examination. Medication changes should be made by, or in consultation with, the patient's transplant team. Outpatient or inpatient management depends on the severity of illness; the need for ongoing immunosuppression often requires admission when symptoms interrupt maintenance of medication.

Solid-organ rejection and graft-versus-host disease are immune-medicated inflammatory reactions that may present with fever, signs and symptoms, and laboratory and radiographic findings that resemble infection. Infection and rejection (or an exacerbation of graft-versus-host disease) can occur simultaneously, and treatment should be started for

TABLE 297-2 Physical Examination in Transplant Patients

Examination	Comments
Volume status	Check static vital signs, orthostatic blood pressures, and pulse. Use US to assess inferior vena cava diameter as a measure of intravascular volume status.
Head, ears, eyes, nose, and throat	Periorbital edema (glomerulonephritis), retina (CMV or toxoplasmic chorioretinitis, *Listeria* endophthalmitis), sinuses (*Staphylococcus aureus*, mucormycosis, and invasive fungal disease), mouth (*Candida*, HSV), neck (meningismus, retropharyngeal abscess), lymphadenopathy (CMV, EBV, hepatitis, posttransplant lymphoproliferative disorder).
Lungs	Pneumonia is a common source of infections in transplant patients. *Streptococcus pneumoniae* and other community-acquired agents are still common sources, but opportunistic infections, such as *Pneumocystis jiroveci* pneumonia, *Aspergillus*, tuberculosis, coccidioidomycosis, and viral pneumonias should be suspected. Noninfectious pulmonary infiltrates may also cause dyspnea.
Heart	Pericardial friction rubs as a complication of uremia and a wide range of viral infections. New heart murmur can represent infection.
Abdomen	Peritonitis without a defined source is one of the most common sites for infection in transplant patients. Right upper quadrant tenderness associated with hepatitis B and C, CMV, and EBV. Varicella-zoster virus causes pancreatitis. If left in place, peritoneal dialysis catheters can be sources of infection.
Flank and suprapubic area	The urinary tract was the most common site of infection identified.
Graft	Renal graft usually placed in abdominal flap; inspect (look for signs of wound infection), palpate (graft tenderness and swelling are often seen in acute rejection, outflow obstruction, and pyelonephritis), and auscultate (bruits suggest renal artery stenosis and AV malformation or AV fistula). Deep tenderness over liver graft could indicate abscess.
Rectal	Perirectal abscess is a common, yet often overlooked, source of infection in transplant patients.
Extremities	Access sites for hemodialysis can be sources of infection. Peripheral edema in the transplant patient can represent a number of different etiologies: recurrent versus de novo glomerulonephritis, renal graft failure, liver graft failure, cirrhosis, nephrotic syndrome (from native kidneys), renal vein thrombosis, malnutrition, hypoalbuminemia, and heart failure.
Skin	Rashes are commonly seen in graft-versus-host disease, viral syndromes (hepatitis B and EBV), cellulitis from indwelling catheter sites, nocardial cutaneous lesions, and drug reactions.
Mental status/ neurologic examination	Cyclosporine/tacrolimus neurotoxicity, steroid psychosis, HSV encephalitis, *Listeria* meningitis/encephalitis, and cryptococcal meningitis.

Abbreviations: AV = atrioventricular; CMV = cytomegalovirus; EBV = Epstein-Barr virus; HSV = herpes simplex virus.

both. When suspecting acute rejection or acute graft-versus-host disease, consult the transplant team about treatment. Typically, high-dose corticosteroids are given, but the steroid, the dose, and the duration of therapy should be confirmed.

POSTTRANSPLANT INFECTIONS

Infections account for a large number of deaths in transplant patients, with many undiagnosed until autopsy. Viral and bacterial illnesses may occur concurrently. Febrile episodes in the early phase after allogenic stem cell transplantation are likely related to infections secondary to neutropenia. Immunosuppression-induced blunting of the inflammatory response may mask the classic signs, symptoms, and laboratory markers of infection if the patient presents early in the course of the illness. Later in the course of infection, patients may present with more advanced ominous signs such as seizure, obtundation, coma, and cardiac arrest.

TABLE 297-3 Adverse Reactions to Immunosuppressant Medications

Body System	Adverse Effects
Constitutional	Fever, rigors, malaise, dizziness, anorexia
Ophthalmologic	Blurred vision, conjunctivitis, cataracts, papilledema, blindness
Mouth/ears	Gingival hyperplasia, stomatitis, hearing loss, tinnitus
Respiratory	Cough, dyspnea, interstitial lung disease, pneumonitis, pleural effusion, noncardiogenic pulmonary edema
Cardiovascular	Hypertension, tachycardia, bradycardia, cardiomyopathy, congestive heart failure, hypotension, syncope
GI	Nausea, vomiting, diarrhea, epigastric pain, esophagitis, gastritis, hiccups, constipation, hepatotoxicity, ascites, pancreatitis, colonic necrosis, bleeding
Musculoskeletal	Myopathy, osteoporosis, tendon rupture
Hematologic	Neutropenia, lymphopenia, anemia, thrombocytopenia, bleeding, thrombosis
Renal	Nephrotoxicity, oliguria, dysuria, renal failure
Neurologic	Headache, vertigo, paresthesias, tremors, convulsions, agitation, neuropathy, confusion, generalized weakness, leukoencephalopathy, encephalopathy, cerebral edema
Skin	Alopecia, hirsutism, thickening, thinning, necrosis, edema
Metabolic	Electrolyte disturbances (sodium, potassium, calcium, magnesium, phosphorus), fluid retention, hypercholesterolemia, hyperlipidemia, hyperglycemia, hypoglycemia
Endocrine	Adrenal suppression
Immunogenic	Susceptibility to infection, acute allergic reactions, anaphylaxis

CLINICAL FEATURES

The most common reason for an ED visit by a transplant recipient is fever.[4-7] Fever may be masked by immunosuppressive agents and other factors such as steroids, uremia, and hyperglycemia, and may be absent in half of those with infection.[5] Fever may be due to factors other than infection, such as drug effects, hypersensitivity reaction, rejection, or malignancy. Fever in a transplant patient should prompt an aggressive workup, even if low grade.

TABLE 297-4 Physical Examination Clues to Complications of Medications and Graft-versus-Host Disease

Concern	Signs and Symptoms
Edema and other swelling	Assess symmetry, pain, color, temperature, and active range of motion. Suspect infection, orthopedic conditions, deep vein thrombosis (due to immobility).
Skin breakdown	The back, pressure points, heels, elbows, and leg ulcers (due to corticosteroid-induced weakness).
Joint range of motion	Shoulders, elbows, fingers, wrists, and knees (may be limited due to steroid-induced weakness or sclerodermatous skin changes).
Thoracic constriction	Relatively noncompliant edema like swelling on the chest wall. If present, ask about associated dyspnea on exertion.
Abdominal constriction	Firm skin. History of bloating, gas, constipation, diarrhea, nonspecific pains.
Sclerodermatous skin	Sclerodermatous skin changes can affect joint mobility and GI and respiratory function. Note the firmness of edema and skin, especially on the thorax and around joints. A firm, soft leather consistency of swelling, tougher than cardiogenic pitting edema, can be a serious problem. Assess for recent-onset dyspnea on exertion.
Dehydration	Increased thirst, loss of appetite, chills, fatigue, weakness, skin flushing, dark or decrease volume of urine, dry mouth, tachycardia, weight loss.
Electrolyte disturbance	Signs and symptoms of dehydration above, hypotension, headache, bradycardia or tachycardia, irregular heartbeat, tremor, muscle weakness, increased urination, constipation, altered tendon reflexes, mood changes, abdominal pain, weight loss, muscle cramping.

TABLE 297-5 Infections Stratified by Posttransplant Period

Period after Transplant/Conditions	Infection	Comments
<1 mo: resistant organisms	MRSA Vancomycin-resistant *Enterococcus faecalis* *Candida* species (including non-*albicans*)	Opportunistic infections are generally absent during this period as full effect of immunosuppression not complete. MRSA important in HSCT patients.
<1 mo: complications of surgery and hospitalization	Aspiration Catheter infection Wound infection Anastomotic leaks and ischemia *C. difficile* colitis	*Clostridium difficile* common during this period. Early graft injuries may abscess. Unexplained early signs of infection such as hepatitis, encephalitis, pneumonitis, or rash may be donor derived.
<1 mo: colonization of transplanted organ or HSCT neutropenia	*Aspergillus* *Pseudomonas* *Klebsiella* *Legionella*	Microbiologic analysis of aspirates or biopsy from surgery essential for therapeutic decisions.
<1 mo: HSCT-specific infections	Additional bacterial pathogens: *Streptococcus viridans* and enterococci Viral infections include respiratory syncytial virus and HSV	Neutropenia and mucocutaneous injury increase risk for HSCT patients. Lungs, bloodstream, and GI tract most commonly affected sites.
1–6 mo: in patients with *Pneumocystis jiroveci* pneumonia and antiviral (CMV, HBV) prophylaxis	Polyomavirus BK infection, nephropathy *C. difficile* colitis HCV infection Adenovirus infection, influenza *Cryptococcus neoformans* infection *Mycobacterium tuberculosis* infection Anastomotic complications	Activation of latent infections, relapse, residual, and opportunistic infections occur during this period. Viral pathogens and allograft rejection cause the majority of febrile episodes during this period. Polyomavirus BK, adenovirus infections, and recurrent HCV are becoming more common.
1–6 mo: in patients without prophylaxis	*Pneumocystis* Infection with herpesviruses (HSV, varicella-zoster virus, CMV, Epstein-Barr virus) HBV infection Infection with *Listeria, Nocardia, Toxoplasma, Strongyloides, Leishmania, Trypanosoma cruzi*	Discontinuation of prophylaxis at the end of this period may prompt active infection, especially CMV. Graft-versus-host disease and mucocutaneous injury increase risk for HSCT patients.
>6 mo: general	Community-acquired pneumonia and urinary tract infections Infection with *Aspergillus*, atypical molds, *Mucor* species Infection with *Nocardia, Rhodococcus* species	Community-acquired organisms dominate during this period. Transplant recipients have a persistently increased risk of infection due to community-acquired pathogens.
>6 mo: late viral infections	CMV infection (colitis and retinitis) Hepatitis (HBV, HCV) HSV encephalitis Community-acquired viral infections (severe acute respiratory syndrome, West Nile) JC polyomavirus infection (progressive multifocal leukoencephalopathy) Skin cancer, lymphoma (PTLD)	In some patients, chronic viral infections may cause allograft injury (e.g., cirrhosis from HCV infection in liver transplant recipients, bronchiolitis obliterans in lung transplant recipients, accelerated vasculopathy in heart transplant recipients with CMV infection) or a malignant condition such as PTLD or skin or anogenital cancers.

Abbreviations: CMV = cytomegalovirus; HBV = hepatitis B virus; HCV = hepatitis C virus; HSCT = hematopoietic stem cell transplant; HSV = herpes simplex virus; MRSA = methicillin-resistant *Staphylococcus aureus*; PTLD = posttransplantation lymphoproliferative disorder.

Signs and symptoms of infection depend on the type of infection and can, in part, be predicted by the time frame since the transplant (**Table 297-5**).[13] Combining all posttransplant period groups, urinary tract infections (43%) and pneumonia (23%) are likely to be the most common infections.[11] In contrast, a study of 238 ED presentations of febrile pediatric heart transplant patients found pneumonia in 24%, bacteremia in 3%, cellulitis in 2%, and urinary tract infection in 1%; the majority had a negative workup.[12]

DIAGNOSIS AND TREATMENT

The evaluation should include routine testing as well as additional tests based on complaint, history, and physical examination (**Table 297-6**).[14]

Leukopenia can represent acute bacterial infection,[5] and leukopenia with an increase in atypical lymphocytes is commonly seen with viral infections, especially cytomegalovirus. Pulmonary infections that are encountered frequently include *Pneumocystis jiroveci*, *Nocardia*, *Legionella pneumophila*, and *Aspergillus*; these require special stains and studies for accurate diagnosis.

Treatment recommendations should be determined by careful analysis of each individual patient for potential atypical infections requiring specific coverage. Empiric antimicrobial therapy for transplant patients is outlined in **Table 297-7**.[15-17] Empiric treatment prior to confirmatory studies centers first on antibacterial agents, and then, especially if there is concern for meningitis/encephalitis, on antiviral agents such as acyclovir. Discuss treatment of suspected fungal infections or atypical infections with the transplant team.

TABLE 297-6 Diagnostic Tests to Consider in the Evaluation of Infections in the Transplant Patient

Test	Comments
CBC	Leukocytosis or left shift of the WBC count may be blunted by immunosuppressive agents.
Renal function tests: BUN, creatinine	Essential in the evaluation of renal transplant patients, may help determine dosing of antibiotics in all transplant patients.
Liver function tests	May show mild transaminase elevations with cytomegalovirus and Epstein-Barr virus infections, and much higher elevations with hepatotropic viruses such as hepatitis B and C viruses. May be elevated in *Legionella* infections.
C-reactive protein	Significant elevations more likely in infections versus noninfectious infiltrates.
Procalcitonin level	Significant elevations more likely in infections versus noninfectious infiltrates.
CT of the brain	Focal infections in the brain are much more common in this population, but CT should be used only as clinically indicated.
Cyclosporine or tacrolimus level or other levels of immunosuppressants	These levels may be deliberately low depending on the desired level of immunosuppression. Bioavailability may be variable.
Cultures of mouth, sputum, urine, blood, stool, vascular access, and wound sites	Collect as indicated by history and physical. Urine *Legionella* antigen should be considered before treatment of patients with pneumonia with GI complaints. Bacterial and fungal cultures of blood and urine should be obtained on all patients.
Cerebrospinal fluid cultures and antigen tests	Collect as indicated by history and physical.
Serology: cytomegalovirus, Epstein-Barr virus, hepatitis, toxoplasmosis, cryptococcosis	Because viral and fungal cultures are not very sensitive, clinicians should rely on their acumen to order organism-specific antigen assays and antibody titers. When contemplating viral or parasitic infections, these tests should be obtained to allow identification of bacterial, fungal, and viral pathogens.
Chest radiograph	Infiltrates on chest radiograph may reflect infectious or noninfectious complications of hematopoietic stem cell transplant or organ transplant.
CT of the chest	Patients with evidence of pulmonary infiltrates on chest x-ray or high-resolution CT, but without productive sputum, may ultimately require bronchoscopy with bronchoalveolar lavage and transbronchial biopsy for definitive diagnosis.
CT or US to include the graft	These scans can be used to identify likely abscess formation or possible anastomotic leaks.
Tests after admission	Beyond the scope of this chapter, but may include biopsy of the transplanted organ, bronchoalveolar lavage on bronchoscopy, and focused imaging of suspected sites of infection.
Creatine kinase	May have increased levels in infections with certain organisms, such as *Legionella*.

GRAFT-VERSUS-HOST DISEASE

Graft-versus-host disease is a major cause of morbidity and mortality affecting approximately 50% of allogeneic hematopoietic stem cell transplantation patients,[18] but it also occurs after small bowel or liver transplantation.[19] Hyperacute graft-versus-host disease is an unusual and severe form of acute graft-versus-host disease. Onset occurs in the first week after hematopoietic stem cell transplantation and is characterized by fever, generalized erythroderma, severe hepatitis, fluid retention, widespread inflammation, and shock.[20]

Acute graft-versus-host disease is classified as appearance of the disease up to 100 days after transplant. A well-appearing hematopoietic stem cell transplantation recipient with a nonspecific **rash** (most common symptom) or **diarrhea** (second most common symptom) should be suspected of having new-onset or an exacerbation of graft-versus-host disease.[20] The most widely used graft-versus-host prophylaxis includes a combination of a calcineurin inhibitor (e.g., cyclosporine, tacrolimus) with methotrexate.[20] In patients who recover from acute graft-versus-host disease, later long-term complications from chronic graft-versus-host disease are common.

Chronic graft-versus-host disease is a late complication characterized by immune dysregulation.[21] It results in severe morbidity, with complications affecting skin (sclerodermatous contractures), muscles (myopathy), bone (osteoporosis), nerves (peripheral neuropathy), and the cardiopulmonary system (physical deconditioning).[22]

ACUTE GRAFT-VERSUS-HOST DISEASE

Consider graft-versus-host disease in any patient with a rash. Rash is often misattributed as a drug reaction. The typical rash is maculopapular, frequently demonstrating a brownish hue and slight scaling (**Figure 297-1**). The rash can be pruritic and painful. The distribution varies greatly but often affects palms and soles initially, and later progresses to cheek, ears, neck, trunk, chest, and upper back. In the more severe forms, erythroderma or bullae develop.[8] Mucositis has been reported to occur in 35% to 70% of patients.

Diarrhea, GI bleeding, or hepatic dysfunction can occur. Diarrhea, with or without upper GI symptoms such as anorexia, nausea, and emesis, is common. Symptoms include painful cramping, ileus, and, sometimes, life-threatening hemorrhage from the colon. Hepatic involvement is characterized by increase in liver function studies. GI hemorrhage in the early posttransplant period may be a result of coagulation abnormalities, especially thrombocytopenia. The differential diagnosis of GI bleeding in this setting includes all the usual causes of GI bleeding in addition to bleeding due to acute graft-versus-host disease–related damage to colonic tissues and infection (viral, fungal, or bacterial).[18,23] Diagnosis requires endoscopy.

Treatment is directed by the transplant team, typically PO prednisone or IV methylprednisolone, at 1 to 2 milligrams/kg daily, and possibly adjustment of other immunosuppressant doses.[8]

Disposition and interval for follow-up are also determined by the transplant team.

TRANSFUSION-ASSOCIATED GRAFT-VERSUS-HOST DISEASE

Most living cells that are in transfused blood survive for no more than a few days or weeks. However, in some patients, transfused cells engraft, expand, and circulate. When immunocompetent T lymphocytes engraft in an immune-suppressed patient, transfusion-associated graft-versus-host disease may occur and is almost always fatal.[24,25] It is possible to avoid transfusion-associated graft-versus-host disease by irradiating blood products before transfusion. Patients with immunocompromise or other risk factors (**Table 297-8**) should receive irradiated blood products.

SPECIFIC TYPES OF TRANSPLANTATION

RENAL TRANSPLANTATION

Renal transplantation is the preferred treatment for end-stage renal disease. Vascular complications that occur following renal transplantation include renal artery stenosis, allograft infarction, arteriovenous fistulas, pseudoaneurysm, and renal vein thrombosis. Nonvascular complications include ureteral obstruction, urine leak, periallograft fluid collections (hematomas, lymphoceles, and abscesses), neoplasms, GI complications, and posttransplant lymphoproliferative disease.[26] The major causes of renal transplant loss are death from vascular, malignant, or infectious disease, and loss of the allograft from chronic renal dysfunction associated with the development of graft fibrosis and glomerulosclerosis.

TABLE 297-7 Empiric Antimicrobial Therapy

Condition	Antimicrobial Agent	Comments*
All patients	Discuss agent(s) with transplant team.	The transplant team caring for the patient should always be consulted as soon as possible; however, in certain life-threatening situations, empiric broad-coverage therapy may be indicated immediately.
Suspected infection site based on history and physical examination	Site-specific agents are preferable if predicted by initial findings, balanced by known pathogens as listed in Table 297-5.	The urgency for treatment should be based on the patient's presenting condition; bacterial infections are the most aggressive organisms requiring coverage, but some fungal infections may yield sepsis. In general, broad coverage for any suspected site infection is recommended initially pending cultures and further workup to define noninfectious causes of fever.
Neutropenia in the absence of symptoms suggesting site-specific infection	Third-generation cephalosporin such as ceftazidime or a carbapenem plus coverage for MRSA below.	Multiple alternative agents used, including an aminopenicillin plus a β-lactam inhibitor such as piperacillin-tazobactam or cefepime. Monotherapy has fewer complications, but concern for MRSA remains high. Addition of antiviral and antifungal agents should be at the discretion of the transplant team.
Suspected MRSA	Vancomycin	In the majority of patients, MRSA infection should be seriously considered as a potential cause of infection, pending cultures. Linezolid is an alternative antibiotic.
Parasitic infections	Trimethoprim-sulfamethoxazole after discussion with transplant team	Consider *Toxoplasma gondii, Pneumocystis jiroveci*.
Viral infections	Ganciclovir or valganciclovir for CMV, acyclovir for herpes simplex and varicella-zoster	Consider treatment for CMV pneumonia, CMV chorioretinitis, CNS or disseminated herpes simplex or varicella-zoster.
Fungal infections	Discuss with transplant team; agent depends on site and severity of illness	Consider *Aspergillus, Candida albicans, Cryptococcus neoformans.*

Abbreviations: CMV = cytomegalovirus; MRSA = methicillin-resistant *Staphylococcus aureus*.
*Standard doses apply but may be altered by transplant team recommendations.

Medication changes, as well as imaging contrast agent use that may affect renal function (including gadolinium-based contrast agents), should be discussed with the patient's transplant team.

DIAGNOSTIC TESTING

Table 297-6 lists recommendations on diagnostic testing in transplant patients, including renal transplant patients. The serum creatinine level is the most valuable prognostic marker of graft function at all times after transplantation and should be obtained whenever renal failure or infection is suspected. The urinalysis provides important clues to acute changes in graft viability. Red blood cell casts and proteinuria are commonly seen in recurrent or de novo glomerulonephritis. The presence of WBCs, bacteria, and nitrites is helpful in diagnosing urinary tract infections. Proteinuria may signal rejection, drug toxicity, glomerular disease, or other graft nephropathy, although proteinuria from a remaining native kidney should also be considered. Obtain cyclosporine or tacrolimus blood levels for all patients on these medications. Contact the patient's transplant team regarding abnormal drug levels, because low drug levels are sometimes deliberately used to reduce side effects.

FIGURE 297-1. Rash of acute cutaneous graft-versus-host disease. The maculopapular lesions have acquired a brownish hue, and there is slight scaling. IMAGING

Ultrasonography is the best test to detect urinary obstruction. Renal graft ultrasonography can also be useful in patients suspected of having pyelonephritis, vascular abnormalities (stenosis, thrombosis, pseudoaneurysm, and arteriovenous fistula), perinephric abscess, urine leak, wound infection, or an episode of rejection.

MRI can be helpful in evaluating hematomas and other fluid collections, vascular abnormalities, and small infarcts caused by medication-induced vasculitis. Magnetic resonance angiography has the advantage of requiring either no contrast material or a gadolinium chelate that is less nephrotoxic than other agents. However, gadolinium-based contrast agents

TABLE 297-8 Significant Risk Factors for the Development of Transfusion-Associated Graft-versus-Host Disease

Congenital and acquired immunodeficiency syndromes
History of bone marrow (stem cell) transplantation, whether allogeneic or autologous
Transfusions from blood relatives ("directed donation")
Transfusions with fresh whole blood
Premature infants receiving any sort of transfusion
Human leukocyte antigen–matched platelet transfusions
Hodgkin's disease, even when in remission
Leukemia not in remission
Patients treated with purine analogs; the effects of fludarabine and cladribine (2-CdA) persist for a year

TABLE297- 9 Differential Diagnosis of Renal Allograft Dysfunction

Deferential Disorder	Comments
Mechanical	At ultrasonography, a urine leak (i.e., urinoma) appears as a well-defined, anechoic fluid collection with no septations that increases in size rapidly.
Complications of surgery	
Ureteral obstruction	
Urine leak: urinoma, ascites, or abscess	
Vascular	The transplanted kidney is usually placed extraperitoneally in the right iliac fossa. End-to-side anastomosis to the external iliac vasculature provides circulation. Color duplex imaging of the renal artery and vein is helpful in assessing renal vascular stenosis or thrombosis.
Renal artery stenosis or thrombosis (12%)	
Renal vein thrombosis	
Renal artery and renal vein thrombosis are uncommon; they usually occur in the first month after transplant.	
Glomerulonephritis	
Infection	Urinary tract infections are the most common source of bacteremia in renal transplant recipients, and infectious diseases are the second leading cause of death in this population. See "Posttransplant Infections" section.
Urinary tract infection	
Interstitial nephritis from polyoma BK virus, cytomegalovirus, herpes viruses 1 and 2, and adenovirus	
Rejection	Most common presentation of rejection in renal transplant patients is hypertension and falling urine output. Comparison of creatinine at the time of presentation to prior levels is critical. Fever may be a presentation for rejection.
Hyperacute	
Acute	
Late (recurrent acute)	
Chronic cellular	
Chronic humoral	
Recurrent pyelonephritis/vesicoureteral reflux	—
Nephrotoxic agents	Drug serum levels do not correlate well with the degree of renal damage. Nonsteroidal anti-inflammatory drugs are contraindicated in this group. Avoid contrast agents if possible.
Aminoglycosides, fluoroquinolones, cidofovir, foscarnet, sulfonamides, calcineurin inhibitors (cyclosporin A and tacrolimus), nonsteroidal anti-inflammatory drugs, gadolinium-based and some other contrast agents, herbal preparations	
Noncompliance with	Diabetes often follows transplantation; marked exacerbations in hypertension are frequently associated with graft failure.
Medications	
Management of risk factors such as diabetes and hypertension	
Chronic allograft nephropathy	—

TABLE 297-10 Complications of Liver Transplantation

Complication	Comments
Bleeding complications	GI bleeding should be managed in the usual fashion but may signal graft dysfunction.
Biliary complications	Bile leaks present early and biliary strictures present late (>2 mo from transplant). In both cases, cholestatic liver enzymes are elevated, typically with right upper quadrant pain (more pronounced with bile leak).
Bile leak	
Biliary stricture	
Hepatic artery complications	CT with contrast (if renal function adequate) or US is helpful in the evaluation of these conditions.
Hepatic artery thrombosis	
Hepatic vein thrombosis	
Portal vein complications	
Rejection	Early alkaline phosphatase and bilirubin levels rise, followed by a rise in aspartate aminotransferase and alanine aminotransferase.
Neurologic complications	Causes include hemorrhage, cerebrovascular infarct, cerebral abscess, hypertensive encephalopathy, osmotic demyelination syndrome, and sinus thrombosis. MRI is best for evaluation.
Malignancy	Increased risk for squamous cell carcinoma, lymphomas, and posttransplant lymphoproliferative disorder.

can cause acute renal failure in up to 3.5% of patients with underlying chronic renal insufficiency.[27] Therefore, the patient's transplant team should be consulted before using gadolinium-based contrast agents.

GRAFT DYSFUNCTION AND FAILURE

Chronic renal dysfunction precedes the majority of graft failures. Acute renal failure in transplant patients is defined as a 20% rise from baseline serum creatinine levels, as opposed to a 50% rise in other patients with acute renal failure. Consider the conditions described in **Table 297-9** when evaluating possible graft dysfunction or even a small increase in serum creatinine.[28,29]

LIVER TRANSPLANTATION

The most common reasons for ED visits are fever and abdominal pain.[6] Complications include bleeding, rejection, and infection, as well as biliary, vascular, and wound complications. Bacterial infection may accompany acute rejection.[30] Specific complications of liver transplantation are listed in **Table 297-10**. Obtain a CBC with platelet count and differential; serum chemistries, including electrolytes, BUN, creatinine, basic coagulation studies, liver function tests, amylase, and lipase levels; and cultures of blood, urine, bile, and ascites. Radiographic testing as indicated may include chest x-ray and abdominal ultrasonography with Doppler flow studies. US with Doppler can identify fluid collections, thrombosis of the hepatic artery or portal vein, and dilatation of the biliary tree (although the absence of biliary dilatation does not exclude obstruction or other posttransplantation pathology). With partial obstruction, the intrahepatic ductal system often does not appear to be dilated appreciably by US. With complete obstruction, duct dilation is usually seen. Patients often require cholangiography for complete evaluation. Patients with choledochocholedochostomy may be best evaluated by endoscopic retrograde cholangiopancreatography because it permits both a radiographic diagnosis and the potential for nonoperative intervention. Patients with a Roux-en-Y hepaticojejunostomy or those who cannot have endoscopic retrograde cholangiopancreatography must undergo percutaneous cholangiography. Early, broad-spectrum prophylactic antibiotics should be administered before any biliary tract manipulation. Discuss treatment and disposition with the transplant team.

LUNG TRANSPLANTATION

Fever, cough, and increasing dyspnea are common reasons for ED visits in lung transplant patients. Important clinical features to note are the respiratory rate, pulse oximetry measurement, and physical findings of cyanosis, diaphoresis, use of accessory muscles, signs of congestive heart failure, and adequacy of peripheral perfusion. Obtain a chest radiograph and arterial blood gas analysis when adequacy of ventilation is in question. Give β_2-agonists and anticholinergics as indicated. Signs of infection often overlap with the signs and symptoms of rejection, and the management of infection is quite different from that of rejection. A drop in the forced expiratory volume in 1 second of >10% warrants clinical investigation, but pulmonary function testing cannot distinguish between acute rejection, infection, and nonimmunologic causes of respiratory dysfunction such as airway stenosis.[31] Therefore, bronchoscopy is required for specific diagnosis. Lung transplant patients can deteriorate very quickly in the absence of the proper therapy. Thus, it is common practice to cover both infection and rejection until additional histopathologic and culture results are obtained.[32]

TABLE 297-11 Time Course of Lung Transplant Complications

Days after Transplant	Complications Most Commonly Seen in Each Time Period
0–3 d	Hemorrhage from technical/mechanical problems Reperfusion injury Dysrhythmia
3 d–1 mo	Infection: bacterial, mycoplasma, community respiratory viruses Rejection Anastomotic failure Pulmonary embolism Muscle weakness Dysrhythmia
Starting at 1 mo	Rejection Obliterative bronchiolitis Infection Bacterial, fungal, community respiratory viral (can occur at any later time) Mycoplasma 0–4 mo Mycobacteria after 4 mo
Other	Cytomegalovirus infection and *Pneumocystis jiroveci* pneumonia may occur any time, but are more common when prophylaxis is not being given, especially when such treatment has been recently discontinued.

COMPLICATIONS OF LUNG TRANSPLANTATION

Complications occur most frequently in the first year but can occur at any time starting from the first few weeks after transplant and continue throughout the lifetime of the patient (**Table 297-11**).[32,33] Indications for hospital admission are listed in **Table 297-12**.

Acute rejection is common and may occur three to six times in the first postoperative year. After the first year, the frequency of acute rejection decreases, but it can occur for several years after transplant. Signs of rejection include cough, chest tightness, increase or decrease in temperature from baseline of >0.28°C (0.5°F), hypoxemia, decline in forced expiratory volume in 1 second (10% or more), and infiltrates on the chest radiograph. Radiographic abnormalities are less common >6 weeks after transplant, and an acute rejection episode actually may be "radiographically silent" after this. Discuss treatment with the transplant team. If the maintenance immunosuppressant regimen has been tapered, it can be very helpful to return to pretaper dosages. In addition, high-dose corticosteroids are often used to treat acute rejection. The usual dosing regimen is 15 milligrams/kg of IV methylprednisolone each day for 3 consecutive days. After the corticosteroid bolus, if the maintenance prednisone had been tapered, increasing the prednisone to 1 milligram/kg/d and tapering over the next 10 days may be helpful.[31] Clinical response to treatment is gauged by improvements in oxygenation, spirometry, and radiographic appearance and typically occurs within 24 to 48 hours after treatment is initiated. Failure to improve should suggest infection as an alternative diagnosis. After clinical improvement, the maintenance dose of prednisone is increased, with a slow taper back to baseline.

TABLE 297-12 Indications for Hospital Admission for Lung Transplant Patients

Pretransplant patients
Respiratory failure
Infiltrate
Systemic infection
Decompensated congestive heart failure or pulmonary edema
Pneumothorax
Posttransplant patients
Respiratory failure
Acute rejection
Rapidly progressive airflow limitation (forced expiratory volume in 1 second decreases >10% over 48 h)
Infiltrate
Systemic infection
Febrile neutropenia
Pneumothorax

Pulmonary infections from bacteria, fungi, or viruses are the most common causes of morbidity and mortality in lung transplant patients[34,35] (Tables 297-5 and 297-11). Lung transplant patients are at risk for pneumonia because of colonization of the recipient's airway in the setting of transplantation for bronchiectasis and cystic fibrosis and at risk of aspiration in the presence of gastroesophageal reflux disease.[33] Antibiotic selection is best left to the lung transplant specialist.

CARDIAC TRANSPLANTATION

Cardiac transplantation has been applied successfully to patients of all ages, from newborns through persons in their late 60s. Heart transplantation is indicated for patients with end-stage heart failure not remediable by standard medical or surgical therapy. Many in the latter group will have undergone previous coronary artery bypass or valve surgery or been bridged on mechanical assist devices. The leading causes of death in those age 60 to 69 are graft failure and infection.[36]

The success of a heart transplantation operation depends on the ability of the denervated heart to support the normal circulation. The lack of sympathetic and parasympathetic innervation does, however, induce an altered physiologic state. The denervated heart has a normal sinus rhythm with a heart rate between 90 and 100 beats/min. Denervation results in the absence of the initial centrally mediated tachycardia in response to stress or exercise, but the heart remains responsive to circulating catecholamines. Thus, the cardiac response to stress or exertion is blunted. With proper conditioning, patients are able to resume normal activity levels, including vigorous exercise, following transplantation.

The donor heart is implanted with its own sinus node intact to preserve normal atrioventricular conduction. The technique of cardiac transplantation also results in preservation of the recipient's sinus node at the superior cavoatrial junction, and the two sinus nodes remain electrically isolated from each other. Thus, ECGs frequently will have two distinct P waves (**Figure 297-2**). The sinus node of the donor heart is easily identified by its constant 1:1 relationship to the QRS complex, whereas the native P wave marches through the donor heart rhythm independently. The presence of the two separate P waves may lead to confusion about the patient's rhythm, mistakenly interpreting sinus rhythm as second-degree heart block. The ECGs may also be interpreted erroneously as showing atrial fibrillation, atrial flutter, or frequent premature atrial complexes. Some patients may have evidence of "cardiomegaly" related to the transplantation of a heart from a donor who was larger than the recipient (**Figure 297-3**). Clinical evaluation is based on the reason for the ED visit. Chest x-ray, ECG, and further evaluation are based on complications of cardiac transplantation (**Table 297-13**) and underlying patient comorbidities, especially in elderly transplant recipients.

CORNEAL TRANSPLANTATION

Corneal transplantation (penetrating keratoplasty) is the most common form of human solid tissue transplantation. Unlike other tissue and organ transplants, corneal allotransplantation usually does not require systemic or permanent immunosuppression. Reasons for graft failure include corneal graft rejection (30.9%), corneal endothelial cell failure (21.0%), glaucoma (8.5%), and other causes (26.2%).[37,38] **Ophthalmology consultation is required for any change in visual acuity or other ocular signs or symptoms in a patient with a corneal transplant.**

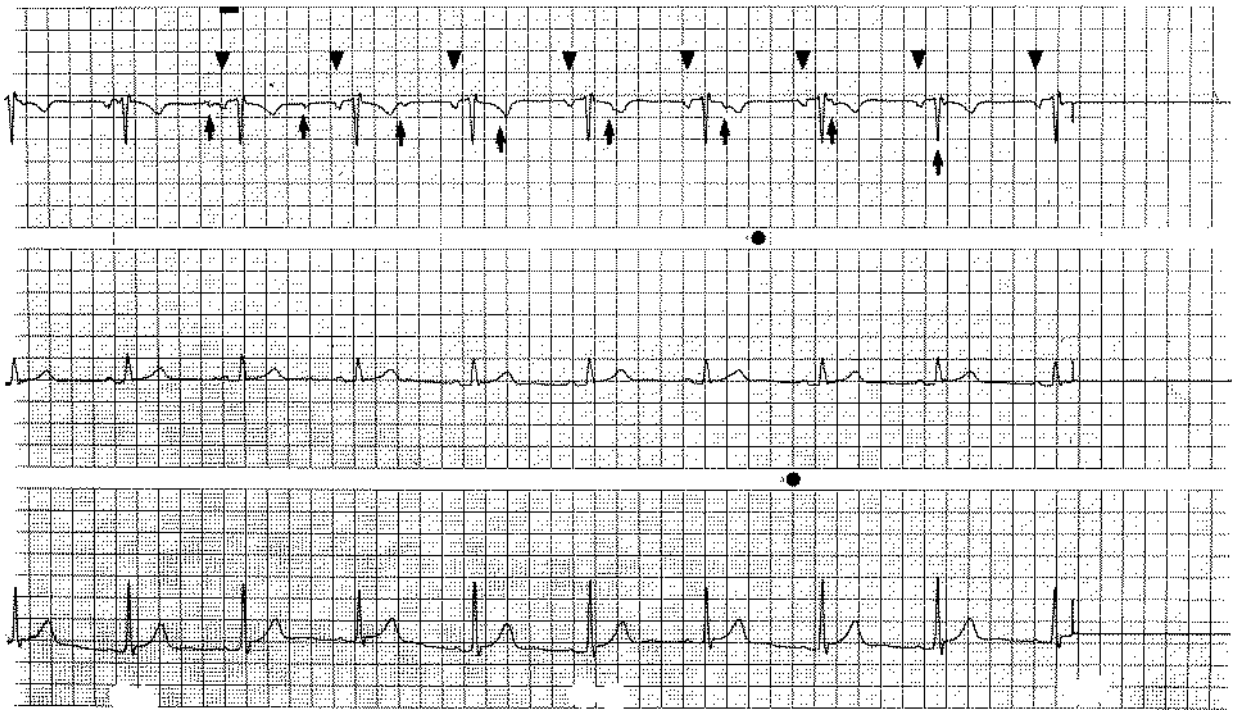

FIGURE 297-2. ECG in a heart transplant patient. ECG demonstrates donor and recipient P waves (*arrowhead* = donor P wave; *arrow* = recipient P wave).

Corneal graft rejection is a specific process in which a graft that has been clear suddenly develops graft edema with anterior segment inflammatory signs. Rejection can occur at any time starting at 10 days after transplant. The inflammatory process starts at the graft margin nearest to the most proximal blood vessels and then moves toward the center to involve the entire graft.[37] Signs and symptoms include eye pain, photophobia, corneal or scleral injection, or decreased visual acuity. Examination may reveal unilateral anterior chamber reaction with keratic precipitate or corneal edema in a previously clear graft. Late graft failure can present with gradual onset of graft edema with no associated inflammation or keratic

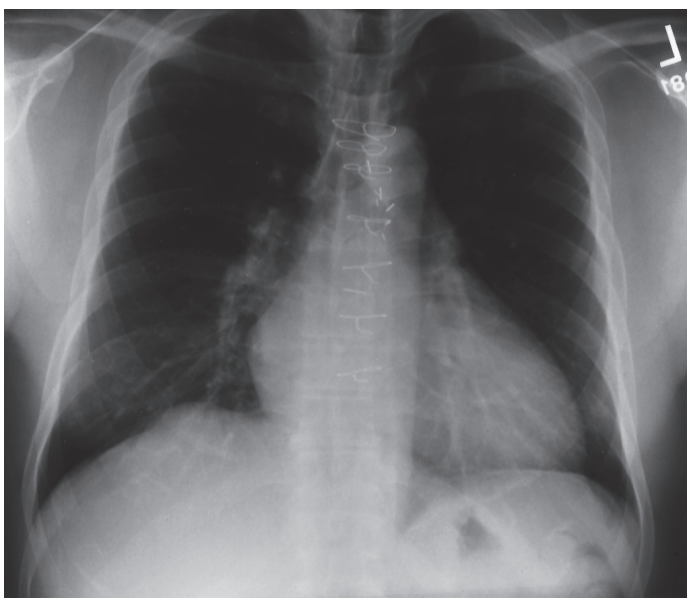

FIGURE 297-3. Chest radiograph of healthy post–heart transplant patient with typical postoperative changes, including "cardiomegaly" due to transplantation of a heart from a donor who was larger than the recipient.

TABLE 297-13 Complications after Cardiac Transplant

Complication	Comments
Altered physiology	See text in Cardiac Transplantation section.
Dysrhythmias	Dysrhythmias after transplantation are frequently due to rejection. Treat the unstable patient presenting in extremis with 1 gram of methylprednisolone IV; delay rejection therapy in the stable patient for consult with the transplant team and biopsy. Atropine has no effect due to denervation.
Sinus node dysfunction	Pacemaker usually required.
Pulmonary complications	Diagnosis may require CT or more invasive diagnostic procedures.
Pneumonia	
Thromboembolic disease	
Exercise-induced hypoxemia	
Pneumothorax	
Interstitial fibrosis	
Cardiac ischemia	Patients do not experience pain due to denervation; symptoms typically occur with complications such as congestive heart failure.
Rejection	Treat the patient presenting in extremis; withhold treatment for biopsy if possible.
Infection	See section "Posttransplant Infections"
Congestive heart failure	Echocardiography can help to determine etiology and therefore ideal treatment.
Ischemic stroke and intracranial hemorrhage	Increased risk after heart transplant.
Complications specific to ventricular assist devices	Increased risk of infection and thromboembolism.
Cardiac allographic vasculopathy	Pediatric heart transplant recipients are at risk for graft coronary artery disease and ischemia. May require retransplantation.

precipitates. Treatment includes topical or systemic steroids, cycloplegics, and immunosuppressive drugs such as local and systemic cyclosporine A and tacrolimus.

Wound dehiscence can occur early or late after corneal transplantation, as a result of infection or after eye trauma. Trauma may be unrecognized or be a result of events such as motor vehicle airbag deployment or a fall with the patient's glasses impacting the eye. There may be globe rupture, slight separation of part of the suture line, or just broken sutures.

Viral,[37] bacterial,[39] or fungal[40] infection can threaten the transplanted cornea. In patients with a history of herpetic keratitis, consider recurrence and examine with fluorescein for characteristic corneal staining and signs of anterior chamber inflammation.[37] Ophthalmology consultation is needed for diagnosis and treatment.

CHAPTER 298

The Patient With Morbid Obesity

Joanne Williams

INTRODUCTION AND EPIDEMIOLOGY

Since 1980, worldwide obesity has more than doubled. In 2008, more than 1.4 billion adults, 20 and older, were overweight. Of these, over 200 million men and nearly 300 million women were obese. Sixty-five percent of the world population resides in countries where overweight and obesity kill more people than underweight. In 2010, more than 40 million children under the age of 5 were overweight.[1]

In children, an age- and sex-specific percentile for body mass index (BMI) determines weight status rather than the BMI categories used for adults, because children's body composition varies as they age and varies between boys and girls.

The Centers for Disease Control and Prevention defines overweight as a BMI at or above the 85th percentile and lower than the 95th percentile for children of the same age and sex.[2] Obesity is a BMI at or above the 95th percentile for children of the same age and sex.[2] The World Health Organization definition is as follows: a BMI ≥25 is overweight, whereas a BMI ≥30 is obesity.[1]

PATHOPHYSIOLOGY

Obesity is an independent risk factor for acute coronary syndrome, especially in those <40 years old.[3,4] Atypical symptoms may pose a problem with acute coronary syndrome diagnosis.[5,6] About 11% of cases of congestive heart failure are attributable to obesity alone.[7] The physical deconditioning of obesity manifest by orthopnea, dyspnea, and lower extremity swelling is very similar to symptoms of acute congestive heart failure, making diagnosis problematic. Plain chest x-ray findings of congestive heart failure may be obscured by redundant overlying soft tissue and hypoventilation. Brain natriuretic peptide levels are lower in the obese patient than in the nonobese.[8,9] Cardiomyopathy may affect up to 10% of patients with a BMI >40 kg/m^2 and those with a long duration of significant obesity.[10] Obesity is a risk factor for venous thromboembolism[11] and its recurrence once anticoagulation therapy is withdrawn.[12]

The increase in the prevalence of type 2 diabetes is closely linked to the upsurge in obesity. About 90% of type 2 diabetes is attributable to excess weight.[13] Obesity has been strongly associated with insulin resistance in normoglycemic persons and in individuals with type 2 diabetes.[14]

TABLE 298-1 Diagnostic Criteria for Obesity Hypoventilation Syndrome

Body mass index 30 kg/m^2
Daytime $Paco_2$ >45 mm Hg
Associated sleep-related breathing disorder (obstructive sleep apnea–hypopnea syndrome or sleep hypoventilation or both)
Absence of other known causes of hypoventilation

Abbreviation: $Paco_2$ = partial pressure of arterial carbon dioxide.

The accumulation of fat impairs the function of ventilation in obese children and adults.[15-17] Reductions in forced expiratory volume in 1 second, forced vital capacity,[15,16] total lung capacity, functional residual capacity, and expiratory reserve volume are associated with increasing BMI.[18]

Obesity is a well-recognized risk factor for obstructive sleep apnea. Forty percent of people who are obese have obstructive sleep apnea, and approximately 70% of people with obstructive sleep apnea are obese.[19]

Increased fat deposition in the pharyngeal area along with reduced operating lung volumes associated with obesity reduce upper airway caliber, modifying airway configuration, which in turn increases upper airway collapsibility. Thus, airways are predisposed to repetitive closure during sleep.[20] Daytime sleepiness increases and may be associated with accidental trauma.[19]

Cor pulmonale and hypercapnic respiratory failure are common. Obesity hypoventilation syndrome (**Table 298-1**) was first described over 50 years ago.[21,22] The most common symptoms are (1) respiratory failure, (2) severe hypoxemia, (3) hypercapnia, and (4) pulmonary hypertension.[22,23,24]

ESTIMATING PATIENT WEIGHT

The Broselow tape inaccurately predicts actual weight in one third of children.[25] The significance of this inaccuracy has not been studied in depth. A weight-estimation formula based on mid-arm circumference is reliable for use in school-age children and may be an alternative to the Broselow tape.[26] The formula is as follows: weight (kg) = (mid-arm circumference [cm] – 10) × 3. When compared to the Argal, Advanced Pediatric Life Support, and Best Guess formulas, Krieser et al[27] found that parental estimation of weight was more accurate.[27]

The concern for equipment weight capacity in the adult patient with obesity is an important determination for imaging. Scales in most EDs have a maximum weight capacity of 150 kg. Mechanized beds that weigh patients are not common in the ED but might be a consideration. Patients with obesity tend to significantly underestimate their own weight. A variety of formulas are available to estimate weight in adults who are obese using height and waist, hip, and arm circumference. The formula developed by Crandall et al[28] seems to require the least amount of time and patient manipulation. Two distinct formulas for nonpregnant females and males have been developed as follows:

Nonpregnant females: Weight = 64.6 + 2.15 (arm circumference in cm) + 0.54 (height in cm)

Males: Weight = 93.2 + 3.29 (arm circumference in cm) + 0.43 (height in cm)

SPHYGMOMANOMETRY

Improper blood pressure cuff width and circumference will artificially elevate pressure readings. The standard adult blood pressure cuff is too short for patients with an arm circumference of 32 cm or larger. Patients who are overweight or obese will require cuffs larger in size.

The American Heart Association recommends the following cuff widths when evaluating blood pressure in patients who are obese: (1) for arm circumferences ranging from 35 to 44 cm, a bladder measuring 16 cm in width is needed; (2) for circumferences from 45 to 52 cm, the bladder width should be 20 cm; and (3) in patients with short upper arm length, a 16-cm-wide cuff should be used.[29,30]

TABLE 298-2	Dosing of Select Drugs
Dosing	**Drugs**
Ideal body weight	Penicillins, cephalosporins, linezolid, corticosteroids, H_2-blockers, digoxin, β-blockers, atracurium, vecuronium, fentanyl*, midazolam*, lorazepam*, phenytoin, propofol
Total body weight	Succinylcholine, rocuronium, unfractionated heparin, enoxaparin, vancomycin
Dosing weight	Aminoglycosides, fluoroquinolones

*Initial dose based on total body weight.

MEDICATION DOSING

Little evidence-based literature is available for appropriate dosing in obesity, and nearly none is available in the obese child. Fortunately, many drugs used in resuscitation are not lipophilic, and lean body mass is a reasonable dosing guide. Altered physiology is characterized by an increased clearance of hydrophilic drugs, a larger volume of distribution for lipophilic drugs, and a decrease in lean body mass and tissue water content, as compared to their lean counterparts.[31] Altered mechanics can predispose the morbidly obese to systemic toxicity due to either overdosing or lack of efficacy from underdosing.[32,33]

A weight-based medication schedule uses ideal body weight, total body weight, or dosing weight to avoid systemic side effects and lack of clinical efficacy by underdosing. Ideal body weight according to the Devine formula is as follows[34]:

Ideal body weight (male) = 50.0 kg + 2.3 kg (each inch >5 feet)

Ideal body weight (female) = 45.5 kg + 2.3 kg (each inch >5 feet)

Dosing weight is an adjusted body weight of overweight or obese patients and is used only for drugs for which there are recommendations specifying that the actual body weight should be adjusted to use in the dose calculation.

Dosing weight = Ideal body weight + [0.4 × (Actual – Ideal body weight)]

Exception: If actual < ideal body weight, then the dosing weight = actual

Table 298-2 divides select drugs into ideal body weight, total body weight, and dosing weight dosing.[35] **Fentanyl and the benzodiazepines are lipophilic and have a prolonged half-life in obese patients.** With these drugs, the initial dose based on total body weight may be needed, but subsequent doses should be based on ideal body weight.[36] It is best to check with a pharmacist for specific dosage regimens.

VASCULAR ACCESS

Vascular access is problematic. Patients who are critically ill and morbidly obese patients require fluid administration often guided by central venous pressure and urine output.[37] Central venous pressure placement is extremely challenging even for the most skilled physician. In the obese patient, the distance from skin to vessel is much further than normal, anatomic landmarks are obscured (**Figure 298-1, A and B**), and the angle of approach may be too steep to allow cannulation even after reaching the vessel. There is no clear consensus as to the preferable site and approach to central venous catheterization. In general, there is an increased incidence of infection and deep venous thrombosis when using the femoral approach.[38] If this proves to be the only option, then use this site.

The internal jugular vein can be accessed with equal success to the subclavian approach in patients who are obese. The success rate might be increased with the head maintained in the neutral position, thereby reducing the risk of overlap of the internal jugular vein over the carotid artery.[39]

A

B

FIGURE 298-1. A and B. Difficulties in landmark identification.

A US-guided 15-cm catheter can be used to cannulate the brachial or basilic vein.[40] Another approach is the use of a pediatric central venous catheter placed into the basilic vein. The pediatric central venous catheter is 8 cm (3.15 in) in length, is a double-lumen catheter, and has 18- and 20-gauge lumens.[41] Longer catheters can also be considered to guard against inadvertent dislodgement.

IMAGING

Attenuation severely limits the image quality of plain radiographs (**Figure 298-2**). Increasing exposure time can improve the image but at the expense of increased radiation. Motion artifact increases with increased exposure time. Multiple cassettes may be required if the patient is too large for a single 14 × 17–inch film. Patients may be able to stand for plain radiography if too large for the tables.[42]

Newer CT scanners can accommodate up to 660 lbs. If the patient outweighs equipment capacity, veterinary schools and the local zoo are options.

In the patient with obesity and blunt abdominal trauma who is too large for imaging equipment, consider diagnostic peritoneal lavage.[43] Most standard MRIs have a maximum shoulder-to-shoulder width of 52 inches (137 cm) and weight limits of 300 to 350 lb (136 to 159 kg).

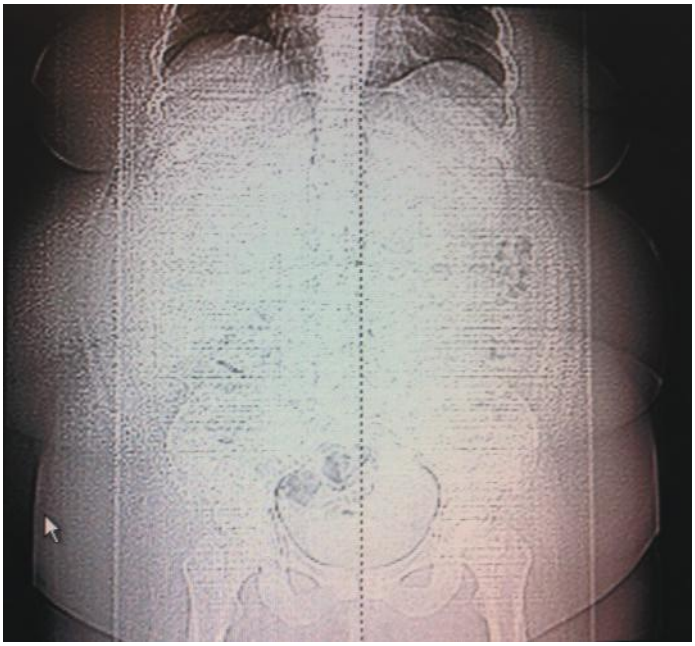

FIGURE 298-2. Attenuation can blur findings on plain radiographic films.

PROCEDURAL SEDATION

Give procedural sedation drugs and pain medications cautiously. Select doses at the lower end of the range, and titrate to effect. Local and regional anesthesia might be considered for complicated or prolonged procedures.[44]

AIRWAY MANAGEMENT

Difficulty with mask ventilation, rapid oxygen desaturation, and altered pharmacokinetics can make airway management challenging.[45] Impedance to airway management is caused by excess fatty tissue externally on the breast, neck, thoracic wall, and abdomen and internally in the mouth, pharynx, and abdomen. The respiratory compromise that is associated with morbid obesity leaves little room for error.

Patients who are obese have increased intra-abdominal pressure and increased incidence of hiatal hernia and gastroesophageal reflux disease. These characteristics render patients more prone to aspiration during airway management.[46]

Patients who are obese will desaturate more rapidly after preoxygenation than their lean counterparts. When no cervical spine injury is suspected, desaturation may be partially prevented by keeping the patient in a 25-degree head-up position during preoxygenation.[47]

Two-person bag-valve mask (BVM) with a two-handed bilateral jaw thrust is recommended in patients who are morbidly obese. If tolerated, an oral airway may be used to prevent the tongue from occluding the airway. The early use of noninvasive positive-pressure ventilation may abate the need for endotracheal intubation. High expiratory positive pressures may be needed.

Obesity is not a contraindication for rapid sequence intubation. Advance preparation is critical, and assessment for a potential difficult airway is of utmost importance.[48]

The "sniffing" position results in suboptimal positioning for laryngoscopy in patients who are obese, and this may also confound results and falsely worsen graded views.[49] The "ramping" position (**Figure 298-3A**) offers improved intubation conditions in patients who are morbidly obese compared to the "sniffing" position (**Figure 298-3B**). This position is achieved by placing multiple folded blankets under the upper body, head, and neck until the external auditory meatus and the sternal notch are horizontally aligned.[50]

First give consideration to awake intubation, given that patients who are obese may be difficult to mask ventilate and rapid oxygen desaturation may occur after the ablation of spontaneous ventilation, especially

A

B

FIGURE 298-3. The ramping position **(A)** is more effective for intubation than the sniffing position **(B)** in patients with morbid obesity.

in patients with a BMI greater than 40 kg/m^2.[51-53] The awake intubation may be performed either by the nasotracheal or orotracheal routes.

The relative benefits and risks of the awake intubation approach must be weighed against the merits of rapid sequence intubation, which reduces risk of aspiration, improves intubating conditions, and results in easier insertion of advanced and rescue airway devices. During rapid sequence intubation, the chance for first-pass success can be optimized by video laryngoscopy. The intubating laryngeal mask airway is effective in obesity and should be readily available because surgical access to the airway may be difficult. The bougie is a good rescue device.[54]

Percutaneous and open surgical access to the airway may be difficult when landmarks are obscured by excess soft tissue and a short neck in the "cannot intubate, cannot ventilate" scenario.[55] Obesity and a short neck are associated with difficult transtracheal needle ventilation and retrograde tracheal intubation.[56,57] However, in the elective surgical airway management setting, cricothyroidotomy is technically feasible even in patients with difficult neck anatomy caused by obesity.[58] Unfortunately, the luxury of a controlled environment is often not an option for the emergency physician.

Until the proper size tracheostomy tube is located, a 6-mm-inner-diameter endotracheal tube passed through a cricothyroidotomy incision may serve as a temporizing measure.[59] There is limited literature concerning the success rates of surgical airways in patients in the emergency setting. Even in an ideal setting, cricothyroidotomy requires more than 100 seconds to achieve ventilation,[57] and the procedure is rarely performed in the ED.[60]

With respect to ventilator management, adjust tidal volume as per body weight and initially keep it at 8 mL/kg of ideal body weight in patients in whom mechanical ventilation is necessary, but patients with

acute respiratory distress should be ventilated with much lower tidal volume. Lower tidal volumes can be compensated for by increasing the respiratory rate to maintain normal minute ventilation and thus avoiding hypoxemia and hypercarbia.[61] During prolonged ventilation, ventilatory settings are determined by serial measurements of arterial blood gasses and peak airway pressures.[62]

LUMBAR PUNCTURE

In the patient who is obese, lumbar puncture is best performed in the sitting position. US may help identify vertebrae.[63] A formula for predicting the required lumbar puncture depth was developed by Abe et al.[64] The formula is as follows:

Lumbar puncture depth (cm) = 1 + 17 (weight [kg]/height [cm])

Success rate can increase with the awareness of the predicted depth.[65]

A 22- to 24-gauge needle allows adequate flow and easier passage and may also decrease the likelihood of postpuncture headache. Fluoroscopy may be required in extreme, technically difficult, or unsuccessful cases.

TRAUMA

Victims of motor vehicle accidents who are obese (BMI >31 kg/m^2) have significantly more rib fractures, pelvic fractures, pulmonary contusions, and extremity fractures and fewer head and liver injuries.[66]

Mildly overweight patients, not the morbidly obese, are less prone to intra-abdominal injury because of the protective effect of the abdominal fat, known as the "cushion effect."[67]

CHAPTER 299

Palliative Care

Robert J. Zalenski
Erin Zimny

INTRODUCTION

The goal of palliative care is to relieve the suffering of patients with serious illness. Regardless of the patient's prognosis, relief of suffering should be a primary goal for both emergency medicine and palliative care.[1] **Palliative care** is defined by specialty advocates as the physical, spiritual, and psychosocial care given by multiple disciplines to patients and their families who are living with life-threatening illness.[2] Although these principles are applicable to all stages of a patient's illness, a palliative care consultation from the ED is generally considered in the context of previously predicted end-of-life care. **Hospice care**, a branch of palliative care, is a comprehensive program of palliative treatment that is appropriate when patients with chronic, progressive, and eventually fatal illness are determined to have a life expectancy of 6 months or less. Palliative care is patient centered rather than disease centered. It strives to ensure that the patient or his or her (formal or informal) representatives have chosen realistic goals of care after the patient's diagnosis, prognosis, and therapeutic options have been considered. This discussion and decision making should take place during a meeting that includes the patient's healthcare team, surrogate decision maker(s), and those loved ones who are privileged to receive confidential information.

Palliative care is guided by the axiom that distressing symptoms should be treated. It thus provides expert assessment and treatment of symptoms, including pain, dyspnea, and vomiting. Pain is the most common reason for seeking care in the ED, accounting for 58% to 78% of visits in the United States.[3-5] Unfortunately, only 60% of patients reporting pain receive pain medications, and 74% of patients who present in pain are discharged in moderate to severe pain.[6] Dyspnea is the sixth most common chief complaint and vomiting the ninth most common chief complaint of patients presenting to the ED[7]; statistics are not available to document the success or failure of the emergency physician's attention to alleviating these symptoms.

Palliative care also trains healthcare professionals to compassionately communicate diagnosis, prognosis, and treatment alternatives and guide the formulation of a therapeutic plan. Palliative care clinicians work to coordinate caregivers and interventions for the patient and family, to make care more effective, and to lessen the stress and obstacles for achieving satisfactory outcomes. Standards for compassionate care spelled out by the Institute of Medicine[8] and numerous professional societies require that distressing symptoms be alleviated concurrently with all treatments directed toward the pathology of the medical disorder. The patient or surrogate must play a key role in decisions regarding care.

The subspecialty of hospice and palliative medicine was co-sponsored by the American Board of Emergency Medicine, recognized by the American Council of Graduate Medical Education, and officially approved by the American Board of Medical Specialties in 2006. In the spring of 2007, the American Board of Emergency Medicine approved the seating of duly qualified emergency physicians for the new Palliative Care Specialty. The first American Board of Medical Specialties board exam, administered in 2008, qualified the first emergency medicine physicians for practice of the subspecialty of hospice and palliative medicine.[9]

In June 2008, the American College of Emergency Physicians issued the policy statement, **Ethical Issues and End-of-Life Care** (**Table 299-1**).[10] In March 2008, the Emergency Nurses Association published a position statement, **End-of-Life Care in the Emergency Department**, spelling out practice and leadership roles for nurses in the ED. And most recently, on November 10, 2011, The Center to Advance Palliative Care (the primary advocate for palliative care in the United States), released its **Improving Palliative Care in Emergency Medicine (IPAL-EM)** project. This project informs and enables EDs to develop thoughtful, creative, and streamlined programs to integrate palliative care into the day to day operation of the ED.[11]

TABLE 299-1 The American College of Emergency Physicians Board of Directors: Ethical Issues at the End of Life

The American College of Emergency Physicians believes that:
Emergency physicians play an important role in providing care at the end of life (EOL).
Helping patients and their families achieve greater control over the dying process will improve EOL care.
Advance care planning can help patients formulate and express individual wishes for EOL care and communicate those wishes to their healthcare providers by means of advance directives (including state-approved advance directives, do not attempt resuscitation orders, living wills, and durable powers of attorney for health care).
To enhance EOL care in the ED, the American College of Emergency Physicians believes that emergency physicians should:
Respect the dying patient's needs for care, comfort, and compassion.
Communicate promptly and appropriately with patients and their families about EOL care choices, avoiding medical jargon.
Elicit the patient's goals for care before initiating treatment, recognizing that EOL care includes a broad range of therapeutic and palliative options.
Respect the wishes of dying patients including those expressed in advance directives. Assist surrogates to make EOL care choices for patients who lack decision-making capacity, based on the patient's own preferences, values, and goals.
Encourage the presence of family and friends at the patient's bedside near the end of life, if desired by the patient.
Protect the privacy of patients and families near the end of life.
Promote liaisons with individuals and organizations in order to help patients and families honor EOL cultural and religious traditions.

TABLE 299-2 Description of Palliative Care in Emergency Medicine

Who: Patients with serious, potentially life-threatening illness and their families.

What: From potentially curable conditions in the presence of chronic devastating disease when standard treatment impedes the patient's remaining quality of life, to incurable conditions like stage IV heart failure, metastatic lung cancer, or advanced dementia.

When: After a lifespan-limiting prognosis has been defined, or when requested by patients and their families to enhance the patient's quality of life. Late-stage palliative care for incurable illnesses with a prognosis estimated of six months or less is provided in the United States under the hospice benefit of Medicare.

Where: In the ED and every other setting in which the patient receives care, or wishes to receive care, such as at home.

Why: Because the relief of suffering is the primary goal of medicine, and there are few places with greater patient suffering than in the ED.

How: The patient/family decide the goals of care after a realistic discussion based on diagnosis, prognosis, and effectiveness of potential therapies. An interdisciplinary team consisting of at least the doctor and nurse provides care measures, such as symptom relief, and initiates the coordination of care needed to reach the patient's goals. Most commonly this occurs in consultation with a palliative care service, unless the emergency physician is trained in palliative care.

Who Decides: The patient, provided he/she retains decision-making capacity, or the surrogate decision maker, the legally appointed Durable Power of Attorney for Healthcare or closest family relative who speaks for the patient.

By implementing principles of palliative care (**Table 299-2**), emergency physicians will become better skilled at assessing patients' preferences and health status to determine whether initiating aggressive therapy is both concordant with the patients'/surrogates' preferences and potentially beneficial. Patients already receiving a palliative care approach will be able to have their existing care plan continued in a coordinated fashion when presenting to the ED for worsening symptoms, although they would be more optimally managed as outpatients.[12]

EPIDEMIOLOGY

In 2006 in the United States, 36% of people who died were receiving hospice care at the time of death, and a total of 1.3 million people received hospice care in 2006. Although hospice was initially designed for cancer patients, 53.6% of patients enrolled in hospice in 2005 had a noncancer diagnosis. About 58% of U.S. residents die in an acute hospital setting.[13]

In 2002, there were 12.7 million people aged >65 years in the U.S.[14] In 2030, there will be over 72 million elderly people. The **Hospitalized Elderly Longitudinal Project** study found that the very elderly (>80 years) are most likely to want and to consider comfort care as the best option when facing serious chronic illness.[15] The surge in growth in the aging population will increase the demand for quality palliative care.

The U.S. healthcare enterprise is facing a large crisis due to the high cost of health care, particularly Medicare. Approximately 30% of healthcare costs occur in the last 6 months of life. Data from the Health and Retirement Study showed that 51% of those over age 50 visit the ED during their last month of life, 77% of those are admitted to the hospital, and 68% of those admitted die during their hospital stay.[16] A meta-analysis published in 1999 found that the use of hospice saved as much as 40% of healthcare costs during the last month of life, and 17% over the last 6 months of life.[17] A subsequent study found that hospice care reduced Medicare costs during the last year of life by an average of $2309 per hospice user.[18] Admitting eligible patients to hospice is one promising route for addressing the quality/cost chasm.[19]

Currently, only 4% to 7% of hospitalized patients are referred to palliative care or hospice directly from the ED.[20-22] The average time in the hospital before transfer to a palliative care bed is 5 to 9 days.[21,22]

IDENTIFYING PATIENTS FOR PALLIATIVE CARE

In 2011, the Center to Advance Palliative Care released its Improving Palliative Care in Emergency Medicine program, a program that provides a thoughtful approach to palliative care practice in the ED, formulated for and by emergency clinicians. The program covers all aspects of palliative care in the ED.[11] Emergency physicians have enthusiastically received the Improving Palliative Care in Emergency Medicine program,[11] despite expressing concerns about the challenges facing them when discussing palliative or hospice care with patients such as interruption of workflow, lack of long-term relationships with patients, and lack of training to facilitate interactions.[23]

Palliative care needs include the management of a cluster of technologies associated with diagnoses of advanced, frequently incurable conditions.[24] Patients whose long-term care needs are complex and require skilled nursing care for transfusions, tracheostomy care, or infusions of antibiotics or inotropes are likely in need of palliative care, especially if the disease is progressive.

FUNCTIONAL DECLINE

Functional decline is the loss of the ability to care for oneself. This ranges from the loss of complex abilities, like driving, shopping, and managing finances, to basic activities like ambulating to the bathroom and getting safely out of bed. The loss of activities of daily living is the cardinal feature of decline, especially if accompanied by unintentional weight loss, and indicates the need for increased care assistance and suggests a short life expectancy.

PROGNOSIS

Space in this textbook does not allow for a comprehensive discussion of formulating a prognosis and how to share it with patients and families. There are several key diagnoses and prognostic findings that are extraordinarily helpful to understand. Patients with chronic, progressive, life-threatening diagnoses will almost always benefit from palliative care. Those with extensive disease, be it metastatic cancer, organ failure, or neurologic deterioration (with anorexia/cachexia and decreased self-care) are frequently on a dying trajectory.[25] Examples of diagnoses of patients who may benefit from palliative care are listed in **Table 299-3**. A predictive instrument known as the **Palliative Prognostic Score** correlates with prognosis.[26] Elements of the Palliative Prognostic Score include ability to ambulate, provide self-care, and maintain oral intake,

TABLE 299-3 Common Diagnoses and Key Findings of Patients Who May Benefit from Palliative Care

Diagnosis	Key Findings
Solid organ neoplasm	Widespread metastasis unresponsive to treatment
End-stage heart failure	Significant symptoms at rest despite therapy
End-stage COPD	Significant symptoms at rest despite therapy
Advanced dementia	Impaired mobility and inability to communicate health needs
Degenerative neurologic disease	Inability to complete ADLs or communicate health needs
End-stage AIDS	Multiple opportunistic infections and/or AIDS dementia
End-stage renal disease	Patient no longer willing or able to undergo dialysis
End-stage liver disease	Repeated episodes of hepatic encephalopathy, bleeding, or symptomatic ascites resistant to medical therapy
End-stage rheumatologic disease	Inability to complete ADLs without significant discomfort
Multisystem trauma	Nonsurvivable injury
Burn	When age plus percent burn exceeds or nears 140
Multiorgan failure	When two or more key body systems fail
Any chronic, progressive, debilitating disease	Whenever symptom burden exceeds resources and the ability of the patient and/or family to cope with medical condition

Abbreviations: ADLs = activities of daily living; AIDS = acquired immunodeficiency syndrome; COPD = chronic obstructive pulmonary disease.

and level of consciousness. A bed-bound patient completely dependent for all care with reduced oral intake and a diminished level of consciousness has a Palliative Prognostic Score of 10% and a 1-week median expected survival.[26]

REFRACTORY AND COMPLEX CONDITIONS

Multiple visits to the ED for the same condition generally indicate that the plan of care is failing. There may be many reasons for this, but the overall indication is that the patient is becoming resistant to physician-led interventions, and this suggests the potential benefit of palliative therapy.

DISCUSSING PROGNOSIS; SETTING THE PLAN OF CARE

DETERMINING PATIENT DECISIONAL CAPACITY AND IDENTIFYING SURROGATE DECISION MAKERS

The ED team should immediately identify the decision makers when a debilitated patient arrives in crisis to the ED. **A patient with decisional capacity is one who has the mental ability to grasp and retain information about his or her condition, weigh risks and benefits, and demonstrate these abilities by verbalizing a medical decision**[27] (see chapter 303, "Legal Issues in Emergency Medicine," for a more detailed discussion of patient capacity). **Table 299-4** lists phrases to aid meaningful communication with patients and families.[28] If the patient lacks decisional capacity, then the patient's advance directive should be accessed and the named surrogate decision maker should be contacted as soon as possible. If none of these resources are available, then the closest family member(s) should be consulted regarding the plan of care. If no one is available to speak for the patient, then the treating physician should act in the patient's best interest. This may include an order to "do not resuscitate" the patient if it is clear that aggressive therapy would not be beneficial.

TABLE 299-4 Key Communication Phrases[28]

Determining Decision-Making Capacity
Will you describe your current condition?
Tell me about the treatment options we have just discussed.
Explain to me why you feel that way.
Quality of Life
What symptoms bother you the most? What concerns you the most?
Prognosis
Has anyone talked to you about what to expect?
Do you have any sense of how much time is left? Is this something you would like to talk about?
Talking with Surrogate Decision Makers
These decisions are very hard; if [the patient] was sitting with us today, what do you think [he/she] would say?
Can you tell me why you feel that way?
It is not a question of whether we *will* care for your [loved one], but *how* we will care for them.
Then we will do everything possible to keep your [loved one] comfortable, but we won't be providing ineffective and burdensome therapies such as CPR or intubation.
Discussing Palliative Care or Hospice Referral
To meet the goals we've discussed, I've asked the palliative care team to visit with you; they are experts in treating the symptoms you are experiencing. They can help your family deal with the changes brought on by your illness.
Breaking Bad News—Death Pronouncement
I wish there is more we could have done; I'm very sorry for your loss. This has to be really difficult for you. Is there anyone I can call to be with you now?

FAMILY MEETING

Once the physician has determined the patient's decision-making capacity, chronic health status, a clinical diagnosis for the current visit, and a general understanding of the patient's care preference, the doctor and team are prepared to have an abbreviated family meeting with the decision maker(s) to discuss the approach to care. The physician must be clear in his/her own mind whether there is any available therapy that will restore the patient's health; have access to the advice of consultants, specialists, and the patient's primary care physician; and be prepared to issue honest, compassionate, and helpful recommendations based on his/her own assessment.

A productive approach to start such meetings is to ask the surrogate decision maker what he or she understands about the patient's past health and current condition (see **Table 299-4**). After patiently listening, the physician should share his or her insight into the patient's condition and prognosis while monitoring the family's reaction to determine whether the ED team and the family are in agreement. An example of a physician's opinion in a particular case follows: "Your mother's advanced medical condition cannot be cured, and her illness has made her defenseless against the bacteria in her own body. Treating her again and providing another round of intensive care will not bring her health or immune system back to normal, but may only prolong her suffering."

The next step is to ask the surrogate decision makers whether they know about the patient's values and preference for care, for example, how their mother would wish to be treated in the current circumstances. If the answer to that is unknown, ask how the surrogate decision makers would wish to be treated if they were in the same condition.

Based on the response to these questions, the plan of care should be negotiated and jointly affirmed. If the patient decision maker(s) indicate that they must have full resuscitative efforts despite your reservations, you can explore that thinking with them, although it would be best to provide symptom-blunting treatment (such as opiates) along with intubation or central line insertions.

Cultural difference should be taken into account when discussing treatment options with patients and families, including religious preferences. African Americans are more likely to select aggressive treatment options and less likely to select hospice care than non-Hispanic whites.[29] Reasons cited for end-of-life preferences among African Americans facing these decisions include historical mistrust toward the healthcare system and the importance of spirituality.[29]

CODE STATUS

Do not resuscitate (DNR) is a medical order, like intubation, oxygen, or IV fluids. Although a DNR order can be written by the physician without the agreement of a surrogate or family member, the order must be in accord with state law and hospital policy. However, DNR status or other limitations of resuscitation should evolve directly from harmonious decisions reached at the family meeting. Code status orders should be written on every patient justifying the particular approach recommended. There is no ethical obligation to provide ineffective and burdensome care.[30] Families are often grateful when a physician compassionately recommends treating a patient with comfort measures rather than prolonging his or her suffering with nonbeneficial interventions.

The Center for Ethics in Health Care at Oregon Health & Science University developed the **Physician Orders for Life-Sustaining Treatment** in 1995.[31] Since then, the program has expanded to 13 states, with 21 more states currently developing similar programs. This brightly colored form allows a patient to effectively communicate his or her wishes and have those wishes documented as a transportable medical order that is valid across all healthcare settings (ED, nursing home, community). The Physician Orders for Life-Sustaining Treatment form is helpful in initiating conversations about treatment preferences and can prevent unwanted resuscitations by EMS.[31]

CONSULTATION OPPORTUNITIES

Palliative care consultation services are likely available at your hospital and should be used just as you would any specialist consultation. ED consultation can provide assistance when conducting a family meeting

or when access to an inpatient hospice or palliative care unit is needed. When symptom relief, medical decision making, or disposition and coordination of care are beyond your expertise or available time, a consult is appropriate. Notify the patient's attending physician of the consultation if time allows.[32]

TREATMENT/SYMPTOM MANAGEMENT

The most common targets of symptom management are pain control, dyspnea, nausea/vomiting, constipation, and agitation.

PAIN CONTROL

Acute and chronic pain are addressed elsewhere in detail (chapters 35 and 38, respectively). The biggest obstacle to aggressive pain management with opiates has been the fear of respiratory depression. Opioid dosing is reviewed in chapter 35, "Acute Pain Management," and is an essential skill in the practice of emergency medicine. It is also important to understand the progression of side effects from opioids, because these will serve as warnings to reduce the dose or delay the next dose of opioids. Respiratory depression is not a sudden occurrence, but instead is part of a progression that starts with sedation, somnolence, and then respiratory depression.[33] The safety of patient-controlled analgesic devices is predicated on this concept. A patient can be safely dosed and redosed until the pain is palliated, as long as level of consciousness is monitored. IV opiates reach maximum therapeutic levels and have peak effects/side effects at 6 to 10 minutes. **Therefore, IV pain medications can be safely redosed every 15 minutes until relief is reached if potential adverse effects are monitored.**

DYSPNEA

While identifying the cause of dyspnea and treating the underlying pathology may bring definitive relief, treatment should also be offered to palliate the symptoms. Although opioids have traditionally been withheld due to concerns about respiratory depression, opioids are beneficial in treating the agitation and anxiety provoked by dyspnea.[34] When treating breathlessness/dyspnea in an opioid-naïve patient, start with a dose of morphine 0.05 milligrams/kg IV, and monitor for sedation and hypoventilation. This is half of the starting dose of morphine when it is used to treat pain. Use a goal of maintaining a respiratory rate of at least 10 to 12 breaths per minute.

NAUSEA/VOMITING

Understanding the underlying cause of nausea can help identify the class of antiemetic drugs most likely to be therapeutic. Chemotherapy-induced nausea often responds to high doses of serotonin 5-hydroxytryptamine-3 antagonists such as ondansetron. Corticosteroids such as dexamethasone also may improve nausea from chemotherapy. Steroids can also improve symptoms caused by increased intracranial pressure and bowel obstruction from cancer. Dopamine antagonists such as haloperidol or droperidol are used for refractory nausea in the palliative care setting. Metoclopramide is excellent for the symptoms of diabetic gastroparesis or compression of the stomach due to tumor or ascites.

CONSTIPATION

Constipation is a commonly seen side effect in patients on opiates for pain control. Patients prescribed opiates need a concurrent bowel regimen, such as an osmotic agent (i.e., polyethylene glycol) or stimulant laxatives. A digital rectal exam is also important to rule out a suspected fecal impaction. When evaluating a patient for constipation, an abdominal radiograph can help to evaluate the amount of stool and lower the index of suspicion for bowel obstruction.

AGITATION

Patients with terminal illness may become agitated, with or without delirium. The causes of this agitation are multifactorial, including pain, effects of the terminal illness, anxiety, terminal restlessness, breathlessness, and mental anguish. The indicated class of medications varies depending on the situation but includes antipsychotics such as haloperidol, anxiolytics such as midazolam, and opiates such as morphine. There is no evidence that these palliative interventions hasten death.[35]

DISPOSITION AND COORDINATION OF CARE

Although the majority of patients consulted to palliative care services from the ED will be admitted to the hospital, outpatient treatment is always an option, depending on the resources available and the patient's needs.

OUTPATIENT PALLIATIVE CARE REFERRALS

Many hospitals and medical groups are accelerating the fielding of outpatient palliative care teams. Such teams are a resource for you, your patient, and family caregivers for appropriate care and follow-up, including measures that will prevent return ED visits, by providing effective care at home or in a nursing facility.[36] It can take a hospice referral to prevent readmission from a nursing home for a patient with advanced dementia, persistent vegetative state, or disabling stroke, so consider recommending hospice admission to the admitting physician to facilitate instituting palliative goals and care plans for the patient.

HOSPICE REFERRALS

Patients who qualify for the hospice benefit should be aware of these outstanding programs of care for the physically declining patient. Inpatient hospice units, where patients can be directly admitted, provide a good option for care and rapid ED disposition if available at your hospital.[37] Not all families are eager to hear the word "hospice," but such a recommendation should be phrased in a way that sends a message about your concern for the patient and his or her health status.

Patients are eligible for hospice care by Medicare regulations if they wish to take a palliative approach to their condition and if they have a prognosis that, in the judgment of two physicians, is likely ≤6 months, given the usual and natural course of the illness. Hospice referrals can be made from the ED for patients with qualifying debilitating illnesses, such as dementia with sepsis or stage IV cancer with poor performance status. Referrals also can be made for patients with clearly expressed prior wishes for comfort care should they sustain a catastrophic acute illness, such as those with an intracerebral bleed, infarcted bowel, devastating neurotrauma, or renal failure in the advanced heart failure patient, leading to multiorgan failure.

SPECIAL TOPICS

IMMINENT DEATH

It is common in the ED to receive a patient whose death is likely imminent. Such a patient has entered the process of multiorgan failure due to a disease such as sepsis, vascular crisis, uremia, or metastatic cancer. Vital signs indicate a patient in extremis; breathing may be irregular with pauses; a Foley catheter finds an empty bladder or only a small amount of concentrated urine. The assessment that a patient's death is imminent should be communicated to family members and the primary care physician. Agreement should be sought to offer comfort measures only. Opiate infusions plus intermittent or infused midazolam should be initiated and titrated to patient comfort. Delirium therapy can be directed to underlying cause (pain, fever) or, if not known or reversible, treated with 0.5- to 5-milligram doses of intravenous haloperidol. A total dose of 5 milligrams can produce a calming effect on a patient and, by extension, his or her family.

OPIOID DOSING AND ROTATION

In the opioid-naïve (hydrocodone, oxycodone, morphine, hydromorphone, and methadone) patient, a 2-milligram dose of IV morphine or

a 0.5- to 1-milligram dose of hydromorphone is a reasonable starting dose. This should be administered every 15 minutes until the pain is relieved by approximately 50%. Dose stacking will produce additional, cumulative effects when the doses have all been distributed to the μ-receptors. In the opioid-tolerant patient, the average 4-hourly dose of opioids already prescribed should be doubled for severe pain and increased by 50% for moderate pain (pain scale score of 4 to 6).[38] Smaller doses are required in elderly patients, those with a low body mass index, patients with unstable vital signs, or those with baseline severe cardiorespiratory compromise (e.g., chronic obstructive pulmonary disease) because such patients are at risk for hypoventilation.

CARE OF THE PREVIOUSLY DESIGNATED HOSPICE PATIENT IN THE ED

Occasionally, hospice patients may be directed to the ED. The three most common scenarios are (1) a hospice patient with an acute symptom crisis (2) a hospice patient who has a health concern unrelated to the hospice diagnosis; or (3) a patient who has previously revoked and signed out of hospice and presents to the ED.

A patient enrolled in hospice may be hospitalized under the care of hospice (general inpatient hospice) if there is an acute symptom crisis related to the hospice diagnosis. An inpatient setting can allow for more aggressive treatment of symptoms such as a pain crisis, new onset dyspnea, or other concerning symptoms. A patient may also be sent to the ED for a new medical issue unrelated to the hospice diagnosis. For example, a patient admitted to hospice for refractory heart failure may fall and fracture a bone. The fracture is unrelated to the hospice issue.

A patient may revoke hospice care at any time for any reason, and may present to the ED for aggressive treatment rather than a palliative approach. Occasionally a patient or family may panic and call 911 when there is a change in the patient's health status. The ED physician should care for the patient as appropriate. It can be very helpful to contact the patient's hospice agency. Someone should be available 24 hours a day and may be very useful in helping to clarify the patient's goals and disposition.

PRACTICE GUIDELINES

Clinical practice guidelines have been published by the Improving Palliative Care in Emergency Medicine project, and can be found at : http://ipal-live.capc.stackop.com/downloads/ipal-em-clinical-practice-guidelines.pdf

CHAPTER 300

Death Notification and Advance Directives

Lindsay Weaver
Cherri Hobgood

DEATH NOTIFICATION

Death notification is perhaps the most difficult, emotionally laden communication that physicians must perform. In most situations, the notification of death occurs during the first meeting of the emergency physician with the deceased patient's family. The notification often comes after extensive resuscitation efforts, creating a upheaval of emotion for the physician and ED staff leaving the team emotionally and physically exhausted.[1,2]

For survivors, death notification is a life-altering event. The language used during the communication, the venue, and the characteristics of the individual delivering the news create indelible memories for the family.[3]

EFFECTS ON SURVIVORS

Because death that occurs in the ED is frequently sudden, unexpected, and often violent, survivors can develop complicated bereavement and/or posttraumatic stress disorder.[4-7] Death notifications that provide limited or incorrect information about the death or occur in chaotic settings with limited support may exacerbate the grief reaction.[6] When properly performed, death notifications may mitigate substantial negative effects on surviving family members.[8] A well-delivered death notification can reduce the incidence of posttraumatic stress disorder in the families of patients who died suddenly, particularly notifications involving the loss of a spouse or the death of a child.[9]

EFFECTS ON PHYSICIANS

Physicians find death notification physically and emotionally difficult, with evidence of increased heart rate, heart rate variability, and cortisol levels immediately after the event.[10-13] Common emotional reactions in emergency physicians faced with the task of death notification are sadness (60%) and disappointment (38%), resulting in insomnia in 37%.[13] The cause of death, the patient's age, the presence of family, and the similarity to self are the most common reasons cited by emergency physicians for powerful impact of a recent death notification experience.[13,14] The need to rapidly switch between the cool emotional state required to lead a resuscitation and that of a warm empathic informant bearing difficult and tragic news may exacerbate this situation for the physician. The following factors also increase the stress level for the physician: racial and ethnic differences between the physician and the family, lack of a clear family leader, a nontraditional family (e.g., broken or blended), and situations in which the physician is personally emotional or cannot control his or her own reaction.[15]

Skillful death notification is a priority in emergency medicine practice.[2,3] Protocols to enhance communication skills for delivering bad news in the ED improve satisfaction of survivors.[16] The use of successful methods to communicate effectively with families may also mitigate physician burnout and reduce stress on ED staff.[17] First, providers must seek to understand and anticipate their personal emotions. Second, providers must learn to use compassionate communication methods in the delivery of this information. Third, providers must provide precise and complete information to families. Understanding and using compassionate methods of information exchange are critical to success. Providers must learn to recognize emotions, even when they are indirectly expressed, and allow these to be aired and displayed without judgment.[18]

GRIEV_ING© A METHOD FOR DELIVERY OF DEATH NOTIFICATION

The **GRIEV_ING©** mnemonic is a method for delivering concise and accurate death notification. This mnemonic provides physicians with an organized, sequenced approach to deliver the news of death (**Table 300-1**).[19] The structured organization of communication elements provides a coherent sequence of information to the family that is easy for providers to remember and ensures complete information transfer to the family.

G (GATHER)

As early as possible during the resuscitation, instruct ED staff, nursing, social work, or chaplain services to "gather" the family. Place the group in a quiet, private environment with few distractions. Assist the family with outreach to other family members or friends. **Gathering** allows the physician to deliver the information a single time, ensuring that

TABLE 300-1 The GRIEV_ING Mnemonic

G	Gather	Assemble the family in a calm, considerate place for the discussion. Gather as many family members as time allows. This mitigates the need for multiple episodes of information delivery. This step may be done by ED support staff.
R	Resources	Ask for any additional support available to aid the family (e.g., hospital chaplain services, family ministers, additional family and friends [especially if the survivor is alone], and, if needed, an interpreter).
I	Identify	Upon entering the room with the family: Identify yourself Identify the deceased patient by name Identify the family's state of knowledge. Are they aware of the situation, or will news of the death be unexpected?
E	Educate	In a concise manner, educate the family about the events that have transpired since the patient entered care. EMS should be included in this description. Fire a "warning shot" by stating that you bring "very bad news." Tell them the current state of their loved one.
V	Verify	Confirm the news of death. State emphatically that their family member is dead. *Be clear!* Use the words dead or died. Express your sincere condolences.
_	Space	Stop talking. Allow the news to settle and give them time to process the information.
I	Inquire	After a brief interval, ask if they have any questions. Then take the time to answer all of them.
N	Nuts and bolts	Provide additional information on: Organ donation. Funeral service that will collect the body. The deceased's personal belongings. Be sure to offer the family the opportunity to view the body.
G	Give	Give the family your card and contact information. Offer to answer any questions that they may have later. Return their call if contacted. Express condolences.

everyone hears the same information. This also allows the family to support each other during this most difficult time.

R (RESOURCES)

Ask if there are any needs, and work to collect any needed items. Ask about desires for a chaplain, minister, or priest who may provide support for the family. Obtain interpreter services if needed.

I (IDENTIFY)

Confirm that the deceased individual is properly identified. As the physician and staff join the family, they must clearly identify themselves and their role in the resuscitation. They must then clarify and confirm that the family is associated with the deceased individual. This can be done by saying the patient's full name, for example, *"Are you the family of Ellen Smith?"* Ask the family members to state their relation to the patient. Identify the next of kin. All discussion moving forward is between you and the next of kin. Face that person directly and ask permission to discuss the events of the day in the presence of the extended family and those gathered in the room.

Ask for a brief statement of the state of knowledge of the family regarding the patient's status. This final step is important because it allows you to begin your story of the day's events at the point their knowledge ends. This assists you in providing complete and essential information. Depending on the prior state of knowledge, the family will process information differently and at different rates. Your story will be very different for family members who witnessed a complete arrest versus those who last saw their family member healthy. The following is an example of an introductory narrative:

> *"Good Afternoon, my name is Dr. Hobgood. I am the attending physician taking care of Mrs. Ellen Smith. Are you the family of Mrs. Smith? Thank you for coming. Would you mind introducing yourselves and your relationship to Mrs. Smith? Thank you. Mr. Smith, do I have your permission to discuss Mrs. Smith's case in the presence of your family? Thank you.*
>
> *Before I begin, it would be helpful to understand what you already know about what is going on. Can you tell me what you know about what happened to Mrs. Smith today?"*

If possible, before you begin your discussion, ask the family to take a seat. You and your team should sit as well. Having the family sit reduces the risk of falling and sustaining injury during the notification. Position yourself across from the next of kin, preferably at eye level, and address the majority of the dialogue to that person. This posture creates open communication and allows you to assess understanding as you deliver the information. As a physician, a seated posture indicates that you are open to discussion and are willing to remain as long as needed.

E (EDUCATE)

From this point forward, your role is to educate. Your description of the event should begin at the conclusion of the family's knowledge of events. The narrative should be a focused summary of the scene, including any EMS response and the events in the ED. Communicate with nontechnical, nonmedical words; be thoughtful with your language and listen and watch for incomprehension. **Throughout your summary, on multiple occasions, provide the family with "warning shots," such as "this is difficult news," "the information that I am relating is bad news," or "the news that I am bringing may be difficult for you to hear."** These "warning shots" are a communication strategy intended to adjust the family toward the idea that they are about to learn something difficult and portend the disclosure of death. Carefully observe the family's reactions and those of the next of kin. If it appears that they do not understand the severity of events, reemphasize the finality of the news. Once the family appears to be following your story with clarity then you must disclose the death.

V (VERIFY)

Continuing your dialogue seamlessly, you will "verify" the death. You should unequivocally state that their family member has died. You must decisively affirm this fact clearly and say the words *death*, *died*, or *dead*. Provide your condolences on their loss. This may include language such as "I am sorry for your loss" or "I can see how difficult it is for you to learn of the death of your [mother, brother, sister, friend, etc.]." Without knowing the religious convictions of the patient and everyone present, it is inappropriate to say "they are in a better place" or that the events "were God's will."

_ (SPACE)

Now **stop talking.** Give the family some room to comprehend what you have just said. Even families who were anticipating the death will need a moment to register the information and compose themselves. Once you have allowed an adequate period of time to pass, you may move into the last three steps of notification.

I (INQUIRE)

The next phase, "inquire," is a very natural progression of the dialogue. Ask the family, "Are there any questions for me?" or "How can I help you?" In most cases, if the preceding steps have gone well and there has

been complete information transfer, then there will be no major questions. The family may ask if there was pain or suffering. This is a difficult question to answer. Maintaining your credibility is important and you can never state with full certainty that the patient did not suffer. If you did everything possible to mitigate pain and suffering while the patient was in the ED, you can reassure the family with this fact.

N (NUTS AND BOLTS)

The "nuts and bolts" are the necessary practical things that require attention. The physician has several key tasks at this stage. Inform the family that they will need to complete documents before they leave the hospital. You should also ask the family's wishes regarding autopsy and **organ donation** (see sections below). You should also offer the family the chance to view the body after it is appropriately prepped. This preparation includes removal of blood and secretions, closing the eyes, and covering the body except for the hands and face. It is fine to remove tubes and catheters as long as it is not a medical examiner's case. If the patient is disfigured, cover the wound as best as possible with towels or bandages. Sometimes it is impossible to completely cover wounds, particularly if they are on the face. You should warn the family that there is trauma or if tubes must be left in place and that these sights may result in a lasting memory of their loved one. Let them know that you are willing to take them to the bedside but that these wounds will be difficult for them to see. In all situations, it is best to have the family members seated.

G (GIVE)

The concluding step in the notification process is "give." During this period, you give the family your name and, if possible, your business card. Inform them that if they call you may not be immediately available but that you will contact them after you receive the message. If they reach out to you, be sure to return the call. Typically, calls are made to provide additional clarity or to thank you. Express your condolences and then close the encounter.

WHAT REACTIONS TO EXPECT

Responses to loss vary greatly. Families often describe themselves as numb immediately after learning of the loss. They have difficulty processing information and making decisions. Following the initial shock, the family may experience denial, anger, and/or guilt.[20] Denial is most typically expressed as incredulity and is thought to be a defensive mechanism, because it permits additional time to comprehend the new situation. Your role is to understand this condition and allow time and, if needed, provide additional information to confirm death. Seeing the body of the deceased may help the family to accept the truth. Anger is not unusual. Be prepared to react in a supportive manner rather than responding with anger or becoming defensive. If the family or individuals react with charges of negligence or malfeasance on the part of the care team, keep calm and provide support in a nonjudgmental way. These are typically expressions of grief and misplaced guilt.

The survivors' culture is an important predictor of the types of emotional responses that may be exhibited. These may range from no expression of emotion to wailing and hysterical collapse. Allow these expressions and remain calm and respectful. If you want to touch the grieving individual, the shoulder is the most suitable location.

SPECIAL SITUATIONS

LONG-DISTANCE NOTIFICATION

Occasionally, death notification must be made to survivors over the telephone. The GRIEV_ING protocol steps are still appropriate. Ask the survivor to "gather" other family members to join on the phone. If the survivor is alone, ask the survivor to get "resources," such as friends, relatives, or personal clergy, and call you back. At that time, proceed with the rest of the steps of in-person notification. After notification, the survivors may wish to come to the hospital to attend to the "nuts and bolts." Recommend that they do not drive alone and assure them someone will be available to answer all of their questions.

AUTOPSY AND MEDICAL EXAMINER CASES

The Joint Commission requires that physicians ask families if an autopsy is desired. Autopsies are voluntary and serve to clarify premortem diagnoses or aid in the diagnosis of new diseases. Autopsies do not prevent an open-casket funeral. If there are religious concerns, a chaplain can help. Local and institutional policies regarding autopsy billing and payment vary; however, if the family will be charged for the autopsy, they should be informed.

Depending on state laws, certain deaths must be referred to the medical examiner or coroner for investigation and/or autopsy. Deaths the medical examiner may choose to investigate are death due to trauma, homicide, suicide, or medical procedures; death from a disease that is a public threat; death of a person in custody or incarcerated; pediatric and sudden infant death syndrome deaths; and deaths that are unexpected and unexplained. An autopsy may or may not be performed in these cases, but the family is not allowed to refuse investigation or autopsy by the medical examiner if that is necessary. Families are still permitted to view the body, but they are discouraged from removing mementos or disturbing the body until after the medical examiner investigation. **Do not remove resuscitative lines and tubes in a medical examiner case.** Designation or the death as a medical examiner case does not prevent organ donation, but the consent of the medical examiner is required before organ procurement.

ORGAN DONATION

Currently >123,000 patients are on the national transplant list, and 21 people die daily waiting for a transplant.[21] The Joint Commission requires physicians to contact an organ-procuring agency for all deaths in the ED. The kidney, heart, liver, lungs, pancreas, and intestines are the most needed organs by critically ill patients. Tissues such as cornea, bone, skin, tendon, fascia, cartilage, sphenoid veins, and heart valves are also harvestable.

Traditionally, the family consent process has been the largest single obstacle to obtaining organ donation. The best predictor of consent is the family's initial reaction to the request for donation. Currently, all 50 U.S. states have first-person consent and registry laws associated with the Department of Motor Vehicles.[22] These laws increase families' satisfaction and likelihood of consent for organ donation.[23] Trained organ procurement specialists should manage conflicts with the family disagreeing with the deceased's stated wishes. They are trained in this type of conflict resolution and are aware of each state's laws. Physicians can provide information while allowing the coordinator to initiate and lead the conversation about organ donation. The role of the ED physician is to notify the family of the grave prognosis or death of the patient and remain supportive and available to the family.

WITNESSED RESUSCITATION

Emergency physicians should consider developing programs to educate staff and develop procedures to routinely invite family members to observe resuscitation in the ED.[24-26] Family-witnessed resuscitation gives family members closure and comprehension of the patient's situation and grave condition.[24] Emergency medicine providers may be concerned about the family interfering with resuscitation efforts, patient confidentiality, increased litigation, distraction from resuscitation efforts, wrongly prolonging the code, and increased stress for the family and staff members.[24] However, many of these concerns have been found to be unwarranted. In one study, family members who witnessed CPR had fewer symptoms of posttraumatic stress disorder and less complicated grief 1 year after the death.[27] It is essential, however, to consider the safety of the healthcare team. Therefore, family members should be screened for appropriateness to attend the resuscitation and escorted out if safety becomes a concern.[28] A staff member should prepare the family

members for what they may see during the resuscitation and then remain with them to offer support, answer questions, and explain procedures.[24] Involving the family in the resuscitation may allow the emergency medicine provider to establish a relationship with the survivors and facilitate in death notification.

PEDIATRIC DEATH

Recognizing that the death of a child in the ED is uniquely different from other ED deaths, the American College of Emergency Physicians and the American Academy of Pediatrics addressed challenges by developing a set of principles.[28] They recommend ED physicians provide "personal, compassionate and individualized" support through a "family-centered and team-oriented approach." [28] The family-centered approach begins with allowing the family to be with the child during the resuscitation. After the child's death, the family should be encouraged to stay with the child. The healthcare team should respect families' "social, religious, and cultural diversity."[28] Many pediatric deaths are medical examiner cases. Therefore, tubes and lines may need to be kept in place, which may affect what the family can do. The team-oriented approach provides appropriate resources, including organizations and individuals that may assist families, and a coordinated response to the child's death.[28] In more than one third of pediatric deaths, an autopsy provides information of undiagnosed findings and complications.[28] Knowledge of an organic, identifiable cause of death may help to alleviate guilt, offer a source of comfort to the family, and help with future family planning. It may also provide a sense of solace to the family to know that the information gained is useful to help prevent the future suffering of other children. Organ donation may also provide a source of comfort. The ED physician should notify the child's pediatrician concerning the circumstances of the child's death so that the pediatrician can follow up with the child's family and siblings.[29]

ADVANCE DIRECTIVES AND PHYSICIAN ORDERS FOR LIFE-SUSTAINING TREATMENT

Only 20% to 30% of American adults have an advance care directive.[30,31] The traditional "do not resuscitate" (DNR) form facilitates the patient's or surrogate decision maker's refusal of cardiopulmonary resuscitation should the patient sustain a cardiac or respiratory arrest. However, DNR forms generally do not outline the patient's treatment wishes for a life-threatening condition. [30] The inadequacy of DNR forms led to the development of Physician Orders for Life-Sustaining Treatment forms, including other states' iterations (e.g., Medical Orders for Life-Sustaining Treatment, Physician Orders for Scope of Treatment). The Physician Orders for Life-Sustaining Treatment form is meant to translate a patient's end-of-life wishes into actionable physician orders. Forms may include directives concerning the patient's code status; desire for further medical interventions including hospital transport, intubation, IV fluids, and comfort measures; desire for antibiotics; and desire for artificial nutrition. Forms are transportable (authority transferred from the patient's living situation to the ED) and may be brought into the ED from extended-care facilities, from patients' homes, and with EMS.[32] These directives should be honored in the ED.

WITHDRAWAL OF LIFE-SUSTAINING TREATMENT

At times, it is appropriate to move from aggressive life-sustaining treatment to comfort measures for patients who are in imminent death in the ED. The patient and family should agree that continued aggressive therapies are futile. Discuss possible symptoms and outcomes. For example, patients may display restlessness, dyspnea, or air hunger that can be upsetting to the family. Explain that medicine will be given to treat symptoms and alleviate suffering. Explain that the time course is unpredictable. Encourage the family to stay and care for the patient and to notify a nurse and physician for concerning symptoms.

When possible, move the patient to a room that is quiet, private, secluded from high-traffic areas, with low lighting, and of sufficient size to accommodate chairs for the family. Offer to call the chaplain. Turn off or silence all alarms in the room, and remove any unnecessary equipment from the patient, such as cardiac leads, blood pressure cuffs, cardiac pads, and oxygen saturation monitors. Comfort treatment is further discussed in chapter 299, "Palliative Care."

CHAPTER 301

Prison Medicine

Stephen H. Boyce
Richard J. Stevenson

INTRODUCTION

An established principle in civilized societies is that prisoners are entitled to the same level of medical health care as the law-abiding community.[1] Other ethical considerations involve the issue of prisoners' human rights.[2] The exact medical service provided will vary between countries and, in the United States, varies between states.[2] The concept of prison health care in general is the subject of debate and outside the remit of this chapter.

EDs may have to provide emergency health care to prisoners. Prisoners could be inmates of a local prison or recently arrested and detained in police custody. Many prisons have internal medical services of varied capability. There may be a ward or bedded observation unit for the management of uncomplicated medical conditions. Nursing staff are on duty for the full 24 hours working on a shift pattern. Doctors are present mainly for normal working hours, providing night, weekend, and holiday coverage on an on-call basis. Facilities will vary from site to site but may include radiography, a minor surgical treatment room, and consulting rooms for ambulatory care visits by local specialists. On-site or frequent access medical specialties can include a general prison medical officer(s), psychiatrists, psychologists, alcohol and drug abuse counselors, and social workers.[3]

DEMOGRAPHICS OF THE PRISON POPULATION

The population of a prison is not representative of the general population; typical characteristics are listed in **Table 301-1**.[4,5]

Within the prison, there exists a pool of chronic disease and drug misuse that can lead to significant morbidity and acute medical problems.[3] Disease profiling of prison inmates exhibits higher prevalence rates of certain diseases than those reported for the general population. The most common disease groups are infectious diseases (hepatitis, tuberculosis, human immunodeficiency virus/acquired immunodeficiency syndrome), diseases of the circulatory systems (ischemic heart disease, hypertension), diseases of the respiratory system (asthma, chronic obstructive pulmonary disease), and musculoskeletal and psychiatric conditions.[6] A study

TABLE 301-1 Prisoner Characteristics

Male
Age 15–44 y
Racial or ethnic minority (~60%)
Poorly educated
Lower socioeconomic classes
Smoker
Alcohol and/or drug misuse
Mental health problems (~70% carry ≥2 mental health disorders)
Chronic disease

of prisoner mortality (while incarcerated) attributed the most common causes of death to ischemic heart disease, followed by cerebrovascular disease, neoplasms, and pneumonia.[7] Upon release, former prisoners are at significant risk for suicide or accidental drug overdose within the first year.[8] With the prison population increasing, in particular elderly prisoners and those from an ethnic minority group,[9,10] the prevalence of chronic disease rises, increasing the likelihood of acute medical problems.

Persons in police custody are often intoxicated with alcohol and/or drugs. Common presenting complaints are injuries (sustained prior to or during arrest), exposure to police incapacitants (handcuffs, tear gas or pepper spray, electronic weaponry, batons), complications of substance misuse, and acute behavioral disturbance.

The demographics of police detainees are similar to those in prison; important differences to note are a higher incidence of females, and around 30% of detainees are not registered with a primary care doctor.[11,12] Adherence to treatment for long-term medical and psychiatric illness is very poor among those in police custody.[12]

SPECIFIC MEDICAL ISSUES

ACUTE MEDICAL EMERGENCIES

Prison medical emergencies should be managed according to standard treatment guidelines and protocols. If the prisoner requires admission after treatment, the prison authorities must make the necessary security arrangements at the facility of presentation or the referral location (**Table 301-2**).[3]

TRAUMA

Prison is a violent place. Violence among inmates is common. Minor injuries may be treated at the prison medical center. In one study, 18% of prison-related visits to the ED were due to violence.[3] Penetrating stab wounds, head injuries, fractures, soft tissue injuries, and wounds may result from violence. In severe cases, trauma resuscitation, emergency surgery, and admission may be required.

Injuries Associated with Police Restraint Persons in police custody often attempt to resist arrest; the police then may deploy tactics and equipment to aide in restraint and control. As a result, a variety of injuries may occur, including skin wounds, minor head injury, and joint dislocation.[13] Injuries secondary to a handcuff application include neuropathy (in particular, the superficial branch of the radial nerve), and fractures of the ulna styloid. The use of a baton commonly results in soft tissue bruising; however, lacerations and fractures may occur.

Conducted electrical weapons (TASER®) have two methods of application: "drive-stun," whereby direct contact to the skin by the device is used, and "shooting," whereby two small darts attached to wires are fired into the skin to deliver the electric current. Complications associated with the use of such devices relate primarily to dart penetration (e.g., the trachea,[14] brain,[15] eye,[16] and chest wall), resulting in pneumothorax.[17] The proarrhythmogenicity of a conducted energy weapon is subject to debate[18,19]; however, there has been a report of atrial fibrillation following its use.[20] Clinical management of individuals subjected to such devices is aimed at treating any complications secondary to penetrating injury. Electrocardiograms are advised, and for patients with pacemakers or internal defibrillators, device interrogation is warranted. Finally, the predisposing condition necessitating the requirement for the use of a conducted energy weapon should be assessed and, if necessary, treated.

DRUG ABUSE

It is estimated that 70% to 80% of prison inmates have been involved in some form of drug abuse before detention, with one-fifth being injecting opiate abusers.[3,21] Many inmates are on drug rehabilitation programs and maintained on regular doses of methadone or a similar opiate substitute. The main problem for emergency care is the provision of adequate analgesia. Due to the high level of opiate tolerance, standard doses of opiates (morphine, hydromorphone) may produce no analgesic effect. This can lead to high doses of opiate being given before producing an adequate analgesic effect.[22] If a prisoner is placed on a controlled opiate detoxification program sustained by the use of naltrexone, a long-acting opiate receptor blocker, opiate analgesia will have no effect regardless of the dose given.[23] An alternative form of analgesia will be required (e.g., nonsteroidal anti-inflammatory drugs, which may or may not be effective). Ketamine is another option for pain relief.

Concealed Drugs A person detained in custody may be suspected of concealing drugs in the rectum or vagina. Within the United Kingdom, unless the patient consents to the examination and removal of any such substances, any action is against the policy of the British Medical Association, even if the practitioner is protected legally by a warrant issued from the appropriate jurisdiction.[24] Legal practice may differ between countries. If the patient's ability to make an informed decision regarding their health care is compromised, then removal of drugs from the body is warranted should signs of drug toxicity be evident.

PSYCHIATRIC CONDITIONS

Within the prison population, there is a high prevalence of psychiatric illness. The most common is a personality disorder, found in 65% of men and 42% of women.[6] The main ED contact with psychiatric problems will be related to deliberate self-harm and personality disorders, manifesting as manipulative behavior, fictitious illness, and Munchausen-type behavior. Other presentations include deliberate insertion of foreign bodies or alleged ingestion of objects or substances.

EXCITED DELIRIUM SYNDROME

Excited delirium is a condition that has been formally recognized by the American College of Emergency Physicians as "a unique syndrome which may be identified by the presence of a distinctive group of clinical and behavioral characteristics that can be recognised in the pre-mortem state."[25] Once the domain of the forensic literature, recognition of excited delirium in the premorbid state is increasing.

Attempts to apply strict diagnostic criteria are hampered by a lack of quality research. By the very nature of the presentation, patients are in extremis both mentally and physically. **Table 301-3**[25] reports the frequencies of the presenting signs and symptoms.

TABLE 301-2 Common Clinical Conditions Seen in the ED[3]

Myocardial infarction
Acute coronary syndrome
Cerebrovascular accident
Exacerbation of chronic obstructive pulmonary disease
Acute asthma
Pneumonia
Overdose
Diabetic ketoacidosis
Alcohol liver disease
Deep venous thrombosis
Acute abdomen

TABLE 301-3 Features of Excited Delirium

Features	Frequency, % (95% Confidence Interval)
Increased pain tolerance	100% (83–100)
Tachypnea	100% (83–100)
Sweating	95% (75–100)
Agitation	95% (75–100)
Tactile hyperthermia	95% (75–100)
Police noncompliance	90% (68–99)
Lack of tiring	90% (68–90)
Unusual strength	90% (68–90)
Inappropriately clothed	70% (45–78)

The pathophysiology underlying excited delirium has yet to be fully elucidated; a background of stimulant drug use (predominantly cocaine) or, rarely, psychiatric illness is a consistent feature. Individuals exhibit confusion and agitation. Attempts to reason with patients and transport to medical facilities are met with resistance and aggression, often necessitating physical restraint. It is then observed that the detainee has pronounced tactile hyperthermia, struggles violently, and suffers cardiac arrest, from which successful resuscitation is rare. Severe metabolic acidosis, bradycardia, asystole, and pulseless electrical activity are the predominant preterminal findings.[26]

Treatment of excited delirium syndrome is predominantly aimed at reducing agitation. This can prove problematic, with issues regarding the safety of medical and law enforcement personnel, administration of parental medications, and the relative urgency necessary to reduce mortality. Physical restraint should be for as short duration as possible to reduce agitation and muscle activity–driven heat production. Intravenous access may prove difficult, and the intramuscular route for sedation is a viable, although slower onset, alternative.

Pharmacologic sedation is recommended: benzodiazepines (first line), antipsychotics (should not be used if long QT syndrome is suspected), and the dissociative anesthetic ketamine.[27] The choice of drug used will depend on user experience and route available; combination therapy allows reduced doses of each class of drug, minimizing the side effect profile.

As with any sedation, the ability to manage sudden loss of the patient's airway and facilities for resuscitation must be available. In some cases, rapid sequence induction of anesthesia may be necessary due to the large doses of sedation required and for definitive airway protection.

Supportive treatment is vital for patients with excited delirium, including cooled IV fluids, whole-body cooling (antipyretics are ineffective), and treatment of any electrolyte disturbance. Hypoglycemia, hyperkalemia, and rhabdomyolysis may be encountered. Metabolic acidosis is invariably present and may improve with fluid administration and cooling.

HEPATITIS C

Hepatitis C prevalence in prisoners is higher than in the general population, with studies demonstrating a prevalence of 25% to 39%.[6,28,29] Contrasting the range of values for hepatitis C prevalence within the community against the prevalence of hepatitis C in prisons, there is a theoretical risk of a several hundred–fold greater chance that a prisoner may be a hepatitis C carrier compared with a member of the general public. This raises issues regarding possible needlestick injuries or contamination with infected body fluids. All emergency personnel must be aware of the increased risk of contracting hepatitis C infection when dealing with prisoners and exert extreme vigilance in their clinical procedures.

SPECIFIC CONSIDERATIONS

SAFETY OF STAFF AND PATIENTS

The management of even one prisoner, disruptive or otherwise, will interfere with the running of the ED. The hospital has a duty to ensure that members of staff are not placed in undue danger. If possible, the management of the prisoner should be expedited to minimize disruption. This, in turn, allows the responsible officers the opportunity to return the prisoner to a more secure environment as soon as possible. Staff may be exposed to the risk of violence, but this should be minimal due to the use of restraints by prison officers. The presence of a restrained prisoner may alarm other patients or relatives within the ED, as they may erroneously assume the prisoner is either violent or dangerous. Examining the patient in a quieter area of the ED can help minimize other patients' natural anxieties.

USE OF RESTRAINTS

Prisoners will be restrained when arriving at the ED by virtue of the fact that they are in state custody. The physical mechanism of restraint will be variable but can include handcuffs, hand and foot cuffs with connecting shackles, or handcuffs with a chain attached to the prison officer (escort chains). Many doctors feel uncomfortable in dealing with prisoners who are shackled and are either unaware of the ability or unwilling to approach this issue with the prison officers.[30]

Legislation regarding the shackling or restraint of prisoners will vary between states and countries. In Scotland, for example, the prisoner must remain restrained to two prison officers at all times in the ED and throughout the course of the hospital admission period. Law governs the situations where the removal of restraints is acceptable. Restraints can be removed if the patient is unconscious, anesthetized, being resuscitated, or for "other good medical reasons."[3]

Cases have been highlighted in which female prisoners have given birth while restrained with chains, raising issues regarding the welfare and human rights of prisoners. Even when restraints are removed, the prison officers must maintain a line of sight with the prisoner and must be present at clinical emergencies such as resuscitation. Staff may be uncomfortable working with prison officers in close proximity, and restraints can present a mechanical obstruction to treatment.

Prisoners are not restrained in all countries. With the issue of human rights being raised, the British Medical Association produced a set of guidelines for doctors dealing with prisoners in the hospital setting.[31] The main points raised in these guidelines include advising doctors that they can request the prison officers to remove restraints to examine a patient fully and facilitate treatment, unless there is a high risk of escape or violence. In hospitals that treat prisoners on a regular basis, an area of the department should be modified into a secure area for examination. No blanket policy can exist, and all prisoners should be managed on a case-by-case basis.

However, these concerns must be balanced with the state's public and legal responsibility to carry out a prison sentence and ensure the safety of the general public. Management of prisoner patients requires consultation at a local level between the hospital and prison authorities.

MEDICAL CONFIDENTIALITY

Prison officers will be present at the consultation and during treatment. This raises issues regarding the doctor–patient relationship and medical confidentiality. There is a difficult balancing act between confidentiality for the prisoner and the legal responsibility to protect the public. In cases of nonviolent or minor offenders, the police or prison officers may step outside the room to allow a private consultation to take place. However, in the case of serious criminal offenses, the need for public safety will override medical confidentiality. A prisoner may have the right to challenge this in court, an argument best reserved for the legal profession.

COMMUNICATION

If prisoners are referred to the ED by a prison medical officer, they should be accompanied by a referral letter detailing the nature of the complaint, past medical history, medication, and whether the prisoner is high risk for violence. A medical chart from the prison will occasionally accompany the patient. If insufficient information is delivered with the prisoner, contact the prison medical officer. Once the consultation is complete, the prison medical officer should be advised of the outcome and any investigation results with electronic, paper, or telephone communication, as appropriate. In certain situations, liaison between the medical teams may avoid admission because the prison ward may have the facilities to handle continuing care.

When discharging from the ED back to the prison or police custody suite, consideration for the safety of the detainee is warranted. Police custody is no substitute for observation or administration of treatment for individuals who would otherwise be admitted to a hospital.

CHAPTER 302

Military Medicine

INTRODUCTION

Care for combat casualties is somewhat different from care for civilian trauma casualties, even though many civilian trauma management principles apply, and conversely, some military techniques have been adapted to the civilian sector. The principles of military medical care are applicable to care in civilian mass casualties, in remote settings, for tactical medicine, and in bioterrorism incidents. Civilian emergency medicine should regularly follow military medical advances and adapt as appropriate.

Advanced trauma life support approaches are well applied in a hospital setting, but in combat, how do you function without ancillary staff? What do you do without ready access to a surgical team? How will you manage in the dirt, at night, while engaged with enemy forces? Simple tasks such as obtaining vital signs or auscultating lung sounds are very challenging. Chapters 7, "Bomb, Blast, and Crush Injuries," 8, "Chemical Disasters" and 9, "Bioterrorism," discuss many conditions relevant to the combat situation. **Table 302-1** lists the roles of medical care for combat casualties.

EQUIPMENT

Combat situations require a properly supplied aid bag. A blood pressure cuff and central-line kit have little use on the battlefield. Pack one item that serves multiple purposes, rather than two or three items with limited applications. For example, a cravat can be used as a standard field dressing, pressure dressing, or tourniquet or to hang an IV bag, cover a face as a dust mask, protect against sun exposure on head or neck, filter parasites from water, or even clean weapons.

See **Tables 302-2 and 302-3** for examples packing list for aid bags. Not all items will be needed or packed in one bag; the nature of the mission, duration, terrain, weather, and other factors guide the packing list. Consider maintaining two or more different packing lists for different purposes (i.e., one for battle injuries and one for nonbattle injuries).

Have a copy of the nine-line medical evacuation request secured to the radio, train on your personal equipment, maintain it, and pack smartly to ensure easy access to critical items.

TACTICAL COMBAT CASUALTY CARE

The body of highly developed, standardized, prehospital combat trauma guidelines designed to address preventable causes of death is known as Tactical Combat Casualty Care (TCCC), which is organized into three phases of care: care under fire, tactical field care, and casualty evacuation.

TABLE 302-1 Military Roles of Medical Care

Role 1: self/buddy aid, nonmedical unit level combat lifesaver, medic or corpsman aid up to battalion aid station
Role 2: brigade or division level, medical companies/battalions, support battalions, forward surgical teams, PRBCs, limited x-ray and lab capability, damage control care for evacuation to next role
Role 3: corps level, combat support hospitals, in-theater military treatment facility (MTF), comprehensive stabilizing care for evacuation out of theater
Role 4: definitive care, ultimate treatment capability, full rehabilitative care, tertiary care MTF, typically located in continental United States or comparable out-of-theater safe havens

Abbreviation: PRBCs = packed red blood cells.

TABLE 302-2 Trauma Pack Suggested Packing List

Combat Application Tourniquet (Composite Resources, Rock Hill, SC) or equivalent (× 4–5) or Delfi EMT tourniquet (Delfi Medical Innovations, Inc., Vancouver, Canada) (× 1)	3-inch self-adherent elastic roll dressing × 4 (open package and pre–dog-ear exposed end for rapid utilization)
Examination gloves, heavy duty, four pairs	Hemostatic bandage (4 × 4 bandage) × 4
Protective ballistic eye wear	Large abdominal dressing (can also be used to stabilize flail chest segments)
Cervical collar, adjustable	Surgical skin stapler† (for rapid hemostasis of scalp lacerations)
Nasopharyngeal airway with water-based lubricant packet × 2	IV fluid administration kits × 2–3
Hypothermia prevention and management kit	500 mL Hextend × 2
Cricothyrotomy kit*	500–1000 mL colloid or crystalloid IV solution (250–500 mL bags)
Betadine swab	16-, 18-, and 20-gauge IV catheters
No. 20 scalpel	IV administration set, 10 drops per mL
Tracheal hook	Penrose drain or other tourniquet
No. 5 or 6 Shiley tracheostomy tube	Betadine wipe × 2
Securing tape or strap	Benzoin swab × 2 (aids dressing adherence in the presence of sweaty or bloody skin)
Endotracheal intubation kit†	
AA battery laryngeal scope handle	1-inch tape, short roll
Physician's preference of laryngeal scope blade	Clear IV site dressing (Tegaderm)
7.5-mm endotracheal tube	2 × 2-inch gauze
Stylette	5-mL syringe (for external jugular vein placement)
10-mL syringe	Saline lock
Carbon dioxide colorimetric indicator or esophageal bulb indicator	1 m of string, 550 paracord or cravat prefolded and taped (to expediently hang IV bag)
Carabiners/D ring × 2	Thermal angel or equivalent fluid warmer
Benzoin swabs	IO infusion system (sternum IO device)
1-inch tape	Pressure infuser bag
Oropharyngeal airway	Combat wound prophylaxis kit (3 medication pack)
Skin marker (to mark centimeters at the teeth on cheek to confirm tube placement during transport)	Wound antibiotic of choice × 3 doses (see section on antibiotics for options)
	10-mL sterile water or normal saline vial × 3
Adult bulb suction device such as Suction Easy (Remote Medical International, Seattle, WA)	10-mL syringe × 3 21-gauge needle 1.5 inch long × 3
Adult bag-valve mask	Gatifloxacin, 400-milligram tablets × 6
3 inch long 12-gauge catheter × 2 (decompressing tension pneumothorax in large adults)	Rocephin, 1-gram vial × 1 (CNS wound prophylaxis) Combat wound pain control kit
Adhesive one-way flutter valve/seal × 2–4 with benzoin swabs (sucking chest wound dressing with valve)	Cartridge unit (syringe holder to create a drug delivery system) Morphine, 10-milligram cartridge ampules × 5–10
Finger pulse oximeter	Nalbuphine hydrochloride, 10-milligram cartridge ampules × 3†
Stethoscope	19-gauge filter needles × 3†
Trauma shears	1-mL syringes × 3†
Field tube thoracostomy kit†	21-gauge needle 1.5 inch long × 3†

(*Continued*)

TABLE 302-2 Trauma Pack Suggested Packing List (*Continued*)

1% lidocaine with epinephrine, 10-mL vial	Acetaminophen, 500-milligram capsules × 10
10-mL syringe	Narcotics accountability paperwork with pen
1.5-inch 21-gauge needle	Cravat bandage × 3
Sterile gloves	SAM (structural aluminum malleable) splint (SAM Medical Products, Portland, OR) × 2
Betadine swab × 3	4-inch elastic wrap × 2
No. 10 scalpel	Gastric sump tube with water-based lubricant packet
Large curved Kelly forceps	60- or 35-mL syringe
32F–36F thoracostomy tube	Light-emitting diode headlamp with green lens filter (red filter will "wash out" blood)
Heimlich chest drain valve (or Penrose drain)	Mass casualty patient cards
0 silk (30 inches long) on a straight needle (needle driver not required to secure tube)	Red, green, blue, yellow safety light sticks (five of each)
3 × 18-inch Vaseline gauze	Fine-point indelible marker
4 × 4-inch gauze × 2	Fox eye shield
Benzoin swabs	Small sharps container
3-inch 3M Soft Cloth Surgical tape (3M, St. Paul, MN), one roll (appears to stick to bloody, sweaty patients better than most)	Large burn dressing (consider a roll of plastic cling wrap) Compact casualty blanket
6-inch Israeli Battle Dressings (First Care Products, Lod, Israel) × 4	Folding litter†
Kerlix large roll dressing (Covidien, Mansfield, MA) × 4–8	Compact traction splint†

*"Kits" are packaged together as a functional unit in a resealable plastic bag or vacuum sealed with quick open tabs.
†Optional items.

PHASE 1: CARE UNDER FIRE

This first phase of care occurs when the patient and care provider are under effective enemy fire. The medical actions taken are extremely limited: protect the casualty and move him or her to safety. The urge to tend to a casualty must be tempered by situational awareness: return fire, and secure the site before tending to casualties. The application of a tourniquet for massive bleeding is the only intervention typically performed in this phase (also see "Tourniquets," in chapter 254, "Trauma in Adults"). Needle decompression, fluid resuscitation, and cervical spine immobilization are not performed when under fire.

TABLE 302-3 Drop-Down Leg Pouch Suggested Packing List

Light-emitting diode headlamp with green lens filter
Combat Application Tourniquet (Composite Resources, Rock Hill, SC) or equivalent × 2
Examination gloves heavy duty (one pair)
Nasopharyngeal airway 32F
Compact percutaneous cricothyrotomy device (Lifestat device; French Pocket Airway, Inc., New Orleans, LA)
Trauma shears or rescue knife
Adhesive one-way flutter valve/seal × 2 with benzoin swabs
12- or 14-gauge 3 inch long catheter
6-inch Israeli Battle Dressing × 2
Kerlix Large Roll dressing (Covidien, Mansfield, MA) × 2
3-inch 3M self-adherent elastic roll dressing (open package and pre–dog-ear exposed end)
1-inch medical tape, one roll
9-line medical evacuation card

TOURNIQUET APPLICATION

With massive hemorrhage in a combat setting, a tourniquet is the first-line intervention.

Casualties with tourniquets applied before the onset of shock have a survival rate of 94%, but those with tourniquets applied after shock develops have a survival rate of 17%.[1,2]

There are a number of basic considerations for tourniquet application.[3] A wide tourniquet (at least 1.5 inches wide) causes less soft tissue damage and is more comfortable for the patient. To control hemorrhage from a large vessel, a tourniquet must have a windlass to gain a mechanical advantage when tightening. Tourniquets without a windlass cannot attain sufficient force to stop arterial bleeding. In combat, we use a tourniquet that can be applied with one hand for self-treatment.

Place the tourniquet about 2 inches proximal to the wound. Tighten to greater than arterial pressure, because tightening that exceeds venous but not arterial pressure may increase bleeding. Apply the tourniquet until the distal pulse disappears. If no distal pulse is present on initial evaluation, apply the tourniquet with a force estimated to be greater than the systemic blood pressure. If placement of a single tourniquet does not control bleeding, place a second tourniquet immediately adjacent and proximal to the first.

The U.S. Army Institute of Surgical Research (http://www. usaisr.amedd.army.mil) has identified three 100% effective tourniquets[4]: the Combat Application Tourniquet® (CAT) (Composite Resources, Rock Hill, SC), the Delfi EMT Pneumatic Tourniquet (EMT) (Delfi Medical Innovations, Inc., Vancouver, Canada), and the Special Operations Forces Tactical Tourniquet (SOFTT). The CAT and SOFTT are both strap tourniquets that use a built-in windlass as the mechanism for tightening (see Figures 254-1 and 254-2). Of these two strap-type tourniquets, the CAT is less painful, easier to use, smaller, and lighter than the SOFTT (59 grams vs 160 grams). The EMT (see Figure 254-3) is wider, less painful, and less likely to induce nerve damage than the strap tourniquets. The EMT weighs 215 grams and, when packaged, is similar in size to the SOFTT. The CAT tourniquet is standard issue to U.S. military personal. The EMT tourniquet is issued for medical evacuation vehicles and role I to III medical facilities. All of these tourniquets are available through the military medical supply system (http://www.usamma.army.mil/).

POSTTOURNIQUET CARE

The safe time limit for tourniquet application and the point at which limb loss becomes inevitable have not been determined. Tourniquets are routinely left in place for up to 2 hours in the operating room, and this is the basis for the recommendation to remove a tourniquet within 2 hours, situation permitting. It is certain that for every minute of tourniquet application time, the greater is the chance for permanent damage.[5] At 6 hours with a tourniquet in place, it is probably best not to remove it; at this point, the release of potassium, lactate, myoglobin, and other toxins from a severely acidotic limb into the circulation would likely cause more systemic harm than benefit. There are, however, several cases of limb salvage with tourniquet times greater than 6 hours.[6] Additionally, keeping a limb with tourniquet cool, but not freezing, may extend the safe application time substantially.

A tourniquet is a temporizing measure. The next step is to convert the tourniquet to an effective pressure dressing, using direct pressure and a basic gauze roll and elastic wraps and/or hemostatic agents, if required. A knee or hand can apply additional pressure to the bleeding site. Once an effective pressure dressing is applied, release but **DO NOT REMOVE** the tourniquet. If no bleeding occurs, leave the tourniquet in place but with all pressure released. If bleeding recurs, retension the tourniquet to control bleeding.

PHASE 2: TACTICAL FIELD CARE: THE PRIMARY SURVEY

This phase begins once the patient and provider are no longer under effective enemy fire. Conduct a complete primary survey and perform life-saving interventions.

Combat medicine deviates from the universally accepted *a*irway, *b*reathing, and *c*irculation (ABC) algorithm. Massive hemorrhage is the most common correctable cause of death on the battlefield, and lethal exsanguination can occur in minutes. Airway compromise accounts for relatively few combat deaths, and respiratory difficulties typically progress over time. This is the reason that TCCC recommends the modified primary survey algorithm of **MARCH**:

Massive hemorrhage
Airway
Respiratory
Circulation
Hypothermia prevention/Head injury

After hemorrhage control, the algorithm mirrors the ABC algorithm, with the additional consideration of a closed head injury and hypothermia prevention as primary survey responsibilities. If a problem is noted during any part of the algorithm, it is addressed before moving further down the algorithm.

In a tactical setting, simple parameters such as level of consciousness and pulse strength are indicators of peripheral perfusion. Is the casualty verbally responsive? If yes, you have already gathered critical information: the blood pressure is strong enough to provide a modest level of cerebral perfusion, and the airway is patent. If the soldier's peripheral pulse is weak or absent, level of consciousness is altered, or if not verbally responsive, then immediate intervention is needed before moving down the algorithm.

MASSIVE HEMORRHAGE

Topical Hemostatic Agents If the wound is not amenable to tourniquet use and a pressure dressing is inadequate, use a hemostatic agent (**Figure 302-1**). The TCCC Committee recommends the following agents: Combat Gauze, Celox Gauze, and ChitoGauze. Combat Gauze (Z-Medica Corporation, Wallingford, CN) uses a zeolite compound impregnated into surgical gauze, which can be easily shaped into any wound. Celox Gauze (Medtrade Products LTD, Electra House, Crewe, UK) is a chitosan-impregnated gauze, as is ChitoGauze (HemCon Medical Technologies, Portland, OR).

To apply any of these gauze-like hemostatic agents, prepare the wound by evacuating excess blood, taking care to preserve any clot that may have formed around the damaged vasculature; pack the hemostatic gauze directly over the site of the most active bleeding; repack or adjust the gauze for optimum placement; use additional hemostatic agent as required. Hold direct pressure for a minimum of 3 minutes, then reassess for bleeding and repack as needed. Secure the hemostatic agent in place with a pressure dressing.

Junctional Hemorrhage Junctional hemorrhage (from the "junctional" anatomic area between the limbs and intracavitary areas of the abdomen or thorax) is difficult to control. Hemorrhage in the axilla and groin is not amenable to tourniquet application and hemostatic agents.[7] Specialized junctional tourniquets may be beneficial in certain cases. Presently these include the Abdominal Aortic Tourniquet,[8] the Combat Ready Clamp,[9] the Junctional Emergency Tourniquet Tool,[10] and the SAM Junctional Tourniquet. Each product has specific directions for application.

FIGURE 302-1. Examples of hemostatic dressings. [Image Reproduced with permission from COL Ian S. Wedmore, MD, FACEP, FAWN, DiMM.]

Systemic Hemorrhage Control: Tranexamic Acid Tranexamic acid decreases mortality in trauma.[11] It is recommended for use in all casualties that require significant fluid or blood products. Tranexamic acid is most effective when given within 1 hour of injury and must be given within the first 3 hours. The dose is 1 gram of tranexamic acid in 100 mL of normal saline.[12]

Prior to the Clinical Randomization of an Antifibrinolytic in Significant Hemorrhage (CRASH) study and introduction of tranexamic acid, recombinant factor VIIa was considered for use by some special operations forces.[13] The advent of tranexamic acid, with its ease of administration, efficacy, and improved safety profile (the risk of systemic hypercoagulability has always been a concern), has limited the use of recombinant factor VIIa to very specific intraoperative clinical scenarios.

AIRWAY

Airway intervention during the primary survey is similar for both combat and civilian casualties. Less than 1% of combat trauma requires lifesaving airway intervention in the prehospital setting.[14,15]

Lack of spontaneous respirations is a grievous prognostic sign. If there are no spontaneous respirations after opening the airway, the casualty is triaged to the expectant category (expected to die) in a mass casualty (MASCAL) situation (defined as more casualties than resources available); if the situation and resources allow, perform advanced airway techniques including cricothyrotomy,[16] supraglottic airway[17] intubation, and mechanical ventilation. If space is limited, cricothyrotomy equipment is the most important.[31] The threshold for performing a cricothyrotomy during combat should be low. It is critical to confirm placement and firmly secure the airway.

RESPIRATORY/BREATHING

Tension Pneumothorax The nearly universal use of body armor in present combat operations provides critical protection to the chest and upper abdomen, as evident in the 5% to 7% thoracic wound rate, the lowest in U.S. military conflicts.[18] Many combatants are alive today because of the proper use of body armor.

In a tactical setting, the threshold to perform a needle decompression is very low, as most casualties with penetrating chest trauma will have some degree of hemo-/pneumothorax, and even in the absence of tension pneumothorax, needle decompression is unlikely to cause harm. Use the largest and longest catheters available, because catheters are apt to kink or occlude, and the needle will have to penetrate through several inches of muscle and soft tissue to enter the thorax. The TCCC minimum standard is the 14-gauge 3 inch long needle, as any shorter length will often not penetrate through a muscular chest.[19] Also, there are 10- and 12-gauge catheters available in 3-inch lengths that are highly recommended over the standard, universally available 14-gauge catheters because they are even less likely to kink or occlude with patient movement. Two locations are recommended: (1) the second intercostal space, midclavicular line; or (2) the anterior axillary line at the fourth to fifth intercostal space (see chapter 68, "Pneumothorax," for further discussion).[20]

Penetrating Chest Trauma Penetrating chest trauma with open pneumothorax or sucking chest wounds is common with large injuries to the chest wall. There are many chest seals, including valved/vented and nonvalved/vented chest seals. The updated TCCC standard is to use a valved/vented chest seal as the first choice. If not available, then an unvented seal can be used, but the patient will need to be continuously reassessed for the need for possible needle decompression.[21] Most casualties encountered in a combat setting are bloody and sweaty; applying a chest dressing that actually adheres to the chest is no small accomplishment and requires some skill and proper preparation of the skin. Wipe the skin as dry as possible. Consider using tincture of benzoin or Mastisol to facilitate dressing adherence if it is available and you have the luxury of time.

Chest Tubes Many physicians come into a field environment expecting to perform sophisticated interventions such as tube thoracostomy or thoracotomy at the point of injury. At this phase of tactical field care, do not expect to perform either of these procedures. The casualty is better served if you focus on basic, lifesaving procedures, prepare for immediate evacuation, and leave more sophisticated interventions for the next level of care. The lifesaving intervention for a chest injury is needle decompression; a chest tube is not immediately required. Needle decompression can be as effective as a chest tube in a patient for up to 4 hours if the patient is not subjected to much movement.[22] Needle decompression can be repeated as needed.

CIRCULATION

The TCCC mainstays of circulation management are the appropriate use of low-volume resuscitation (also known as **hypotensive or hypovolemic resuscitation**) and the selection of appropriate resuscitation fluids. The first step is vascular access.

IV Access Smaller-bore IVs (primarily 18-gauge catheters) are preferred in a tactical environment. Large-bore IVs are more appropriate to administer blood products, which typically are not an option at this phase of field care, and 18-gauge catheters are more than adequate to provide fluid resuscitation in a tactical setting. If blood products are available, then a larger-gauge catheter is indicated.

It is critical to firmly secure the catheter in the combat setting. Use a clear adhesive bandage first; then wrap enough tape to ensure that the catheter will hold in place if you were to throw the IV bag. There are also commercially available IV catheters with Velcro wraps that work very well. There is no one right way to secure a catheter, but give due attention to this because vascular access is the lifeline for severe combat casualties.

Intraosseous Access An intraosseous (IO) line is the alternative to IV access. There are a number of IO devices available commercially, designed for different osseous points of access. Nearly universal use of body armor in the modern tactical environment protects the sternum, so this site is ideal for IO access. Provide secure catheter fixation to prevent dislodgement during patient movement. Some devices may require a removal instrument, which you should secure to the patient; without this removal instrument, the catheter must be surgically removed at the next level of care.

Permissive Hypotension/Low-Volume Resuscitation Following the landmark 1994 Ben Taub study[23] and with subsequent extensive supporting research, permissive hypotension is the TCCC standard for treating noncompressible hemorrhage. **Noncompressible hemorrhage** is bleeding that occurs in any body part or area that cannot be controlled by a tourniquet or other method of compression. In combat injuries, this equates to penetrating wounds of the abdomen, thorax, and possibly junctional areas. This type of bleeding tends to decrease or even clot once the blood pressure has decreased significantly; however, at this low level of blood pressure and tissue perfusion, the casualty will eventually reach a state of irreversible shock. Providing large-volume resuscitation will initially raise blood pressure and perfusion, but it is also likely to "blow out" any formed clot, resulting in immediate rebleeding and further dilution of clotting factors as additional fluid is given to maintain blood pressure. This vicious cycle leads to rapid death.

We attempt to increase the survival time of casualties by maintaining a delicate balance between a blood pressure high enough to provide adequate tissue perfusion but low enough to avoid clot "blow-out" and clotting factor dilution. **Current recommendations are to maintain a mean arterial pressure of 60 mm Hg or a systolic blood pressure of approximately 80 to 90 mm Hg.**[24,25] A blood pressure of 80 to 90 mm Hg is clinically noted by a normal level of consciousness and a weakly palpable radial pulse.[26] Multitrauma patients with a head injury can be difficult to manage. If hypotensive resuscitation is required in a head-injured casualty, try to maintain a systolic blood pressure between 90 and 95 mm Hg.[27,28]

Resuscitation Fluid The prehospital resuscitation fluid of choice for combat trauma has changed over the last 10 years of U.S. military conflict. The goals of the TCCC Committee in recommending the appropriate resuscitation fluid are the following:

1. Enhance the body's ability to form clots with platelets, plasma, and red blood cells at sites of active bleeding.
2. Minimize adverse effects (edema and dilution of clotting factors) resulting from iatrogenic resuscitation injury.
3. Restore adequate intravascular volume and organ perfusion prior to definitive surgical hemorrhage control.
4. Optimize oxygen-carrying capacity as much as possible.

The current resuscitation fluid recommendations for a severe hypovolemic shock are as follows, in order of preference:

Fresh whole blood

Blood components in a 1:1:1 ratio of packed red blood cells (PRBCs):plasma:platelets

Blood components in a 1:1 ratio of PRBCs:plasma

Plasma: freeze-dried plasma or fresh frozen plasma appropriately reconstituted

PRBCs

Hextend

Lactated ringer's or Plasmalyte

Whole-Blood and Blood Component Infusions In the combat setting, prehospital blood transfusion is carried out under specifically approved theater protocols by specially trained and certified providers. For example, several special operations units can give European-produced freeze-dried plasma under an approved protocol.

Fresh whole blood is the TCCC primary resuscitation fluid of choice because it has all the required blood components in their natural state and provides a survival advantage to casualties with severe trauma and shock.[29,30] The use of whole blood in civilian institutions is rare. However, in a battlefield environment, whole blood is often obtained from fellow soldiers known as "walking blood banks" who are the only available blood source. During Operation Iraqi Freedom, 13% of blood transfusions used fresh whole blood.[28]

All U.S. combatants are tested for human immunodeficiency virus on a regular basis, but not for hepatitis. There is a U.S. Food and Drug Administration–approved rapid test (QuickVue; Quidel Corporation, San Diego, CA) for human immunodeficiency virus and hepatitis B and C that has been used for timely screening (manufacturer reports >98% sensitivity and specificity). All potential donors should be screened for risk, although perceived risk is often outweighed by potential benefit; additionally, all recipients and donors have blood samples sent to the Armed Forces Blood Program for retrospective analysis. The collection kits for fresh whole-blood transfusions are readily available through military medical supply channels. Because whole-blood transfusions are the treatment of choice for severe trauma and shock, we expect future developments in whole-blood storage to increase its availability for resuscitation.

If fresh whole blood is not available, the next preferred choice is plasma, PRBCs, and platelets in a 1:1:1 ratio.[31,32] A unit of plasma is given first, followed by the PRBCs, and then platelets. In addition to PRBCs, the military is now fielding frozen red blood cells and deglycerated red blood cells to augment current supplies of liquid-packed red blood cells.

The next preferred choice is PRBCs and plasma in a 1:1 ratio if platelets are not available.[33,34] Plasma is again given first followed by PRBCs. Advances in warm platelet storage will hopefully increase the availability of platelets in the near future.

If availability of blood products is limited, you may have to choose between PRBCs and plasma alone. There is some debate as to whether PRBCs or plasma alone is best, so product availability is more likely to drive this decision. Although availability of plasma is somewhat limited, some special operations combat medics now carry freeze-dried plasma as compared to PRBCs. The freeze-dried plasma concentrate currently carried by our medics is produced in France and available for use by North Atlantic Treaty Organization countries[35]; however, the French freeze-dried plasma should only be used to resuscitate casualties who have given prior informed consent, given the theoretical risk for transmission of certain viral diseases. Units that intend to use freeze-dried plasma typically arrange for consent of their soldiers prior to deployment and provide some method of identification for those who give consent and those who do not.

Colloids and Crystalloids If no blood products are available, **Hextend** (hetastarch in lactated ringer's solution) is recommended. There is no overwhelming evidence supporting the use of crystalloid over colloid in the young, healthy combat trauma casualty; additionally, colloid has a clear advantage from a weight/volume perspective in the prehospital environment, where the medic must carry the fluid on his back. Hetastarch 500 mL provides intravascular volume expansion of 600 to 800 mL. Hextend is potentially protective against multisystem trauma–induced acute respiratory distress syndrome, induces a favorable acid-base balance, and results in less severe coagulopathy.[36] Indiscriminate colloid use can have coagulopathic and immunologic effects, but these adverse effects typically do not occur with colloid administrations of <1500 mL.[37,38]

If fluid resuscitation requires >1500 mL of colloid, lactated ringer's solution is given next. Initial use of colloids to replenish intravascular volume during resuscitation must be balanced at some point with an appropriate volume of crystalloid to avoid extensive intracellular dehydration. Start with a 500-mL bolus, and repeat the bolus in 30 minutes if there is no clinical response, using pulse strength and level of consciousness to guide the volume infused. Maintain a systolic blood pressure of 80 to 90 mm Hg, but in head injury, a systolic blood pressure between 90 and 95 mm Hg is the goal.

One liter of infused lactated ringer's results in only 200 to 250 mL of intravascular volume expansion; normal saline is not recommended for resuscitation due to the hyperchloremic acidosis it produces.[39] Additionally, aggressive resuscitation with saline-based resuscitation strategies is associated with a number of adverse effects, including increased bleeding, acute respiratory distress syndrome, multiorgan failure, acute coronary syndrome, and increased mortality.[40-42]

Other Resuscitation Solutions Hypertonic saline (7.5% saline) has some benefits in the intensive care setting[43-45] but has not been evaluated in combat.[46] Hypertonic saline is neither commercially available nor Food and Drug Administration approved, and is not an option for use by U.S. Armed Forces.

Hemoglobin-based oxygen-carrying solutions are promising in theory, but at this time, clinical trials are ongoing and no hemoglobin-based, oxygen-carrying solutions are presently approved by the Food and Drug Administration or available on the commercial market.[47,48]

Oral Hydration Common practice in the civilian community is for patients to avoid any oral intake because of the risk of aspiration during anticipated surgery. In the combat setting, there are often limited IV fluids available and long waiting times for evacuation or surgical intervention. In the patient with a normal level of consciousness, the risk of aspiration is very low and outweighed by the benefit of maintaining adequate hydration and patient comfort if evacuation is delayed. As such, oral fluid hydration is acceptable for combat casualties in many situations, even if surgery is anticipated at the next level of care. The only contraindication is active vomiting or an altered level of consciousness that increases risk of aspiration. Time to surgery is not an issue in oral provision of clear liquids to combat casualties.[49]

HYPOTHERMIA AND HEAD INJURY

Rewarming a hypothermic casualty can be very difficult, so it is better to prevent than to treat. Under TCCC, we prevent hypothermia by wrapping the patient in a multilayer insulating wrap with a vapor barrier liner.

Closed head injury is one of the final considerations in this modified algorithm. If a casualty has an altered level of consciousness, it is either because of inadequate cerebral perfusion or cerebral injury. If hypovolemic shock has been ruled out or treated and the mechanism is consistent with closed head injury, then treat accordingly. Have the patient recline with the head elevated at 30 degrees. Give oxygen to maintain an oxygen saturation of at least 90%. Maintain a systolic blood pressure of at least 90 mm Hg.[26]

SECONDARY SURVEY

Expose the casualty as much as the tactical situation will allow. Be prepared to preserve body heat to avoid hypothermia. Stabilize fractures and treat less severe wounds. **Continually reassess the casualty.** This may seem obvious, but a tactical environment with multiple casualties is chaotic. Do not expect to have an assistant to monitor each casualty or call out periodic vital signs. Attend to the casualties who require intervention, but remember to reassess everyone. This can be as quick as asking a quick question to assess airway, hemodynamic status, and level of consciousness, or quickly palpate a radial pulse to determine rate and strength; obtain blood pressure if possible and if there are concerns about hemodynamic status. The character of the peripheral pulse and the Glasgow coma scale are reliable severity indicators.[50] Recheck dressings or bandages for continued bleeding.

PAIN CONTROL

Pain control is crucial for facilitating transport and patient comfort. Under TCCC, there are three primary pharmacologic modes of pain control. For lesser injuries with normal mental status, use a combat pill pack. This contains two 500-milligram acetaminophen tablets and a meloxicam tablet. This combination is effective for moderate pain control, does not affect mental status, and is administered orally. Because meloxicam has a favorable side effect profile and no effect on platelet function, it is the TCCC nonsteroidal anti-inflammatory drug of choice.

FENTANYL AND KETAMINE

For more severe pain, we recommended either **oral transmucosal fentanyl citrate lozenge**, informally known as the fentanyl "lollipop," or **ketamine**. Oral transmucosal fentanyl citrate provides rapid-onset, long-lasting pain relief for severe pain without the need for an IV. When placed into the buccal fold and slowly sucked on, 25% of the fentanyl is absorbed sublingually, with onset in 15 minutes. The remainder that is swallowed enters the GI tract and loses about 50% of its bioavailability through first-pass effect, but the remaining 50% is slowly absorbed, providing more extended pain relief for the next 4 to 6 hours.[51] An 800-microgram fentanyl lozenge is the recommended starting dose. Rapidly chewing and swallowing the lozenge will decrease the total amount of fentanyl received, because less is absorbed sublingually and more enters the digestive system, which is subject to first-pass effect. Should the casualty swallow the lozenge, he or she is generally not at risk of an uncontrolled fentanyl bolus. To avoid swallowing, the recommended technique is to tape the lozenge to the patient's finger, which will deter swallowing and prevent overdosing should the patient become somnolent (as the lozenge attached to the hand will fall from the mouth). If pain control is not achieved in 15 minutes, a second 800-microgram lozenge can be placed in the other cheek. Fentanyl can also be given intranasally with the use of a nasal atomizer.[52] If an IV is available, then IV fentanyl or IV ketamine can be used and titrated to effect.

Ketamine at subdissociative doses is an effective pain control agent. It can be given IM, IV, IO, or intranasally via nasal atomizer or syringe with rapid onset and good efficacy. The initial dose is 50 milligrams IM or intranasally repeated every 30 minutes and titrated to effect or 20 milligrams IV/IO by slow push repeated every 20 minutes and titrated to effect.

For treatment of nausea, the TCCC Committee now recommends ondansetron, oral dissolving tablets every six hours as needed.

ANTIBIOTICS

All war wounds are dirty and contaminated. Early antibiotic use with such wounds may decrease subsequent infection.[53] For those able to tolerate PO administration, a single 400-milligram dose of oral moxifloxacin, found in the combat pill pack, is recommended. For casualties with hypotension or an altered level of consciousness, administer either cefotetan, 2 grams, or ertapenem, 1 gram IV.

SPECIFIC INJURIES

BURN CARE: THE RULE OF 10S

TCCC has adopted the rule of 10s for burn management, which is clinically effective and easy to implement in a prehospital environment.[54] For burns >20% total body surface area, first estimate the total body surface

area burned to the nearest 10%. Then, **for adults weighing 40 to 80 kg, give IV fluid as follows: 10 mL × % total body surface area burn per hour. For every 10 kg of patient weight above 80 kg, add another 100 mL of fluid per hour** (resuscitation for hemorrhagic shock takes precedence over resuscitation for burn shock).

For example, for a 90-kg patient with 40% total body surface area burns, the following would be given: 40% × 10 mL = 400 mL, plus 100 mL for 10 kg above the 40 to 80 kg range, giving a total of 500 mL of IV fluid per hour. Once the patient is at a higher level of care, the fluid rate can be adjusted based on clinical status and urinary output.

BLAST INJURIES

Injuries from explosions have historically been the leading cause of deaths in combat. This trend has continued, as we see approximately 50% of combat deaths and 77% of all injuries in the global war on terror caused by explosions. There is the tendency to rely on common clinical indicators to triage blast casualties. Tympanic membrane perforation and hypopharyngeal petechiae are common findings in blast casualties; however, no correlation has yet been shown between these findings and level of injury. There are many factors that contribute to a pattern of injury, such as body orientation relative to the blast and confined versus open space, so be wary of relying on a particular clinical finding to triage casualties.[55] If anything, the most reliable sign may be respiratory distress immediately after the blast. Casualties with clinically significant lung injury typically manifest as respiratory failure within minutes of the blast.[55,56] See chapter 7 for detailed discussion.

CERVICAL SPINE INJURY

As discussed earlier, the vast majority of penetrating injuries in the combat setting do not require cervical spine immobilization, unless there is direct injury to the neck with associated neurologic deficit.[57] In fact, cervical spine immobilization (particularly with a cervical collar) will impede the ability to manage the more immediate concerns of a penetrating neck injury. Therefore, cervical spine immobilization for penetrating injury in a combat casualty is not recommended. Blunt head trauma should be treated with cervical spine immobilization, situation permitting, as practiced in the civilian sector.[58]

ABDOMINAL TRAUMA

Although body armor does provide some protection to the upper abdomen, the lower abdomen is still relatively vulnerable. There is a groin attachment for the issued body armor that provides some protection to the lower abdomen, but it is not composed of a rigid Kevlar plate that is used to protect the chest and back; rather, this is a flexible Kevlar material that allows for movement at the hips, while providing some level of protection to the lower abdomen and groin region. Use of this additional piece of equipment has become more prevalent among our combat troops.

With a significant large-vessel (aorta, inferior vena cava, iliac vessels), liver, or splenic injury, there is not much a combat physician can do to save a casualty. In this situation, stabilize the casualty as best as possible, start an IV, administer antibiotics, and transport to a higher level of care with surgical capability immediately. For management of difficult-to-control, noncompressible massive hemorrhage, see the TCCC section on massive hemorrhage control.

If there is a bowel evisceration, replacing the contents will minimize insensible fluid and heat loss and allow for easier casualty movement. First remove any significant particulate matter or dirt; then attempt to replace the bowel contents intra-abdominally (this might not be possible if there is significant bowel edema and/or a small abdominal defect); cover exposed bowel and abdominal defect with a moist dressing; cover with plastic wrap or other fluid-impervious dressing to minimize insensible fluid loss; start an IV and administer IV fluids as needed; and administer IV antibiotics in preparation for evacuation.

PELVIC TRAUMA

The standard torso body armor does not provide any protection to the pelvis. A groin attachment protects the genital region and does provide some protection for the perineum, but the inguinal regions, containing large neurovascular bundles, are left largely unprotected. As such, the femoral vessels are vulnerable to penetrating injury, often resulting in life-threatening hemorrhage.

A tourniquet or pressure dressing to a proximal femoral artery or vein injury may be ineffective. For this type of injury, use of a hemostatic agent is imperative. Direct pressure should be applied to gain immediate control of the bleeding. Vessel clamping should only be attempted if an effective tourniquet or pressure dressing cannot be applied, a hemostatic dressing is not available, there is no device to control junctional hemorrhage, and there is no ability for immediate evacuation.

Pelvic fractures can result in significant hemorrhage that is difficult to control. Determination of a pelvic fracture, if not obvious, should be done from symptoms of pain and a clinical suspicion. The practice of "springing" or doing a "pelvic rock" is no longer recommended because this technique is likely more harmful than beneficial.[59] Past recommendations of improvised pelvic splinting with a sheet to produce needed compression for hemorrhage control can be used (if no other more effective options are available), but such splinting is inferior to more recent commercially manufactured pelvic splints and binders.[48,59]

EXTREMITY AMPUTATION

About 7% of wounded soldiers in Operation Iraqi Freedom and Operation Enduring Freedom had a major extremity amputation, and 50% of soldiers killed in action or who died of wounds had major amputations.[60] Field treatment of an amputation is focused primarily on hemorrhage control and preserving as much tissue as possible. Often the vessels of the limb have retracted from the initial force of the amputation, making it particularly difficult to identify and control hemorrhage. It may appear that hemostasis has been achieved with little effort; however, effective hemorrhage control may be necessary in the form of a hemostatic agent, pressure dressing, or tourniquet because delayed bleeding often occurs as the damaged vessels relax and dilate shortly after the patient appears stable. Constant reevaluation of the patient is essential. A partial amputation where the limb is still attached by substantial tissue or bone should be treated the same as an open fracture with hemorrhage control, wound debridement and irrigation, antibiotic administration, and splinting in an attempt to salvage the limb.

MASS CASUALTY TRIAGE

Mass casualty or MASCAL events are generally defined as situations in which the number and needs of the casualties exceed available resources (personnel and supplies). Three casualties might represent a MASCAL for one inexperienced physician, whereas 30 casualties might not represent a MASCAL for five well-prepared physicians.

Triage is a critical aspect of managing a MASCAL (**Table 302-4** provides one example of a simple triage algorithm). Another very effective method for handling a large number of casualties is the SALT mass casualty triage methodology (**Figure 302-2**). **SALT stands for sort, assess, lifesaving interventions, and treatment/transport,** which are the key activities that must be accomplished during the triage process.

THREE-TIER PRIORITIZATION

SALT begins with a global sorting of casualties, prioritizing them into three tiers for individual assessment. The triage physician directs casualties to walk to a designated area "if they need help." Those who follow the command to walk are the last priority for individual assessment, because they demonstrate an intact airway, breathing, circulation, and mental status and are therefore the least likely to have a life-threatening condition. The remaining casualties should then be asked to wave or be observed for purposeful movement. Those who remain still and do not move, as well as those with obvious life-threatening injuries, such as massive external hemorrhage, are assessed first. Those who wave are individually assessed next, followed by the ones who previously walked to a designated area. Although this initial sorting is not perfect, it is an attempt to organize numerous casualties.

TABLE 302-4 Mass Casualty Triage Algorithm

AIRWAY: *Is the casualty moving air?*
Yes—assess breathing
No—open airway, moving air now?
Yes—assess breathing
No—EXPECTANT
BREATHING: *Respiratory rate >30 breaths/min?*
Yes—IMMEDIATE, address cause
No—assess circulation
CIRCULATION: *Radial pulse weak/absent or heart rate >140 beats/min?*
Yes—IMMEDIATE, address cause
No—assess mental status
MENTAL STATUS: *Responds to simple commands?*
Yes—NOT an IMMEDIATE
No—IMMEDIATE, address cause

INDIVIDUAL CASUALTY ASSESSMENT

The second step of SALT is to perform individual assessments and apply lifesaving interventions, such as controlling massive external hemorrhage or opening an airway. Lifesaving interventions must meet all of the following criteria: can be provided quickly; can greatly improve a casualty's likelihood of survival; does not require the physician to stay with the casualty; are within the physician's scope of practice; and require only immediately available equipment. After appropriate interventions are performed, casualties are prioritized for treatment and assigned to one of the following triage categories: **immediate, delayed, minimal, and expectant** (includes the dead for the purpose of military triage), known in the military by the acronym **DIME**.

Colored triage tags or chemical light markers can mark casualties based on triage category. Colored triage tags typically are red for immediate, yellow for delayed, green for minimal, and black for expectant or deceased. If chemical light sticks are employed, red is typically used for immediate, green/yellow for delayed, and blue for expectant. Avoid using green and yellow chemical lights for different triage categories to mirror the markings on the triage tags, because it may be difficult to distinguish the two colors during night operations.

The **field triage score** is another easy, rapidly applicable method to identify casualties who are more seriously injured and expected to have a higher mortality. The field triage score is based on two variables: character of the radial pulse and the motor component of the Glasgow coma scale (GCS-M), namely the ability to follow commands. A weak or absent radial pulse, which correlates with a systolic blood pressure of ≤90 to 100 mm Hg, is assigned a score of 0, whereas normal pulse character (systolic blood pressure >90 to 100 mm Hg) is assigned a score of 1. Similarly, an abnormal GCS-M (<6) is assigned a score of 0, whereas the ability to follow simple commands (GCS-M of 6) receives a

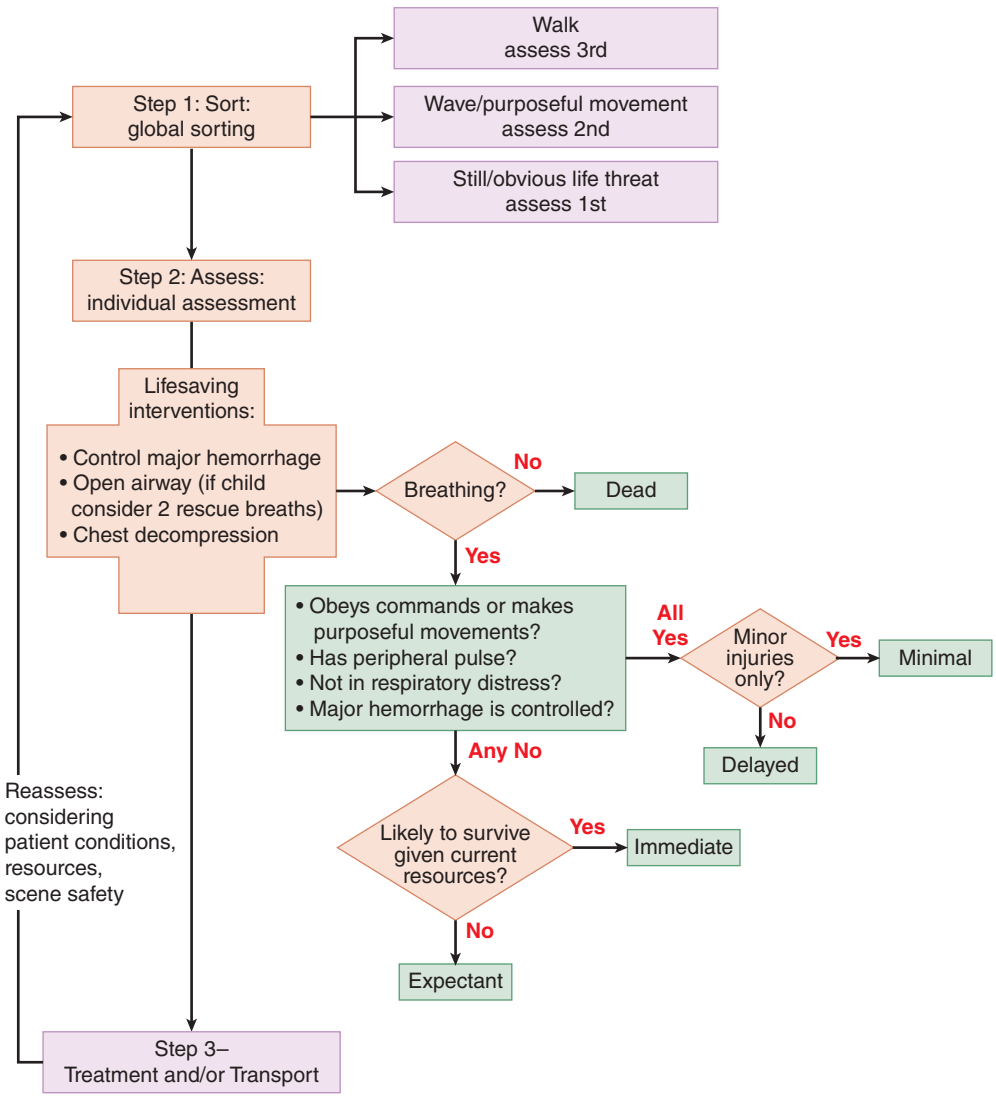

FIGURE 302-2. SALT (sort, assess, lifesaving interventions, treatment/transport) triage algorithm.

score of 1. A casualty can therefore receive an aggregate field triage score of 2, 1, or 0. A retrospective review of 4988 casualties in Iraq and Afghanistan from 2002 to 2008 demonstrated that those with a field triage score of 2 had a mortality of only 0.1% (5 of 4366), whereas those with a field triage score of 1 and 0 had a mortality of 10.8% (33 of 540) and 41.4% (34 of 82), respectively.[61]

Triage categories are not the same as evacuation categories. Triage identifies the severity of a casualty's injuries and determines a treatment priority based on the likelihood of survival, whereas evacuation is based on the urgency of transport to definitive care and the likelihood of deterioration over time. Triage is an ongoing, dynamic process, and triage categories may change if an intervention stabilizes a casualty or if a casualty deteriorates clinically. For example, a delayed casualty with second-degree burns over 30% of his body may become immediate if unrecognized inhalational injury leads to airway swelling and compromise.

CPR

Battlefield resuscitation of victims of blast or penetrating trauma who have no pulse, respiratory effort, or other signs of life will not be successful and should not be attempted because CPR on combat casualties has failed to show any benefit.[62,63] Therefore, CPR on the battlefield is not currently recommended. Even in the civilian setting, very few trauma arrest patients survive when prehospital CPR is performed.[64,65] In a tactical situation, CPR should only be considered as a last effort if the situation permits and appropriate resources are available, and in the case of nontraumatic disorders such as hypothermia, near-drowning, and electrocution. Casualties with torso trauma or polytrauma, who are pulseless and apneic, should receive bilateral needle decompression of the chest to ensure they do not have a tension pneumothorax prior to discontinuation of care. CPR may be initiated during evacuation for casualties that do not have obviously fatal injuries and will be arriving at a facility with surgical capability within a short period of time. CPR should not be done at the expense of mission compromise or denying lifesaving care to other casualties.[66]

CHAPTER 303

Legal Issues in Emergency Medicine

Jonathan E. Siff

INFORMED CONSENT

Informed consent is the legal standard under which providers educate patients (those who have the capacity to make medical decisions or their surrogates) about proposed treatments and alternatives.[1] The desirability of informed consent is based on the belief that it fosters the twin concepts of patient well-being and autonomy. Informed consent also provides a legal basis for autonomy.

Providers should act in their patients' best interests while preserving autonomy whenever possible. The American College of Emergency Physicians Code of Ethics[2] recognizes this dual obligation in stating that emergency physicians "serve the best interest of their patients by treating or preventing disease or injury and by informing patients about their condition." The code of ethics goes on to say, "Adult patients with decision-making capacity have a right to accept or refuse recommended health care, and physicians have a concomitant duty to respect their choices. This right is grounded in the moral principle of respect for patient autonomy and is expressed in the legal doctrine of informed consent."[2]

BASIC ELEMENTS OF INFORMED CONSENT

Most patients arriving at the ED sign a general consent for treatment. General consent for treatment is widely understood to cover history taking, standard examinations, and basic procedures such as venipuncture and blood analysis. General consent forms do not provide consent for more detailed, risky, or invasive procedures.

Informed consent requires two conditions: the patient possesses decision-making capacity, and the patient can make a voluntary choice free of undue influence. The process of informed consent begins with the delivery of information to the patient by the provider. The patient must then reach a decision and authorize the procedure or treatment. Each part of the process is considered individually.

Patient Capacity Decision-making capacity (hereafter called "capacity") is the ability of the patient to make informed medical decisions. It is the provider's task to determine the patient's capacity.[3] The definition of capacity varies among jurisdictions, but, in general, capacity describes an individual's ability to make a decision based on personal values and comprehension of the likely consequences of that decision.[4,5]

One definition of capacity as it relates to health care is from Illinois law and reads: "'Decisional capacity' means the ability to understand and appreciate the nature and consequences of a decision regarding medical treatment or forgoing life-sustaining treatment and the ability to reach and communicate an informed decision in the matter as determined by the attending physician."[6] The American College of Physicians Ethics Manual describes decision-making capacity as "the ability to receive and express information and to make a choice consonant with that information and one's values."[4]

Competence, which is often incorrectly used interchangeably with capacity, is a legal term indicating a ruling by a court that a person is able to manage his or her own affairs.[7]

The capacity to make a medical decision is based on several basic abilities: the ability to receive information; to process and understand information; to deliberate about a decision; and to make, articulate, and defend choices. Generally, the physician assesses the above-listed patient abilities informally, by taking a history from an alert patient with no barriers to communication. Any barriers to communication as a result of language should be removed through translation, when possible, by an impartial medical translator.

Patients with altered mental status may not possess the memory or attention to receive and process the information and thus lack capacity.[8,9] However, diagnoses often associated with altered mental status, such as stroke, psychiatric illness, or dementia, should not lead to a presumption of incapacity. Assess whether or not the disorder affects patients' cognitive abilities.[5] Disagreement with the physician's plan does not indicate a lack of capacity if the decision was made in a rational way, which the patient can defend based on their values and beliefs.[9] A patient's decision-making capacity may change over time in the ED based on changes in medical condition, for example, in patients recovering from intoxication, hypoglycemia, or hypoxia.

Capacity may depend on the complexity of the decision and consequences of accepting or rejecting the intervention. For example, a patient may be competent to make a minor decision but not a major decision at a given point in time.[10] The more important the decision, the more important is the assessment.[4,11]

Factors useful to assess capacity are summarized in **Tables 303-1**[1] **and 303-2.**[11]

If a patient has capacity to make a given decision, his or her wishes should be respected.

Free Choice Informed consent must be voluntary and free of coercion. The choice must be free of manipulation or threats by providers, family, or other outside influences, and free of emotional or physical coercion.[2]

Information Necessary for Patient Decision Making The physician must provide the patient with the information needed to make a reasoned, informed decision. Generally, the provider performing the procedure should be the one to obtain consent. A delegate such as a resident or nurse practitioner may obtain consent, but the supervisor is responsible to ensure that consent was truly informed.[12] The required

TABLE 303-1 Factors for Emergency Providers to Consider When Determining Capacity

Presence of conditions impairing mental function
Presence of basic mental functioning (awareness, orientation, memory, attention)
The patient has understanding of specific treatment-related information
Appreciation of the significance of the information for the patient's situation
Patient's ability to reason about treatment alternatives in light of values and goals
Complexity of the decision-making task
Risks of the patient's decision
Patient's ability to describe, and consistency in reporting, the basis of their decision

information for decision making is the diagnosis; the nature and purpose of treatment; risks and consequences of treatment; alternatives and their risks and benefits; and prognosis if treatment is or is not accepted.[12]

How much information is necessary to meet the above requirement depends on the standard of disclosure being applied. There are two standards, each used in a large number of states, that address the details of the disclosure for consent.[12] The "reasonable person standard" for informed consent requires providers to give the patient all the information a "reasonable person" would need to make the same decision under similar circumstances.[13] The alternate standard is the less stringent "professional standard" for informed consent, which requires disclosure to be the same as any reasonably prudent, similarly trained physician would provide in a similar circumstance.[12] Emergency providers are well served to give more, not less, information to the patient.

Discussion and Decision Give the patient the opportunity to ask questions while considering the decision. The patient can be made realistically aware of ED time constraints for decision making, but without using coercion. Patients willing to continue should then give explicit authorization for the treatment or procedure. If the patient agrees too easily, has no questions, or is not engaged in the process, review the situation for barriers to communication such as language issues. A patient who is unable or unwilling to express a preference for a particular course of action may be presumed to lack capacity.[14]

DOCUMENTATION OF CONSENT

When obtaining informed consent, it is the **process** that is most important. Some states have specific requirements regarding written consent.[12] Where specific requirements regarding written consent are not present, oral consent is generally as good as written consent except that written documentation signed by the patient can aid the provider should the consent process be challenged later on.[12] At a minimum, the chart or consent form (material forms are required by Medicare for all nonemergency surgical procedures) should reflect who obtained consent; the provider(s) authorized to perform the treatment; that information on risks, benefits, and alternatives were disclosed; and that the patient had the opportunity to ask questions.[12,13,15] Ideally, the chart will contain both a signed consent form and a well-documented recap of the consent process.[16]

TABLE 303-2 Common Errors in the Assessment of Capacity

Assuming that if the patient lacks capacity for one type of decision, he or she lacks capacity for all decisions
Assuming that legal competence is the same as medical decision-making capacity
Presuming that capacity is constant over time
Assuming that a blood alcohol level is related to competence
Presuming that psychiatric disorders preclude adequate capacity
Failing to ensure the patient has relevant and consistent information before making a decision
Assuming that capacity should only be considered for refusal of treatment
Failure to recognize that the capacity to make decisions varies with the risks and benefits inherent in the decision

EXCEPTIONS TO INFORMED CONSENT

There are a number of exceptions to the right to informed consent in response to specific healthcare situations. These exceptions include emergencies; therapeutic privilege; public health imperatives, such as the treatment of certain diseases; patient waiver of consent; and, rarely, emergency research.[12,17] Of these, only emergencies and public health imperatives are applicable to clinicians working in the ED on a day-to-day basis.

Emergencies **Emergency providers should render needed emergency treatment even in situations where consent cannot be obtained or ascertained in a timely fashion due to the nature of the illness. Implied consent**, the basis of this exception, is that a reasonable person would give consent to emergency or lifesaving treatment.[12,18] If treatment can be delayed without harm, obtain consent before treatment. Should the situation change during treatment, obtain consent before further treatment.

Public Health Imperatives Public health imperatives are situations where the public good may limit individual patient autonomy. Patients with high-risk communicable diseases,[19] such as severe acute respiratory syndrome and tuberculosis, and patients with mental illness who pose a danger to themselves or the public are examples. Each state has regulations regarding communicable diseases and mental health law, and providers should be familiar with rules in their practice location. When patients meet criteria for health department–mandated treatment and quarantine, yet do not give consent, consult hospital infectious disease staff and local health officials as soon as possible.

WHEN INFORMED CONSENT CANNOT BE OBTAINED

If a patient does not have the capacity to give informed consent for a condition where no exception exists or once an emergency has been stabilized and nonemergent decisions need to be made, providers should identify a surrogate decision maker or directive.[2,9] First, inquire about advance directives or healthcare powers of attorney that can provide guidance or specify a decision maker (see chapter 300, "Death Notification and Advanced Directives"). In the absence of a power of attorney, state law may determine the patient's decision maker. A typical decision-making progression would be: spouse, adult children, parents, adult siblings, and the nearest relative not previously described.[20] Surrogates are expected to help providers determine what the patient would want in a particular situation and should not substitute their values for the patient's. Should no person be available for treatment decisions, providers should proceed with the patient's best interest in mind and involve hospital counsel to begin a guardianship process if the patient's lack of capacity is likely to be of significant duration.[10]

INFORMED REFUSAL

Patients may refuse part of a treatment plan, refuse to be evaluated entirely, or wish to leave before the completion of the planned evaluation. In these situations, the physician should ensure there are no miscommunications or misunderstandings at the root of the refusal.[10] Often, when issues are clarified, an agreement can be reached. Second, correct issues that may prevent an open, noncontentious discussion—such issues may be a blanket, a call to the patient's personal physician, or additional pain medication.[10,21] Finally, try to develop an alternative to the original plan that does not significantly alter the risk to the patient. For instance, a patient may not want a certain procedure but would be willing to accept admission for further evaluation.[10]

When communication and negotiation between the patient and provider fail and the patient possesses decisional capacity, the patient may choose to refuse care or end the encounter "against medical advice."

ED DEPARTURE AGAINST MEDICAL ADVICE AND ED ELOPEMENT

Approximately 1.4 million patients left hospital EDs against medical advice in 2010, representing 1% of patients.[22] Studies have documented poor outcomes in patients leaving against medical advice.[23,24] Characteristics of

patients who leave against medical advice include lack of insurance, male, younger age, alcohol or drug dependency, psychiatric illness, and low income.[23,24] Patients often have serious complaints such as chest pain, abdominal pain, or trauma. Patients give many reasons for their desire to leave, including outside obligations such as family or pets, the wish for treatment at another hospital, concerns for cost of treatment, fear of recommended treatment, a desire for tobacco, drugs, or alcohol, narcotic requests, or improvement in the condition that prompted the ED visit.[25]

To proceed with an against-medical-advice discharge, assess the patient's capacity, with special attention to barriers limiting capacity. Alcohol use and psychiatric diagnoses are not absolute barriers to discharge against medical advice, with the exception of suicidal and homicidal patients. Document the patient's behavior that clearly demonstrates there was no impairment of capacity by intoxication or mental illness. Educate the patient about the risks associated with refusing to complete evaluation and/or treatment. Discuss the patient's reasons for leaving, because these often present opportunities for negotiation and convincing the patient to continue care.[9] Use plain language and avoid medical terms. Given the medical-legal and patient risks of against-medical-advice discharge, make a substantial effort to convince the patient to remain but do not resort to threats. Incorrect statements such as "insurance will not pay for this visit if you leave against medical advice" may further damage the patient–provider relationship and discourage the patient from returning.[26,27] Model documentation of an against-medical-advice discharge should contain the following elements[21,28]:

- Documentation of capacity (ideally with examples and examination clearly noted)
- Discussion of the risks reviewed with the patient including what diagnoses were being considered
- Explicit documentation in the chart that the patient was leaving against medical advice and what treatments, procedures, and courses of actions were refused by the patient
- Offers made of alternative treatments or courses of action
- Efforts to involve family, friends, or clergy in the decision
- Explanation of any potentially problematic entries in the chart such as nursing notes or abnormal laboratory values—for example, if the patient has an elevated serum alcohol level, document that the patient is clinically sober and has capacity, if true
- Patient's signature on the against-medical-advice form, and if patient refuses to sign, document that fact
- Documentation of treatment and follow-up provided
- Documentation that the patient was told he or she is welcome to return at any time

While the most important part of documenting an against-medical-advice discharge is the discussion with the patient addressing the items above, having the patient sign an actual against-medical-advice form may help provide further liability protection in three ways: "1) it may terminate the providers legal duty to treat a patient; 2) creation of the affirmative defense of 'assumption of risk'; and 3) the creation of a record of evidence of the patient's refusal of care."[29]

When a patient leaves against medical advice, reasonable treatment should be provided as appropriate for the patient's medical condition and concordant with the patient's wishes. For example, provide antibiotics for infection, aspirin for chest pain, or stabilization for fractures. Tell the patient to return at any time. Provide a listing of resources for close follow-up and instruct the patient on signs and symptoms to prompt a return visit to the ED should the patient change his or her mind.[9,21]

It is also important to document situations when a patient leaves against advice or before treatment is completed without informing ED staff. Out of sight should not equal out of mind. Attempt to locate the patient within the facility and then check logical destinations. Often a phone call to the patient's home, cell phone, or emergency contact can provide an opportunity to encourage the patient to return to the ED. Document such communication attempts and their outcome.

The concepts of patient capacity and informed consent and refusal, their exceptions, and the moral obligations that underlie them should be integrated into daily ED practice.

ISSUES IN THE ED CARE OF MINORS

A minor is generally considered to be anyone less than 18 years of age, and parental consent is generally required for the treatment of minors. However, society and the legal system have determined that, in some circumstances, older children may be able to make many medical decisions independent of their parents.[30] Exceptions to parental consent for minors include emergencies, the treatment of certain diseases and conditions that are in the best interest of the minor or society, minors emancipated under law, and circumstances in which the best interests of the child are not being addressed by parents. State laws regarding minor care vary widely; providers caring for minors should review state regulations and call on legal counsel as needed.

TREATMENT OF MINORS IN EMERGENCIES

Minors often present to the ED without a parent or legal guardian in the care of an alternate caretaker such as a grandparent, school teacher, babysitter, camp counselor, or social worker.

In the United States under the Emergency Medical Treatment and Active Labor Act (EMTALA), EDs are legally obligated to evaluate all patients presenting with a medical condition and stabilize any emergency condition identified. There is no requirement for consent in this situation.[31,32] Providers have latitude in defining an emergency medical condition (EMC), especially if there is a delay in obtaining consent. It is always best to try to find parents or legal guardians while emergency care is being provided. Document all such efforts. Once the emergency condition is stabilized, the need for appropriate parental informed consent applies.

When an adult family member, such as a grandparent or adult sibling, brings the minor to the ED and has granted consent, care should be given while efforts are made to contact the parent or guardian. In the case of preplanned parental absence, not all U.S. states require a signed note from the parent authorizing treatment. In some U.S. states, laws authorize relatives to consent to medical treatment for minors under their care. However, if the treatment proposed carries a substantial risk and is not emergent, contact the parents or guardian before proceeding. Providers may obtain parental consent by telephone. In cases where no appropriate party can be reached to give consent, particularly in the case of invasive procedures, it is recommended that, when possible, the provider document a second opinion agreeing with the need to perform the procedure on an emergent basis.

EMANCIPATED MINORS

Minors who have become independent from the care and control of their parent or guardian are considered emancipated and may provide consent as adults. The definition of emancipation varies, and some states do not have specific emancipation statutes.[33] Common situations in which minors may be considered emancipated include minors who are married, enlisted in the U.S. armed services, pregnant or parents themselves, declared emancipated by a court, or self-supporting and not living at home.

Mature Minor Exception **The mature minor exception states that if a minor is sufficiently mature to understand the nature and consequences of a proposed medical treatment, then the minor should be able to consent or refuse treatment without parental involvement.** The mature minor exception is accepted under common law and, in some states, under specific legislation. Requirements for the mature minor exception are as follows: the child should generally be at least 14 or 15 years old; the treatment should be beneficial, not elective, and of low risk; and the minor must meet the requirements of informed consent.

Given the subjectiveness of this standard, it is prudent to carefully consider each individual case before treating a minor under the mature minor doctrine.[34]

If a minor is considered capable of providing informed consent for a given issue, then he or she should be considered equally capable of refusing that same treatment.

Sexually Transmitted Diseases Exemption All states allow minors to access testing and treatment for sexually transmitted diseases without parental consent. In most states, the minor must be at least 12 years old, but some states have a higher age requirement.[35,36] In some states, testing and/or treatment for human immunodeficiency virus may not be included in the exception.

Prenatal and Pregnancy Care Exemption Many states allow minors to consent to prenatal care and pregnancy-related care. In states lacking such statutes, minors are often provided prenatal care under the mature minor doctrine, particularly if the state allows minors to consent to other reproductive services.[35,36] About two-thirds of the states have laws allowing a minor to consent to treatment for their own child.[37]

Alcohol or Substance Abuse and Mental Health Treatment Exemption Nearly all states allow minors to access treatment for alcohol or substance abuse. A majority of states have no specific laws regarding access of mental health services, and of those that do, the range of services that can be accessed varies.[38]

Sexual or Physical Abuse Treatment Exemption The evaluation and treatment of sexual or physical abuse without parental consent is generally permitted. In many instances, these patients may be treated under the emergency exemption, because minors who have suffered physical or sexual abuse require prompt treatment. However, assuming that the parents are not the alleged perpetrators, seek parental involvement as early as possible.

PRACTICAL IMPLICATIONS OF TREATING MINORS UNDER STATUTORY EXCEPTIONS OR AS MATURE MINORS

The minor consenting to the treatment is generally responsible for the cost of treatment. Once a minor is treated under one of these statutes, the minor should be afforded the same confidentiality as an adult. In some states, certain exceptions exist if the provider feels that it is in the minor's best interest to have the parent notified. The Health Information Portability and Accountability Act of 1996 (HIPAA) Privacy Rule generally defers to state law or other applicable laws that expressly address a parent's ability to obtain health information about a minor including when a parent agrees to a confidential relationship between the physician and the minor.[39] The hospital bill may pose a potential risk for breach of confidentiality if charged to a parent's insurance carrier.

Assent and Refusal by the Older Minor Providers should seek the assent and cooperation of older or "mature" minors even when parents are granting permission for treatment. If the proposed treatment is nonemergent and the older minor refuses to give assent, the minor's decision should be strongly considered.

WHEN THE MINOR'S INTERESTS ARE NOT BEING PROTECTED

In almost all cases, parents make decisions they believe to be in their child's best interests. However, situations arise when the physician wishes to override or delay the decision making of the parent. For example, if the parent is intoxicated, carefully consider the parent's capacity to give informed consent or refuse care for the minor child. If parents disagree with a treatment plan based on religious or moral reasons, the court or child protective agencies may intervene if the disputed intervention is lifesaving. The American Academy of Pediatrics opposes religious doctrines that recommend opposition to medical attention for sick children and states that children who need medical care to prevent substantial harm or suffering should receive that care.[40]

PRIVACY, CONFIDENTIALITY, AND REPORTING

The ideas of privacy and confidentiality are important elements of ethics, religion, and law because they affirm the dignity and value of the individual.[41] Respect for these rights has been a cornerstone of medicine since ancient times. The Hippocratic Oath reads, "All that may come to my knowledge in the exercise of my profession . . . I will keep secret and will never reveal." The American College of Emergency Physicians Code of Ethics states that emergency physicians should "Respect patient privacy and disclose confidential information only with consent of the patient or when required by an overriding duty such as the duty to protect others or to obey the law."[42] The privacy of one's physical person and the privacy of one's personal information (confidentiality)[43] are considered together in this chapter. All states and the federal government have laws that govern privacy and confidentiality, including mandatory or voluntary reporting requirements that may override considerations of individual patient privacy and confidentiality.

BARRIERS TO PRIVACY AND CONFIDENTIALITY IN THE ED

ED barriers to privacy and confidentiality include ED physical design, operational issues, the presence of visitors, students, and other individuals, and video technology.

Design and operational issues that impact privacy and confidentiality include the triage area, frequent movement of patients between beds, open ED areas for documentation and work, and patient placement for close observation to minimize risk from falls or self-harm.[41,43] In addition, the growing problems of ED crowding and boarding lead to the use of hallway beds and nontraditional bed spaces, which greatly reduce the ability of staff to provide optimum privacy and confidentiality to patients.[44] ED staff should be vigilant when conducting interviews, teaching, or communicating to maximize patient privacy and confidentiality.

Students of various disciplines, law enforcement, and visitors should respect patient privacy and confidentiality.[45] Requests from patients to exclude healthcare students from observation or care should be considered, based on the patient's reasons for the request and the specific situation, but not guaranteed.[41,45] Obtain verbal consent from patients for the presence of students who do not participate in care, and accept refusals.

Law enforcement officials may engage in the collection of evidence and the interviewing of witnesses to crimes in the ED. Except where required by law, patients should have the option of whether or not to speak with law enforcement, and patient information releases, not expressly required by law, require the patient's consent.[46] Visitors should generally be allowed (as space permits), with consent from the patient.[41] Patients should be asked verbal permission for providers to discuss personal information in front of the visitor. In some cases, disclosure of certain diseases, such as human immunodeficiency virus, to a third party requires a written consent.[47] Providers should always consider the nature and gravity of the information being related to a patient and should try to give serious or very personal results and diagnoses in private, even if previously given permission to discuss in front of a visitor.

Patients brought to the ED in the custody of law enforcement pose unique challenges. The safety of staff and patients must be balanced with the privacy and confidentiality rights of the individual. The American College of Emergency Physicians recommends providing unbiased, attentive, and complete care to these patients and communicating instructions appropriate to the medical condition to correctional or law enforcement staff as indicated while maximizing patient privacy.[48]

Photography and video performed for the purposes of evidence collection, quality assurance, and documentation may be acceptable under certain circumstances, but patients should give consent except where not required under the law.[49] Photography and filming for educational and publication purposes always require patient consent. Images recorded for nonmedical or educational purposes without consent (especially with cell phones) are generally prohibited.[50,51] Obtain any necessary permissions from hospital administration and learn and follow all applicable policies and state laws surrounding filming and photography of patients

in all circumstances. Cell phones, tablets, and laptop computers with identifiable patient information should be physically secured and protected with a password program, and images should never be sent via unencrypted email.

THE HEALTH INSURANCE PORTABILITY AND ACCOUNTABILITY ACT AND PROTECTED HEALTH INFORMATION

Definitions HIPAA is the most important U.S. law that protects the healthcare privacy and confidentiality of individuals. This legislation required the establishment of standards for the security, exchange, and integrity of electronic health information, and set rules for basic national privacy standards and fair information practices for health care.

The U.S. Department of Health and Human Services produced the "Standards for Privacy of Individually Identifiable Health Information," also called the *Privacy Rule*, in 2000. The rule has been amended several times with a major revision in January of 2013, commonly referred to as the *Omnibus Final Rule*.[52] These rules establish the obligations of "covered entities." Covered entities include "health plans, health care clearinghouses, and health care providers (broadly defined to include anyone who furnishes, bills, or is paid for health care in the normal course of business) and business associates of these entities, who transmit health information in electronic form when dealing with an individual's health information."[53] Only those parts of the privacy rule most applicable to emergency providers will be covered here.

Under HIPAA, health information (often referred to as *protected health information* [PHI]) is "any information, including genetic information, whether oral or recorded in any form or medium that (1) is created or received by a health care provider, health plan, public health authority, employer, life insurer, school or university, or health care clearinghouse; and (2) relates to the past, present, or future physical or mental health or condition of an individual; the provision of health care to an individual; or the past, present, or future payment for the provision of health care to an individual."[53] HIPAA also applies when PHI is transmitted or maintained by a covered entity. The rule also discusses individually identifiable health information, including demographic data such as name, Social Security number, date of birth, and other identifiers that "identify the individual or for which there is a reasonable basis to believe can be used to identify the individual."[53]

Disclosure of Protected Health Information PHI should be shared with the clear understanding that only the minimum amount of information required to accomplish the purpose of the disclosure will be released. These "minimum" necessary standards do not apply to information that is given to patients themselves, used for treatment, or required by law.[54] Covered entities should have procedures in place, including limitations on access to electronic medical records, to ensure that users are able to obtain only that information necessary to their job or business purpose.

HIPAA allows covered entities to use PHI, without authorization, for purposes of treatment, payment, and operations. Treatment is the provision, management, and coordination of health care and related services, including consultations and referrals.[55] The payment exclusion allows a healthcare provider to use PHI to obtain payment or be reimbursed for the care provided to an individual.[55] Operations include a number of activities, including, but not limited to, quality improvement, employee evaluation and credentialing, auditing programs, and business activity such as planning, development, management, and administration.[55] An exception to this rule is that psychotherapy notes often require written consent for their use except for treatment, certain legal matters, and the protection of the public from a serious threat.[56]

There are 12 national priorities, as shown in **Table 303-3**,[57,58] in addition to treatment, payment, and operations usage, for which covered entities are allowed to disclose PHI without authorization. These disclosures are permitted by the law and have specific conditions or limitations to balance the privacy of the individual and the public interest for the information.[57]

Under the privacy rule, the risk of every possible incidental use or disclosure of PHI does not have to be eliminated.[57] Provided the incidental disclosure or use occurs as the unintentional result of a legitimate use or disclosure of PHI, the entity has in place reasonable safeguards (as defined in the rule), and has applied the minimum necessary standard, there is likely to be no violation of the rule.[59]

TABLE 303-3 The 12 National Priorities for Which Protected Health Information May Be Disclosed or Used without Written Authorization

1. As required by law (statute, regulation, or court order)
2. For public health reporting (e.g., vital statistics, disease, adverse event reporting)
3. For reporting abuse, neglect, or domestic violence
4. For health oversight activities (e.g., inspections, audits)
5. For judicial and administrative proceedings
6. For law enforcement purposes (e.g., criminal investigations) under certain circumstances
7. For disclosures about deceased persons to medical examiners, coroners, and funeral directors
8. For organ, eye, and tissue donation purposes
9. For some types of research (e.g., in cases where an institutional review board has waived the authorization requirement)
10. To avert a serious threat to the health or safety of the public
11. For specialized government functions, such as military missions or correctional activities
12. For workers' compensation claims

Patient Rights to Protected Health Information The HIPAA regulations also require that a notice of privacy practices be given to all patients, informing them of their rights regarding their health information.[60] Patients are asked to sign these documents and receive a copy of the notice.

These rights to PHI include access to records in the patient's preferred format, request for amendments, request for additional restrictions, notice of PHI use, and an accounting of disclosures made from their PHI.[61-64] In general, most of these functions will be handled by a hospital's medical records department, but requests to amend records must be addressed by the provider promptly (60 days). If the request is denied, the patient has the right to place a written statement in the medical record disagreeing with the denial.[61]

Law Enforcement Rights to Protected Health Information HIPAA allows the limited release of PHI for certain law enforcement purposes. Release is permitted to respond to a judicially issued warrant, subpoena, court order, or grand jury subpoena. Release is allowed to assist law enforcement in identifying or locating a suspect, fugitive, material witness, or missing person by releasing only the following information: "name and address, date and place of birth, Social Security number, ABO blood type and Rh factor, type of injury, date and time of treatment, date and time of death, if applicable, and a description of distinguishing physical characteristics, including height, weight, gender, race, hair and eye color, presence or absence of facial hair (beard or moustache), scars, and tattoos."[65] Providers may notify authorities of a person's death if a possible criminal activity was the cause of the death. PHI may be released in response to law enforcement requests for information about a victim or suspected victim of crime, with the patient's consent. When a patient, who may be a victim of a crime, is unable to consent, the provider may release information to law enforcement if they believe the release is in the patient's best interests and that the information is not intended to be used against the patient by law enforcement.[53]

Impact of Protected Health Information on Emergency Physicians HIPAA allows for open discussions with primary providers, consultants, and other persons involved in the care of an individual. Primary providers are allowed to discuss a patient, without first obtaining the patient's consent, if the patient is under their care in the ED. Providers are able to release information under the national priorities and as required under state law. If family or friends call and ask about a patient by name, "directory" information may be released unless the patient has requested they not be listed in the directory. Providers are cautioned about releasing additional information over the phone unless

TABLE 303-4 Health Insurance Portability and Accountability Act (HIPAA) Do's and Don'ts

HIPAA Do's

1. Talk openly with patient's primary physician.
2. Discuss protected health information with consultants and other members of the patient's healthcare team.
3. Use protected health information for reimbursement and operational issues.
4. Release records to the patient or an authorized representative.*
5. Discuss patient protected health information with family or friends if the patient is in an emergency situation, unable to consent, and the information would be beneficial to the patient.

HIPPA Don'ts

1. Discuss patients or protected health information in public or unsecured areas.
2. Leave computers with access to protected health information logged on and unattended.
3. Discuss protected health information in front of others without permission.
4. Speak loudly when discussing protected health information, particularly in public areas.
5. Look at records for which you have no legitimate purpose as a provider.

*May require the patient to sign an authorization form.

© Jonathan E. Siff.

they can reasonably confirm the identity of the caller and, if possible, have the patient's permission to release additional health information.

Do not access records for which you are not the treating provider, unless such information is needed for operations, for law enforcement, or for another legitimate reason. Document the reason for access to any chart where you are not the treating provider. Failure to comply with these regulations can lead to significant monetary and even criminal penalties for providers. See **Table 303-4** for some HIPAA do's and don'ts.

Need to Report Protected Health Information **Privacy and confidentiality are not absolute rights.** Ethicists, courts, and legislators have agreed that in some situations, the rights of the individual are overridden by the needs of the public. In many cases, this takes the form of permitted or mandatory reporting of certain diseases, pathogens, forms of abuse, and other medical conditions or situations. Providers should balance confidentiality, patient autonomy, the public good, and legal mandates with possible sanctions for noncompliance and medical-legal risk when deciding when to report a given condition.

Abuse All states require the reporting of suspected child abuse or neglect and generally give providers legal protection as long as reports are made in good faith.[43] Most states have similar reporting requirements for elder abuse. Some of these laws only pertain to those elderly patients who are incapacitated or in care facilities, whereas other states include all persons above a certain age.[66] Mandatory reporting laws for domestic partner violence have been passed in a few states. In some domestic violence cases, reporting may be required based on state laws that mandate reporting of injury during the commission of a crime or injuries from deadly weapons.[67,68] Key to the reporting of all types of abuse is the willingness of the provider to consider and discuss potential abuse cases with patients.[67,69]

Injury by Deadly Weapon or due to a Criminal Act Most states mandate the reporting of injuries from deadly weapons, including stab and gunshot wounds.[67] A number of states also require reporting of injuries that occur as a result of a criminal act but do not require reporting of so-called "victimless" crimes such as drug abuse.[43]

Driving Impairment Many patients have medical conditions that may cause care providers, family, and the public to question their ability to safely operate motor vehicles. In some states, providers are required to report drivers with epilepsy to the department of motor vehicles. Patients with a variety of other medical conditions, such as dementia, vision impairment, Parkinson's disease, and other degenerative conditions, as well as patients on certain medications, may be unable to safely operate a vehicle.[70] A majority of states provide physicians with immunity when reporting impaired drivers. In other states, immunity is not provided, and providers could be found liable for damages resulting from reporting or nonreporting.[67] Many providers have concerns about reporting these patients, and the American Academy of Neurology supports optional reporting of medically impaired or potentially impaired drivers.[70] A study of California emergency physicians found very low reporting rates in compliance with a state law requiring physicians to report all patients with lapses of consciousness.[71] In addition, some states require that providers report drivers who are in accidents while intoxicated.[67]

Infectious Disease Reporting The U.S. federal government requires the reporting of contagious diseases for surveillance purposes.[41] The annual lists of diseases and conditions under national surveillance are available on the Centers for Disease Control and Prevention website.[72] Pathogens on this list commonly encountered by emergency providers may include *Chlamydia trachomatis*, gonorrhea, viral hepatitis, human immunodeficiency virus, Lyme disease, pertussis, and resistant *Streptococcus pneumoniae*. Other pathogens, such as methicillin-resistant *Staphylococcus aureus*, may be reportable to other databases or to state health departments. The diseases under surveillance change as new pathogens are discovered and priorities change; other diseases are deleted from the list as they lose relevance.

Reporting of Medical Errors A number of states and organizations have enacted a combination of mandatory and voluntary reporting systems in an attempt to improve healthcare processes and reduce patient morbidity and mortality due to hospital errors and adverse events.[73] Providers should comply with these systems as required by law.

Reporting of Breaches and Penalties under HIPAA Under HIPAA, any disclosure, access, or use of PHI in a manner not permitted under the law is assumed to be a breach.[74] The covered entity must demonstrate that there is a low probability that the PHI has been compromised based on a risk assessment or face penalties. If a breach is found, notification may be required to the party whose information was compromised, the secretary of the Department of Health and Human Services, and in the case of large breaches the public at large.[75-77] Penalties for violation of HIPAA range from $100 per violation if the covered entity was unaware of the violation and should not reasonably have been aware to $1.5 million per violation if the breach was considered due to willful neglect and not adequately addressed in the required time frame.[75] Federal law also provides for criminal penalties of up to 10 years in jail and $250,000 in fines for HIPAA violations.[78] Providers are strongly encouraged to discuss with their attorney or hospital privacy officer or legal counsel any potential HIPAA violation immediately upon learning of a potential breach to minimize the risk of penalties against providers and organizations.

EMERGENCY MEDICAL TREATMENT AND ACTIVE LABOR ACT

Congress enacted EMTALA in 1985 in response to situations where hospitals refused care to uninsured patients.

EMTALA OBLIGATIONS

EMTALA imposes numerous obligations on hospitals operating EDs. These include the provision of a "medical screening exam," performed by "qualified medical personnel," to look for an "emergency medical condition" (EMC) for all patients who "come to the ED" seeking care for a medical condition. If an EMC is found, the patient must be stabilized (as defined under EMTALA) within the capability of the hospital or transferred, in a specified manner, if necessary, to complete stabilization. Each element will be considered in turn.

"Comes to the ED" Under EMTALA a "dedicated emergency department" is "any department or facility of the hospital, regardless of whether it is located on or off the main hospital campus that": (1) is licensed by the state as an emergency room or ED; (2) is held out to the public as providing unscheduled care for EMCs on an urgent basis; or (3) provides one-third of its outpatient visits for the treatment of EMCs on an urgent, unscheduled basis.[79] Many hospital-owned urgent care centers may meet this definition.

Hospitals must provide a screening examination to any patient who comes to the "dedicated ED" (hereafter "ED") and requests, or has a request made by another, for evaluation or treatment of a medical condition. If a prudent layperson observer would believe the person needed evaluation or treatment for a medical condition, the hospital's obligation under EMTALA is triggered.[79] Note that the language says for a "medical condition," not an "emergency medical condition." Other hospital locations, such as labor and delivery, psychiatric intake areas, and urgent care areas, which meet the above definition, are subject to EMTALA obligations as well.[80] An infant born alive is considered an individual under the law, and therefore, the same EMTALA obligations apply, including when the infant was born in the ED.[31]

Emergency Medical Condition An EMC is a "medical condition manifesting itself by acute symptoms of sufficient severity (including severe pain, psychiatric disturbances and/or symptoms of substance abuse) such that the absence of immediate medical attention could reasonably be expected to result in: 1) Placing the health of the individual (or, with respect to a pregnant woman, the health of the woman or her unborn child) in serious jeopardy; 2) Serious impairment to bodily functions; or 3) Serious dysfunction of any bodily organ or part; or with respect to a pregnant woman who is having contractions: 1) That there is inadequate time to effect a safe transfer to another hospital before delivery; or 2) That transfer may pose a threat to the health or safety of the woman or the unborn child."[79] For pregnant women with contractions, an EMC exists if there is insufficient time to transfer the patient before delivery or the transfer may pose a risk to mother or child.[79] Ultimately, this is a medical decision. If it is determined that no EMCs exists, then EMTALA no longer applies to that patient. It is good practice to note the time that this decision was made. The courts have generally ruled that the physician must be aware an EMC exists before he or she is liable under EMTALA. It is important to understand that for an EMC to be present the patient must have a condition such that the lack of immediate medical attention could result in the consequences outlined above. The rule does not suggest that any particular symptom, including severe pain, is in and of itself an EMC, only that the presence of such symptoms mandates a screening, as described below, to determine if the patient has an EMC.[81]

Medical Screening Examination A medical screening examination is the process required to reach, with reasonable clinical confidence and based on the patient's presenting signs and symptoms, the point at which it can be determined whether an EMC does or does not exist.[31] This may involve a simple process, such as a brief history and physical examination, or a complex process involving ancillary studies, consultants, and procedures.[31]

The screening must be the same for every patient presenting with similar symptoms or complaints to be EMTALA compliant. The courts have generally held that so long as screening examinations are performed in a consistent manner across all patients and in accordance with a hospital's own policies, the EMTALA screening obligation has been met.[80] This is true even in cases of misdiagnosis. The courts have also held that misdiagnosis and the adequacy of screening are issues of negligence and should be addressed under state malpractice statutes. **Nurse triage does not meet the hospital obligation to provide a medical screening examination.**[80]

EMTALA dictates that a hospital may not delay the screening examination and stabilizing treatment to inquire about method of payment or insurance status.[82] Hospitals may follow reasonable registration procedures, including inquiring about insurance, provided that it does not delay the medical screening examination or discourage patients from remaining for evaluation.[82] Requests for copayments or down payments should be deferred until after the screening examination and any indicated stabilization to avoid the appearance that the request for payment could have deterred a patient from continuing to seek care. Similarly, advance beneficiary notices and managed care organization authorizations should be deferred.[80]

Providers are allowed to contact a patient's personal physician for advice regarding the patient's history, treatment, and evaluation (but not to obtain prior authorization) as long as this does not delay the medical screening examination.[83]

Qualified Medical Personnel The statute states that "The examination must be conducted by an individual(s) who is determined qualified by hospital bylaws or rules and regulations."[84] These individuals must be formally recognized by the hospital governing body as qualified to perform this type of examination.[31] Although the regulations do not specify what type of provider (e.g., registered nurse, medical doctor, physician's assistant) should perform the medical screening examination, the qualifications of the provider may be retrospectively reviewed and found inadequate.[80] The regulations specifically allow a certified nurse midwife to certify false labor.[79]

Stabilized The concept of stabilization under EMTALA is not what most clinicians would expect. To have a duty to stabilize, the treating providers must be aware of the presence of an EMC. Under EMTALA, stabilize means to provide "treatment as necessary to assure, within reasonable medical probability, that no material deterioration of the condition is likely to result from or occur during the transfer of an individual from a facility or that . . . the woman has delivered the child and placenta."[79] **Stabilization does not require that the underlying medical condition be resolved.** For example, a patient with difficulty breathing and a history of asthma may be stable once provided with medication and oxygen, despite the fact that the underlying condition of asthma is still present.[85]

The decision regarding whether or not the patient is stable rests with the physician actually treating the patient.[86,87] However, this decision is subjective and may be reviewed with medical hindsight. In an investigation, the burden of proof for stability rests with the transferring hospital.

After stabilization, EMTALA no longer applies, and patients may be discharged or admitted for further care. Once a patient is admitted to inpatient status in good faith, not just for the purposes of avoiding EMTALA obligations, the admitting hospital's EMTALA duty is considered complete.[88]

Transfers in accordance with local protocols, such as a trauma system protocol, will generally meet the stabilization requirement, but the transferring hospital must stabilize within its means first.[31] If a hospital is unable to stabilize the patient, then transfer to a higher level of care is appropriate, and all efforts made to stabilize by the transferring hospital should be documented in the patient chart.[31]

The U.S. Supreme Court has ruled that the hospital or physician does not need to have an improper motive for a transfer to be successfully sued for failure to stabilize under EMTALA.

Below are the definitions for two specific situations (discharges and psychiatric patients) as written in the State Operations Manual used by EMTALA investigators.

Stable for Discharge "Discharge home with follow-up instructions. An individual is considered stable and ready for discharge when, within reasonable clinical confidence, it is determined that the individual has reached the point where his/her continued care, including diagnostic work-up and/or treatment, could be reasonably performed as an outpatient or later as an inpatient, provided the individual is given a plan for appropriate follow-up care as part of the discharge instructions. The EMC that caused the individual to present to the dedicated ED must be resolved, but the underlying medical condition may persist. Hospitals are expected within reason to assist/provide discharged individuals the necessary information to secure the necessary follow-up care to prevent relapse or worsening of the medical condition upon release from the hospital."[85]

Therefore, the availability of follow-up and content of discharge instructions may be reviewed should a complaint trigger an investigation. One area where this is problematic is follow-up for uninsured patients. An emergency physician may be liable for a violation, for not requiring an on-call specialist to come in, if a patient is referred for needed follow-up care, such as fracture reduction, and is subsequently refused care—if the emergency physician was aware, or should have been aware, that the follow-up was unlikely to occur. Should there be any question about the patient's ability to obtain the needed follow-up care, the specialist should be asked to come to the ED to see the patient and provide the needed care.[86]

All discharge instructions should educate patients to return to the ED if they have any problem accessing follow-up care as planned.

Psychiatric Patients "Psychiatric patients are considered stable when they are protected and prevented from injuring or harming him/herself or others. The administration of chemical or physical restraints for purposes of transferring an individual from one facility to another may

stabilize a psychiatric patient for a period of time and remove the immediate EMC, but the underlying medical condition may persist, and if not treated for longevity the patient may experience exacerbation of the EMC. Therefore, practitioners should use great care when determining if the medical condition is in fact stable after administering chemical or physical restraints."[85] Psychiatric patients present one of the greatest challenges under EMTALA due to the difficulty of determining stability and the lack of available psychiatric resources in most communities.

Transfers Under EMTALA, transfer is "the movement (including discharge) of an individual outside a hospital's facilities at the direction of any person" representing the hospital, regardless of that person's employment status with the hospital.[79]

Hospitals are expected to appropriately transfer patients if they do not possess either the "capability" or "capacity" to care for the patient. Capability would include the availability of technology, specialists with the needed skills to care for a patient, and equipment or supplies required by the patient's condition. Capacity looks at numbers and availability of qualified staff, beds, and equipment and what the hospital "customarily does to accommodate patients in excess of its occupancy limits."[79] Therefore, if a hospital routinely opens extra beds to accommodate patients, they must do so if necessary to avoid the transfer of a patient for whom they could otherwise provide care.

Hospitals may not transfer a patient who has not been stabilized unless an appropriate transfer is performed and either (1) the patient requests the transfer and the request is documented in writing, including the patient's awareness of the risks and benefits of the transfer; or (2) a physician documents that the medical benefits of transfer to a hospital with greater resources reasonably outweigh the increased risk to the patient, pregnant woman, or unborn child.[89] An "appropriate transfer" is defined in the EMTALA regulations. The following four elements are required for an appropriate transfer.[89]

1. The transferring hospital stabilized the patient and, when applicable, the unborn child to the best of its ability, minimizing the risks of the transfer to the patient or, in the case of a woman in labor, her unborn child.
2. The receiving (accepting) hospital has the capability and capacity to care for the patient and agrees to accept the individual and provide appropriate medical treatment.
3. The transferring facility sends all pertinent medical records, including test and study results, treatment provided, and the written consent for the transfer. Information not available at the time of transfer must be sent as soon as possible. If the transfer is necessary due to the failure of an on-call physician to appear, that physician's name and address must be provided to the accepting hospital.
4. The transfer must be performed through qualified personnel and transportation as determined by the transferring physician. The accepting facility may not condition its acceptance on the use of a specific transport service or method.[87,90]

If a hospital attempts to transfer a patient to meet its EMTALA obligation and the patient, or person acting on the patient's behalf, refuses the transfer, then the hospital's EMTALA obligation is considered met. The hospital is expected to attempt to obtain written informed refusal, including a discussion of the risks and benefits of the refusal of transfer and describe both the facts of the transfer that was proposed and the stated reasons for refusal.[91]

Hospitals may not penalize a provider who refuses to authorize the transfer of a patient with an unstabilized EMC or take negative action against any employee who reports a violation of EMTALA.[89]

Duties of Receiving Hospitals A hospital with specialized capabilities or facilities such as (but not limited to) burn units, trauma units, or regional referral centers may not refuse to accept a transfer from a referring hospital anywhere in the United States when the patient in question requires the specialized capabilities *and* the receiving hospital has the capacity to treat the patient.[92] The failure of centers with specialized capabilities to appropriately accept patients requiring their services has been colorfully referred to as "reverse dumping." This rule applies even if the receiving hospital does not have its own dedicated ED.[92]

Due to the risk of a citation or lawsuit should a hospital with specialized or higher level services fail to accept a transfer as required by the law, some authors suggest that all transfers be accepted by hospitals with specialized conditions without inquiry into the patient's insurance status.[86] Should the accepting hospital find that the transfer was not appropriate or improperly motivated, it is both their duty and remedy to report the transferring hospital for a potential violation of EMTALA.[86,93] Delays in accepting a patient in transfer who has an unstabilized EMC to receive or confirm financial information may be considered an EMTALA violation by the receiving hospital.[94]

Failure to report an EMTALA violation is itself a violation.

On-Call Responsibilities Hospitals are required to maintain an on-call list of physicians "who are on the hospital's medical staff or who have privileges at the hospital, or who are on the staff or have privileges at another hospital participating in a formal community call plan in accordance with the resources available to the hospital."[95] The call list must specifically name an individual physician with accurate contact information, not solely the name of a group or specialty.[96] The stipulation that the hospital provide these services "in accordance with the resources available to the hospital" leaves considerable leeway for hospitals to decide what services to offer. Physicians who are formally on call must assist when requested to determine if an EMC exists, to help stabilize patients, and to accept appropriate transfers. They must do this in a reasonable amount of time.[31] Although regulations allow for physicians to be on call at multiple hospitals and to perform elective surgery while on call, a clear plan must exist to provide EMTALA care in these situations.[97] It is the responsibility of the emergency physician to determine if the on-call provider needs to appear in person to see a patient. In general, EMTALA does not allow patients to be sent to private physician offices for examination or stabilization, except possibly in cases where the office is part of the hospital-owned facility and on campus with the hospital. One exception may be that of ophthalmologists, who often have specialized equipment not available in many EDs. Hospitals that allow physicians to selectively take call only for their own established patients who present to the ED must ensure the availability of adequate on-call services to all ED patients requiring similar care.[96] If the on-call doctor will not come after substantial efforts from the emergency provider, then the patient should be transferred to receive necessary care. The emergency provider must inform the accepting hospital that is why the patient is being sent and provide them with the on-call doctor's name and address (failure to do so is an EMTALA violation).

The widespread adoption of communications technology has made consults by a variety of electronic methods increasingly common. There is no restriction to the use of any means of communication with consultants.[96]

Table 303-5 outlines some EMTALA do's and don'ts.

ENFORCEMENT OF EMTALA

The U.S. Department of Health and Human Services is responsible for enforcing EMTALA at the federal level. A complaint is required to initiate an investigation of a hospital for an EMTALA violation. The complaint may come from a patient, hospital, hospital employee, or anyone who thinks care has been denied someone inappropriately. Hospitals may not penalize employees who report violations.[89] Punishments under EMTALA can be severe and may include a hospital's exclusion from participating in Medicare and Medicaid in addition to substantial fines. Providers found to violate EMTALA can also be fined and/or excluded from federal programs, making them nearly unemployable.[98]

Physicians, particularly on-call physicians, are relatively unaware of their obligations under EMTALA,[99] and hospitals should educate their staff regarding EMTALA.[88] An EMTALA violation does not imply medical malpractice.

Situations Where EMTALA Does Not Apply or Ceases to Apply Once a patient is admitted, in good faith, as an inpatient to the hospital for further care, EMTALA ceases to apply. However, EMTALA still applies to patients in the ED and patients on observation status such as patients in an ED chest pain unit, an observation area of labor and delivery, or in observation status within the main hospital even if they are on

TABLE 303-5 EMTALA Do's and Don'ts

EMTALA Do's

1. Treat all patients in the same way.
2. Provide a medical screening examination appropriate to the patient's complaints.
3. Appropriately transfer patients you cannot stabilize.
4. Accept transfers who require specialized services your hospital offers, as long as the specialized services have the capacity for care.
5. Involve on-call specialists when needed to diagnose or stabilize an EMC.
6. Educate ED, hospital staff, and faculty on the EMTALA rules.
7. See patients quickly and efficiently.
8. Document the completion of the MSE and if an EMC was identified or not during the visit.

EMTALA Don'ts

1. Substitute triage for an MSE.
2. Discourage or coerce patients away from receiving their screening exams and stabilization.
3. Allow yourself to be convinced that a specialist does not need to come to the ED.
4. Fail to stabilize within your capabilities.
5. Delay the MSE for preauthorization or registration.
6. Fail to follow your own rules, policies, and procedures.

Abbreviations: EMC = emergency medical condition; EMTALA = Emergency Medical Treatment and Active Labor Act; MSE = medical screening exam.

© Jonathan E. Siff.

a unit that also contains patients on inpatient status.[80,87,100] Although Centers for Medicare and Medicaid Services regulations do identify that under the above conditions EMTALA does not apply to inpatients, the subject is not settled law as far as the courts are concerned, so careful documentation of why patients were admitted (to validate the good faith clause) and what status they were in the hospital on (to validate that they were an inpatient) is very important.[100] Inpatients who subsequently develop an EMC are not covered by EMTALA, even if they are physically moved back to the ED; however, they are covered by the Medicare Conditions of Participation. EMTALA does not apply to outpatients who have already begun a scheduled appointment. EMTALA may not apply during a declared national emergency or pursuant to a state emergency or pandemic preparedness plan following the issuance of a waiver under law.[101]

Ambulance "Parking" Prolonged delays in moving patients from EMS care to hospital care, referred to as "parking," is not acceptable and may be considered a violation.[90] This does not mean that every ambulance patient must instantly be taken from the care of EMS, particularly in instances where the hospital may lack capacity or capability to immediately care for the patient.[90] The hospital has an EMTALA obligation to the patient once on hospital property.

Patient-Initiated Transfers Any transfer not for medical reasons is considered a patient-requested transfer. The chart should reflect the patient's reason for wanting the transfer. The transfer must still be an "appropriate transfer."

Use of the ED for Nonemergency Services If a request is made by, or for, a patient presenting for treatment of a medical condition but the "nature of the request makes it clear that the medical condition is not of an emergency nature, the hospital is required only to perform such screening as would be appropriate for anyone presenting in a similar manner to determine" if an EMC exists.[102]

Withdrawal of Request for Screening Patients who fail to start or complete the screening and treatment process fall into one of three categories: patients who arrive at the ED and then fail to even begin their medical screening examination (often classified as left without being seen or left before examination); patients who leave or "elope" without informing staff at any point during the evaluation[103]; and patients who refuse recommended treatment or admission and leave "against medical advice."

In each scenario, the hospital should make a clear, well-documented effort to find a missing patient by overhead paging and a search of the department. The medical record should contain a description of the services offered (examination and treatment) that were refused. The hospital should take all reasonable steps to procure the individual's written refusal on a document that also outlines the risks and benefits of examination and treatment. These issues are very important under EMTALA, as regulations state "that hospitals should be very concerned about patients leaving without being screened. Since every patient who presents seeking emergency services is entitled to a screening examination, a hospital could violate the patient antidumping statute if it routinely keeps patients waiting so long that they leave without being seen, particularly if the hospital does not attempt to determine and document why individual patients are leaving, and reiterate to them that the hospital is prepared to provide medical screening if they stay."

Triage Down Downgrading a patient's triage level from the level required under hospital protocol risks an EMTALA citation and could form the basis for a civil lawsuit.[103,104]

State Law Some states have passed laws that impose additional duties or requirements on emergency physicians and hospitals. Such laws should be followed unless they directly conflict with the federal EMTALA rule, in which case the federal statute takes precedence.

Requests for Testing In some cases, patients may present to the ED for testing, such as x-rays or blood work, under the order of their personal physician. Because these patients are not requesting examination or treatment of a medical condition, EMTALA does not apply. Should the hospital choose to provide the patient with the testing services, these patients should be differentiated from standard ED patients. Separate paperwork defining consent, that a medical screening examination was not requested (signed by the patient), and interactions with the ordering physician should be recorded. Patients who independently present for testing, such as pregnancy testing, should receive a medical screening examination before testing, and if they refuse the screening examination, they should be referred elsewhere for the requested testing.

A common scenario is the patient brought in by law enforcement for alcohol or drug screening. In these cases, if it appears that the patient should be screened (prudent layperson) or the patient or police request an examination, then the screening examination should be done.

Screen Away Programs Such programs aim to comply with the letter of the EMTALA law by performing medical screening examinations and then either sending away those patients found not to have an EMC or requesting payment before treatment. The ethical implications of these programs are beyond the scope of this chapter. Physicians and hospitals should consider the legal risk and ethical and moral implications of such programs, particularly in those cases where alternative sources of care are not provided.[105]

Private Patients in the ED In some EDs, it is common for staff physicians to send their patients to the ED, with plans to meet the patient in the ED. Although this is acceptable, these patients should go through the standard triage process, and if any concern exists about the presence of an EMC, patients should be evaluated in the standard manner by the emergency physician present and stabilized while waiting for the private physician.

"The Guarantee" Some hospitals have begun programs in which they promise a patient will be triaged or seen by a doctor within a specific amount of time. These guarantees are problematic from an EMTALA point of view, as the hospital will likely be held to these times during an investigation.

Pain and EMTALA An epidemic of prescription drug abuse in the United States has led to substantial risk for patients and growing difficulties for providers.[106] Legislation both enacted and pending in many states attempts to address this problem, often placing emergency physicians in a difficult position.[106] While EMTALA indicates that pain may be a symptom suggestive of an EMC, it only requires that the patient with pain receive a medical screening exam consistent with the patient's presenting complaints. Once a patient has been identified as not having an EMC, providers can make reasoned clinical determinations about the appropriateness of opioids and other medications. The Centers for Medicare and Medicaid Services has clarified that the posting of signage that, even when intended as education, discusses restrictions on ED

prescribing or use of opioids may discourage patients from receiving their medical screening exam and therefore would be in violation of EMTALA.[107] Providers and staff should also not discuss with patients the results of state pharmacy database queries prior to the completion of the medical screening exam to prevent the patient from feeling coerced not to complete their exam.[107] The best course in dealing with patients with painful complaints is to provide a medical screening exam each and every time they present to the ED, and once an EMC is determined not to exist, to treat the patient as clinically appropriate based on the clinical scenario, risk for pharmaceutical abuse, and applicable state law.[106]

RISK MANAGEMENT

The ED presents a unique setting in health care where numerous factors interact to create the potential for error.[108,109] These errors can create adverse outcomes for patients and increased medical-legal risks for ED providers. Risk management is the process of identifying and mitigating factors that may be a source of errors. This section will focus on important sources of error in the ED and suggestions for the individual provider to mitigate risk within the confines of their existing care setting.

Studies looking at data from malpractice lawsuits have consistently found that certain presenting complaints and disease processes are associated with poor outcomes leading to legal action. These are summarized in **Table 303-6**.[108-111]

The error types most commonly reported in emergency medicine include diagnostic error or delay, treatment error or delay, improper performance of procedure or treatment, misinterpretation of tests, failure to supervise or monitor a case, and a failure or delay to consult or refer.[108,110] Of these, diagnostic error, which includes failure to diagnose, delay in diagnosis, and wrong diagnosis, is consistently the most frequent and costly, in terms of malpractice claims paid, both in emergency medicine and across all specialties.[108,109,112] Diagnostic error can be defined as a diagnosis that is "missed, wrong, or delayed."[113] These errors lead to permanent injury or death in almost half of filed malpractice cases related to diagnostic error.[109]

One study evaluated the sources of these diagnostic errors in the ED.[111] The study found that cognitive errors encompassing errors in judgment, knowledge, and vigilance or memory contributed to 96% of claims with identified errors. Communication errors, particularly as they relate to patient handoffs, were involved in 35% of diagnostic errors. System errors, including issues with supervision, workload, and fatigue, were noted in 37% of cases; these errors were more prevalent where students or residents were involved. Patient-related factors were involved in an additional 34% of cases. Of note, two-thirds of the errors involved cases in which more than one provider participated in the patient's care, further suggesting the importance of communication-related factors.

TABLE 303-6 Complaints and Diagnoses Associated with High Risk of Diagnostic Error

Chest pain/missed acute myocardial infarction (AMI)*
Wounds (retained foreign body, nerve or tendon damage, poor healing)
Fractures (vertebral, forearm, leg)
Symptom involving the abdomen and pelvis (including appendicitis and abdominal aneurysm)
Pediatric fever
Meningitis
CNS bleed
Stroke
Embolism
Trauma related
Spinal cord injuries
Ectopic pregnancy

*Missed AMI is the most frequently alleged missed diagnosis, is the diagnosis most associated with death, and had an average payout of $245,000 to $600,000.

REDUCING RISK

Improving patient safety and reducing risk in emergency medicine requires a broad focus involving multiple disciplines and addressing numerous issues including, but not limited to, medication administration, electronic health records, ED staffing, flow, and culture, and available equipment and resources.[108,109] Although these systemic changes are often beyond the ability of the individual physician to influence, there are a number of steps each physician can take to reduce the risk of error and of being named in a malpractice suit. Providers can address both interpersonal and clinical issues that may reduce risk.

Some actions that providers can take to establish a good patient–provider relationship are noted in **Table 303-7**.[114] This relationship is key to facilitating good communications and reducing risk. Introductions are simple and important. Tell the patient your name and your place on the healthcare team (e.g., attending or supervising doctor, resident physician, student). Engage the family in addition to the patient, when appropriate and permitted by the patient. Ensure that the patient and family or caretaker understand the diagnosis and discharge instructions, particularly those related to follow-up, treatment, and when to return to the ED. The physician should, whenever possible, personally review the discharge instructions with patients and provide the opportunity for patients and caregivers to ask questions prior to discharge to ensure comprehension.

Providers can also work to change other practice behaviors that may perpetuate or lead to error and risk. Patient handoffs are a significant area of risk for patients and providers. Avoiding limited or rushed patient handoffs and bedside transfers of care, when possible, may reduce the risk associated with shift change and multiple providers on the care team. Providers may fail to consider all the diagnostic possibilities in a transferred or signed-out patient because they receive the patient with a preexisting plan and diagnosis. It is a good practice for providers to meet each patient signed out to them and to evaluate them at least once before discharge.[115] Errors around procedures were the second highest category of error in one ED study.[108] Provide adequate supervision of residents and students performing procedures, provide comprehensive informed consent for every procedure when possible, and follow established best practices and guidelines when present or available for a given procedure to reduce this risk. Avoid criticizing the care provided by other providers, and never make guarantees about patient outcomes.

SPECIFIC HIGH-RISK DIAGNOSES AND TREATMENTS

Certain diagnoses, covering a wide variety of systems and mechanisms, present a high risk to emergency providers, as noted in Table 303-6. Providers should be aware of these diagnoses and their atypical presentations and consider the possibility of a high-risk problem in every patient. Avoid placing a diagnosis on a patient without sufficient clinical certainty. When a diagnosis is uncertain, describe the patient's assessment with symptoms.

The optimal treatment of certain diseases is unclear. Numerous situations exist in which the standard of care is not well defined. Providers should have careful and well-documented discussions with patients and families about what treatments are or are not being given, and why. Although the management of risk and errors in emergency medicine is highly complex, each physician should take it upon himself or herself to do what they can to reduce risk in their own practice and behavior.

TABLE 303-7 Provider Interpersonal Behaviors That Can Reduce Risk

Introduce yourself to the patient and family.
Dress neatly and professionally.
Address patients respectfully.
Sit down at the bedside.
Discuss with patients their expectations of care.
Speak in clear, simple language, avoiding medical terms.
Provide emotional support and show empathy.
Meet each signed-out patient.
Personally provide discharge instructions and answer questions prior to patient departure.

EMERGENCY PHYSICIANS AND DEATH CERTIFICATES

The registration of death is a state function governed by the laws and regulations of the state in which the death occurs. The death certificate is the permanent record of the fact of the death. Information from the death certificate is used as the source for many health statistics, to help determine funding for research, and to help settle the estate of the deceased, and in some states, it is required to get a burial permit.[116] To ensure consistency of the data reported to the National Vital Statistics System, a standard death certificate was created, and all state certificates conform closely to the standard.

The patient's personal (attending) physician usually fills out the death certificate. This physician likely knows the patient better than other healthcare providers and is in the most favorable position to certify the cause of death.[117] In cases in which there is no primary physician and the patient dies in the ED, the emergency physician may be called on to certify the death. Despite the fact that many death certificates contain errors in the assessment of cause of death, a search of the literature has not revealed any reports of physician liability for death certificate errors.[118] In many ED cases, the death will require referral to the coroner or medical examiner's office to certify the death. Cases requiring referral vary by state but may include the situations listed in **Table 303-8**.

The physician who completes the certificate is required to fill out the document in a timely fashion, often within 24 to 72 hours, using black ink and legible writing. In addition to documenting the time and date of death, the physician should indicate an opinion as to the immediate and underlying causes of the death. The immediate cause of death is the final entity causing death. The underlying cause of death is the original condition or diagnosis from which the chain of events leading to death originated. The chain of events should be listed on the certificate from most recent to the final, underlying cause.[118] The manner of death (e.g., natural, accident, homicide) and other significant but not directly linked conditions should be listed separately. In cases in which the disease processes involved are unclear, in some states physicians may qualify their opinions by listing them as "probable."

Terminal events such as cardiac or respiratory arrest should not be listed as the proximate cause of death because they do not indicate the disease process that caused death.

NEWBORNS LEFT AT THE ED

All U.S. states, the District of Columbia, and Puerto Rico have enacted laws allowing a mother and, in some states, either a custodial parent or an agent of the parent to leave a newborn infant at a "safe haven" in an attempt to reduce the numbers of infanticides and abandonments of children in unsafe places.[119] These laws vary with respect to who may leave the infant, how long after birth the child may be left, whom the child may be entrusted to, and the amount of legal protection and anonymity due the person leaving the child.[119] In most states, a healthcare provider or emergency services provider is authorized to accept the child.[119] Providers should be aware of the laws in their state, and every ED should have a policy to deal with this situation.

DUTY TO THIRD PARTIES

The *Tarasoff* ruling set the precedent that a physician owes a duty to a foreseeable third party when the physician is aware of a reasonable risk to that individual. Over the years, courts have extended that duty to include an obligation to warn or protect others against a variety of dangers, including communicable diseases, impaired drivers, employment physicals, and medication or treatment reactions.[120] Physicians have varying obligations and protections under state laws for reporting patients and warning potential victims or authorities when third parties may be at risk.[121] Good patient education, including medication side effects, driving and work restrictions, and strict compliance with state reporting laws, is a good start to minimize this risk.

TABLE 303-8 Cases That May Require Referral to the Medical Examiner/Coroner

Traumatic death
Death due to natural disaster
Individuals in police custody or jail inmates
Death under suspicion of homicide or suicide
Suspicion of poisoning
Sudden, unexplained death not clearly related to preexisting disease

TELEPHONE ADVICE

Calls for telephone advice should be routed to an established "advice line" operated by the hospital, an insurer, or other entity. By dispensing telephone medical advice, a physician may inadvertently enter into a binding physician–patient relationship.[122] ED staff should be taught a standard response to unsolicited phone calls from the general public: they should state that they are not allowed to give advice over the phone and should encourage the patient to come to the ED for evaluation and treatment.[123]

EXTENSION OF CARE OUTSIDE OF THE ED ENCOUNTER

Emergency providers can be exposed to liability extending beyond the ED. Two common sources of this risk are the writing of inpatient orders and responding to emergencies elsewhere in the hospital.[124] Emergency physician orders that cover any part of the inpatient stay are risky because there is a lack of clarity about when the transfer of care to the inpatient provider takes place. The American College of Emergency Physicians recommends that the emergency physician not be compelled to write any orders extending outside of the ED and that medical staff policies provide for timely orders for and evaluation of admitted patients by the inpatient medical staff.[125]

In some EDs, the emergency physician is expected to address a variety of medical issues that may arise on the inpatient floors.[124] Hospitals are responsible for the treatment of inpatients and should not rely on the ED physician to care for inpatients. In cases in which no other option is available, inpatients could be brought to the ED for evaluation and treatment.[126]

NEGLIGENCE STANDARDS

Physicians are generally expected to exercise reasonable care and practice within the accepted standard of care. A failure to do so is considered negligence and is the standard used in most medical malpractice lawsuits. Efforts to protect the healthcare safety net provided by EDs and specialists treating ED patients have led some states to enact a more rigorous standard of negligence for care provided in the ED. This standard is often referred to as "gross negligence." Gross negligence is more serious than negligence and has various definitions across jurisdictions that include "conduct so reckless as to demonstrate a substantial lack of concern for whether an injury results" and a "failure to exercise slight care or diligence."[127,128] The term *reckless* is sometimes used to describe a standard of negligence and generally seems to be equivalent to gross negligence.[127] A third standard, "willful or wanton" misconduct, although not universally seen as separate from the "gross negligence" standard, is often found in "Good Samaritan" laws.[127,129] "Willful or wanton" misconduct suggests behavior "where someone knew that an injury was likely to result from an action and, despite this knowledge, acted with a conscious disregard for the safety of another person."[127] The "willful and wanton" standard requires the provider to know that what they were doing was almost certain to lead to injury.[127]

ROLE AND RESPONSIBILITY OF EXPERT WITNESSES IN EMERGENCY MEDICINE

In a malpractice lawsuit, the plaintiff must prove that the physician has violated the standard of care and was therefore negligent. In most jurisdictions, expert witnesses are brought into court to state their "expert" opinion of the care given and if it violated the standard of care.[129]

The rules about who can provide expert witness testimony vary widely, with some jurisdictions requiring that the expert be of the same specialty as the defendant and others requiring only that the expert be a licensed physician without regard to specialty.[130] The quality of some expert testimony has become a concern of specialty societies, and some societies have begun to call for action against or attempt to sanction members providing misleading or inaccurate testimony.[131,132] The American College of Emergency Physicians has released guidelines for its members when acting as expert witnesses including the belief that expert testimony constitutes the practice of medicine.[133] These guidelines include the expectations that: (1) "the expert witness should review the medical facts in a thorough, fair, and objective manner and should not exclude any relevant information to create a view favoring either the plaintiff or the defendant"; (2) "the expert witness should not provide expert medical testimony that is false, misleading, or without medical foundation"; (3) the expert "be in the active clinical practice of emergency medicine for three years immediately preceding the date of the event giving rise to the case"; (4) the expert is willing to allow their testimony to be submitted to peer review; and (5) "misconduct as an expert, including the provision of false, fraudulent, or misleading testimony, may expose the physician to disciplinary action."[133,134] Emergency physicians acting as expert witnesses should be aware of these guidelines and strive to provide testimony that is a credit to themselves, the legal process, and the specialty of emergency medicine.

OTHER LEGAL ISSUES OF CONCERN

Other areas of ED practice with legal implications are listed in **Table 303-9**. The legal risk varies from state to state, and clearly written guidelines, an understanding of local laws, and an honest approach that avoids any appearance of conflict of interest can minimize risk.

TABLE 303-9 Other Legal Issues of Concern to Emergency Providers

Peer review
Business arrangements (antikickback Stark laws)
Credentialing
Recommendation writing
Emergency situations arising outside of the hospital
Compliance
Medical malpractice
Translation services for patients

DISCLAIMER

This chapter does not address state-specific issues or replace the advice of the hospital attorney in a given situation. The information provided in this chapter is not intended to be legal advice. Laws and regulations are always changing, and this chapter does not replace a timely consultation with an attorney specialized in healthcare issues.
